Lipomatous tumors, the most common mesenchymal tumor, represent nearly half of all benign lesions. They can occur anywhere in the body, but are rarely found in the upper extremities. Most common locations of the lipomas are represented by the subcutaneous tissue of the head, neck, shoulders and back. However, lipomas can develop in deep locations (intermuscularly, intramuscularly, perineural, interosseously) or at a site of prior trauma or having unusual features (angiolipoma, fibrolipoma, chondroid lipoma, lipoma with hibernoma, spindle cell lipoma, myelolipoma, pleomorphic lipoma).

In their typical form, the diagnostic is not a problem for the pathologist, but in unusual cases these tumors can be confused with liposarcoma. Lipomas are slow-growing soft tissue tumors that rarely reach a size larger than 2 cm. Previous studies defined giant lipomas of the upper extremity the lesions larger than 5 cm in any one of their dimensions (1). Their painless slow growth can lead to large size masses at presentation, especially when are located in deep subfascial planes. Clinically, they appear as well-circumscribed, encapsulated masses with a doughy consistency and that are free mobile on the superficial and deep planes.

Cosmetic deformity or compressive symptoms usually bring the patient with lipomatous masses of the upper extremity to doctor earlier than rapidly growing masses in other locations of the body. Giant lipomas of the upper extremity are rare, but when they occur, an appropriate work-up must be done because a tumor of this size warrants a work-up for malignancy (1). This should be followed by adequate open surgical excision with free margins. These patients require repeated examinations over time to monitor the recurrence.

CASES DESCRIPTION

We present a series of eight patients evaluated in our department from 2002 to 2007 with giant lipomatous tumors of upper extremities (Table 1). There were three male and five female, ranged in age from 17 to 77 years (mean age of 55). The tumor's size ranged from 5 to 34 cm. All patients underwent total excision of the tumors with free margins. All specimens were sent to pathology : seven patients had benign tumors and one patient had liposarcoma. There were no recurrences of the tumors. We present three cases in more detail.

Case 1 (patient 1)

Patient H.C., a 61 year-old man was admitted in our department with a large mass in his right deltoid region. The patient reported appearance of the tumor with 6 months before admission. During physical examination was founded a painless mass having about 10/6 cm in size, well-defined, with high consistency, reduced mobility and no overlying skin changes. Ultrasound examination showed in right deltoid area a large tissue mass with heterogeneous appearance, relatively well-defined, poorly vascularized. The lesion disrupts muscle tissue. MRI revealed an expansive process relatively bulky (17/13/7 cm), well-defined, showing homogeneous fatty signal. Lesion is located in the upper third of the arm and develops into the inner part of deltoid muscle penetrating between its threads and dividing it. The mass develops in close proximity to the humerus, but not interested in

Fig. 5. Tumor in lateral region of the right arm

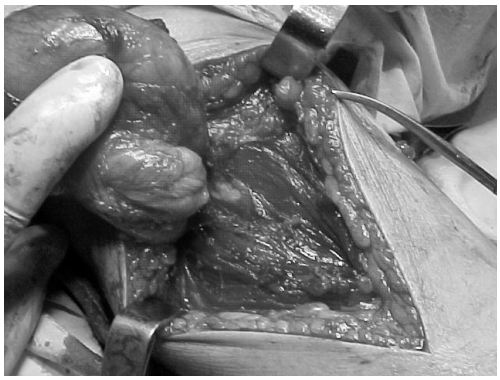

Fig. 6. Deep origin of the tumor between the triceps muscle bundles

its components. MRI appearance is suggestive of lipoma of the right shoulder. A radical excision of the lesion was performed with primary closure. Particularity consists in deep, intramuscularly location of the lipoma in the posterior deltoid beam as the existence of a lipomatous extension going near the humerus into the radial nerve groove. For excision of this extension was necessary to cut back beam of the deltoid muscle. Postoperatively, the patient recovered well with no functional deficits and was discharged after 6 days. Final pathology revealed lipoma (fig. 1-4).

Case 2 (patient 6)

Patient I.A., a 41 year-old woman, presented with a mass on her right arm that appeared about 2 years ago before admission. The patient reported a slow growth of the mass. On physical examination was observed a mass in the lateral region of the right arm measuring about 8/7 cm in size, well-circumscribed, with high consistency, relatively mobile on superficial and deep plans; the overlying skin presented a normal aspect. Sensitive and motor functions were intact throughout his right hand and forearm. Patient presented no other co morbidities and usual analysis was in normal range. Ultrasound revealed a mass within the right triceps consistent with a low-grade lipomatous lesion, likely an intramuscular lipoma. No vascular signal at Doppler examination was found. Plain radiography showed increased dimensions of the soft tissue in lateral region of the right arm; no bone modifications were recorded. The patient underwent complete excision of the lesion, which was found to be of 8/7 cm in size. Postoperative evolution was simple and the patient was discharged 3 days postoperatively. Final pathology revealed lipoma. The particular aspect of this case consisted in deep location of the mass within the triceps muscle bundles that had to be dissociated to address the tumor (fig. 5-6).

Case 3 (patient 2)

A 74 year-old woman was transferred from the department of cardiology because of a giant mass in the left axillary region. The patient presented with congestive heart failure, chronic atrial fibrillation, varicose ulcers of the lower limbs and obesity. She reported a history of 30 years of painless slow growth of this mass. Clinical examination revealed a bulky axillary mass having 30/20 cm, pasty consistency, with visible vascularization on surface. Overlying skin had areas of ulceration. Ultrasound showed a well-defined giant mass with heterogeneous fatty signal and a weak color Doppler signal. Radical excision of a 34/25/6.5 cm

TABLE I
Detailed report of the eight giant lipomatous tumors

P	G	Age	Location	Size (cm)	Pathology	R
1	M	61	Right deltoid region	17 / 13 / 7	Lipoma	No
2	F	74	Left axilla	34 / 25 / 6.5	Fibrolipoma	No
3	F	63	Left arm	12 / 7	Liposarcoma	No
4	M	53	Right arm	5 / 2.5 / 3	Fibrolipoma	No
5	F	54	Right arm	7 / 6 / 4	Angiolipoma	No
6	F	41	Right arm	8 / 7	Lipoma	No
7	M	17	Left forearm	8 / 7	Angiolipoma	No
8	F	77	Scapulohumeral region	10 / 7	Lipoma	No

Abbreviations: P = patient; G = gender; R = recurrence

mass with overlying skin was achieved. Primary closure was performed. Final pathology revealed diagnosis of fibrolipoma. The patient healed well and was discharged without complications.

DISCUSSION

Most lipomatous tumors are benign and can develop alone or in multiple locations. Lipomas occur more frequently in female patients, probably due to their tendency to accumulate more adipose tissue. Solitary lipomas are more frequent in women and the multiple lipomas are more common in men. Usually, lipomas grow with a very slow rate. The cause of a rapid growth to giant lipomas is still a matter of debate. It has been suggested that blunt trauma can cause rupture of the fibrous septa and anchorage connections between the skin and deep fascia, allowing the adipose tissue to proliferate (2). Whatever the mechanism of rapid growth is, when evaluating a giant lipoma of the upper extremity, the main issue is to exclude malignancy. Recent rapid growth, size larger than 5 cm, intramuscular location, have been reported as risk factors for malignancy (1, 3, 4).

Preoperative evaluation of a large mass in the upper extremity must include imaging evaluation. Among imaging techniques, ultrasound seems an excellent test for screening for soft tissue masses because of its safety, low cost, sensitivity and the ability to provide dynamic examination. On ultrasound, lipomas appear usually as a well-defined, hyperechoic solid mass in the subcutaneous layer without a color Doppler signal (5). However, MRI is the best diagnostic tools available. MRI is the method which allows an easy distinction of lipomas from well-differentiated liposarcomas due to increased vascularization seen in septal structures within the lesion (6). On MRI, lipoma appears as a well-circumscribed mass surrounded by a pseudocapsule and has homogenous fat signal. The role of imaging is essential either to confirm the benign or malignant nature of the mass or to give information for a diagnostic biopsy.

The proper management of giant lipomas is represented by surgical excision. Usually, lipomas are well encapsulated tumors allowing relatively easy complete removal. Intramuscular location makes removal more technically difficult and may require removal of some surrounding muscle to en-

sure adequate margins (7). Extensive excision can lead to significant dissections and mobilizations of neurovascular structures. However if a lipoma is incompletely excised it might redevelop. Liposarcomas are notorious for local recurrence, and even with attempted total resection, local recurrence rates can rise up to 50% (1). Pathological examination of the specimen is mandatory to determine final diagnosis and to establish the possible need for further treatment. Surgical excision can be followed by radiation and chemotherapy if malignancy is confirmed.

CONCLUSIONS

Lipomas may develop in single or multiple sites in both superficial and deep intermuscular fat; that might raise issues of dissection, isolation and excision. Preoperatively, imaging diagnosis (MRI is recommended) is important to delineate the extent of the lesion and to assist in operative planning. The indicated treatment is complete surgical excision that might require significant dissection and mobilization of neurovascular structures. It is imperative to discuss preoperatively with patients regarding potential loss of function.

A COMPARATIVE ULTRASTRUCTURAL STUDY BETWEEN COLORECTAL CANCER AND GASTRIC CANCER (Abstract): The large intestine is often the site of a tumor development, colorectal cancer being on the 3rd place as frequency, and having also a high mortality rate. Another malignancy with a strong impact over medicine is the gastric cancer; Even if it`s incidence has a descending course, it still remains one of the main neoplasia with a high mortality, occupying the 3rd place worldwide. Considering the fact that in the specialized literature exists insufficient evidence and often contradictions regarding the morphologic and molecular characteristics found in the early stages of malignization and regarding the limits imposed by the usual photonic microscopy techniques, we considered necessary approaching a comparative ultrastructural study between the two types of cancer mentioned above. **Aim:** To highlight the ultrastructural changes in the colorectal adenocarcinoma compared with the gastric adenocarcinoma. **Material and methods:** The study included a number of 21 patients diagnosed with colorectal and gastric cancer from which we gathered biopsies that were processed and analyzed using a Transmission Electron Microscope Philips CM100. **Results:** The ultrastructural study identifies common characteristics of the malign transformation of both colorectal cancer and gastric cancer and also a series of particularities for colorectal cancer inaccessible for common microscopy techniques. **Conclusions:** New information about the aggressivity and the metastatic potential are accessible through TEM examination, which can improve the therapeutic management of these cases. **Keywords:** COLORECTAL CANCER, GASTRIC CANCER, ULTRASTRUCTURE, ELECTRON MICROSCOPY.

In the XXI century, one of the fundamental issues of medicine is represented by cancer, with its multiple sites of localization, with its multiple cell types and manifestations. Regarding these aspects, the colon is often the site of tumors development, colorectal cancer being on the 3rd place as frequency (along with gastric cancer) and hav-

ing also a high mortality rate (1). The incidence of these pathologies could be decreased, by improving the general population awareness regarding the risk factors, by encouraging the specialty consults at the first symptoms and by convincing the patients to accept the endoscopic examinations as screening tests (2, 3, 4); moreover, the understanding of the mechanisms and reactions that are taking place at the molecular level and puts the tumorigenesis process in motion represents the new approaching in the fight against cancer (2, 3, 4).

In the majority cases of tumors, the cause of death is not represented by the effects of the primary tumor, but by the tumor's cells capacity to migrate and to be sown as secondary tumors, often with a more aggressive form (5). This reaction is made possible through alterations of the cell adhesion mechanisms, abnormal growing factor synthesis, aberrant expression of some proteins involved in maintaining of the cell environment within normal limits (including the cell shape and the cellular motility) (5).

Despite the fact that gastric cancer`s incidence in the last decades has a descending trend (probably because of the lifestyle changes, the fight over *H. Pylori* infection and the screening tests), it still remains one of the main neoplasia with a high mortality rate, being situated on the 3rd place worldwide (6, 7).

The usual photonic microscopy techniques have as a major purpose the establishment of a certainty diagnostic in neoplasia suspicions but are limited in detecting the early changes during tumorigenesis or regarding premalignant lesions; for example, the presence of inflammatory cells is common to family intestinal polyposis syndrome, ulcerative colitis and cancer. The light microscopy allows the identification of the basal cells, but it is not specific for early changes (8, 9). Thereby, the purpose of this research is to bring about a comparative ultrastructural study of colorectal towards gastric cancer, for early identification of changes in localization of colorectal tumors.

MATERIAL AND METHODS

Twenty-one patients suspected of having colorectal neoplasia have been enrolled in this study, with the age between 49 and 75, who came at the Regional Oncology Institute from Iași to confirm their diagnosis through endoscopy and biopsy, subsequently following the establishment of the medical management. Informed consent was obtained from each patient prior to the endoscopic biopsy.

Sixteen of these patients (76.19%) clinically and imagistically suspected of having colorectal cancer asked for a specialized physical examination due to the following symptoms: rectal bleeding, diffuse abdominal pain and transit changes. Other five patients (23.81%) were suspected of having gastric cancer.

All of the patients denied having neoplastic heredo-collateral antecedents, or any other personal important antecedents, except for cardiovascular disease excepting the chronic treatment which could be involved in the carcinogenesis.

Of great significance is the fact that none (0.0%) of the patients underwent chemotherapy, radiotherapy or any other cancer treatment prior to the sample collection.

The tumoral bodies have been spotted due to the colonoscopy and upper gastrointestinal endoscopy and both tumoral and normal tissue have been sampled to be

tested. Some fragments obtained from the gathered tissue samples were processed through the immersion in paraffin technique, sectioned and colored with hematoxylin-eosin (HE), for a diagnosis within the Pathological Anatomy and Morgue Service of the Regional Oncology Institute, Iași and examined with the photonic Olympus BX40 microscope with the Olympus E330 camera attached.

For electron microscopy examination, the other fragments were fixed on ice and there were added few drops of 2% glutaraldehyde, in furtherance to prevent any type of tissue deterioration. Following that, certain pieces were gathered to be processed through the standard technique of the electron transmission microscopy (TEM): double fixing, dehydration using 30% alcohol, at 4°C, for 15 minutes; colored all-together – 2% uranyl acetate 2%, in 30 alcohol, at 4°C, for 45 minutes; dehydration – successive baths of alcohol with increasing concentrations, preceded by absolute acetone, at room temperature, for 20 minutes.

Equal quantity of EPON 812 and absolute acetone was used during overnight time, at room temperature for the impregnation stage. Then, EPON 812 was used for 2 hours at room temperature, and last, the fragments followed the immersion in EPON 812, in gelatin capsules, polymerization and cutting. The development of the sample`s processing technique was staged in the electron Microscopy Laboratory within the Cellular and Molecular Biology Department ("Grigore T. Popa" University of Medicine and Pharmacy Iasi) later steps being carried on within the Electron Microscopy Laboratory of the Life Sciences Institute, "Vasile Goldis" West University (Arad). The examination of the samples was screened with a Philips CM100 electron transmission microscope equipped with a digital video camera with dedicated sensor and photo-taking system.

RESULTS

The examination of hematoxylin eosin (HE) stained samples in the case of tumors with gastric localization revealed characteristic elements based of which in current medical practice the histopathological diagnostic is established: significant desmoplastic reaction, muscular invasion, glandular outbreaks of different shapes and sizes, with muscular layer invasion. In addition, there were depicted lymphatic slits with tumor embolisms, large areas of necrosis and lymphoplasmocitary infiltrate (fig. 1).

Regarding the specimens collected from the tumor formations located in the sigmoid colon, there were identified: irregularly shaped glands, sometimes fused with a high, dysplastic, stratified epithelium, sometimes with imprecisely limited boundaries from the varying thickened stromal lax; cells with heterogeneous appearance, with large, hyper chromatic, large-shaped nuclei, sometimes with secreting vacuoles, glandular tubules invading the sub mucosal area. The hyperchromatic nuclei reverse in their favor the nucleo-cytoplasmic ratio. The stroma is dense, hypercellular, with a rich lymphoplasmocitary infiltrate, dilated vessels, full of red blood cells (fig. 2).

At once, the examination of these samples also revealed anaplastic tumors with tubular atypical glands, which invade the muscle patch, stromal desmoplastic reaction, with the invasion of the subserous. In these areas, the glandular cells exhibit nuclear pleiomorphism and loss of polarity. There were mentioned tumor embolisms in blood and lymph vessels and small mu-

cosecreeting, interstitial focuses (fig. 2).

With reference to the samples collected from the formations in the rectum, it was observed an inconsistent thickened epithelium with nuclear hyperchromatism, with elongated, oval or irregular nuclei, giving the impression of overlapping in certain areas (fig. 3).

The TEM examination in the case of patients diagnosed with gastric cancer, at the level of larger nuclei, it showed a small quantity of nuclear chromatin disposed in an irregular manner, which is characteristic for the malignant transformations; the widening of the nuclear pores followed by the appearance and the presence of some discontinuities of the nuclear envelope.

Along with these, it was detailed a disorganization of the morphological structure of the membrane and the cellular coupling zones - the impermeable junctions did not exhibit a normal architectonic, with a vacuolar structure and enlarged intercellular spaces observed in some areas.

In addition, there are obvious changes in the basal membrane showing disorganized structure and discontinuities, with the presence of the residual material in lamina propria and mitochondrial degeneration of different grades. The same elements are present in the case of peripherally located cells within which nucleoli are observed with changes in both morphological and numerical appearance: either there is only one modified enlarged nucleolus, or two nucleoli with the characteristic appearance of malignant cells (fig. 4, 5, 6, 7, 8).

As regards to patients with localized neoplasia in the sigmoid colon, the examination in the electron transmission microscopy highlights: the presence of hypertrophic nuclei with edentulous appearance and dilated perinuclear cisterns; nucleoli with a disorganized structure, located peripherally to the internal lamina, and in some cells, also located peripherally, towards the inner lamella, two nucleoli were disposed in “glasses” shape - characteristic of the advanced malignant transformation.

Likewise, it is noted perinuclear cytoplasmic vacuolization with the disorganization of the organelles structure - advanced mitochondrial degeneration.

The basal membrane also presents changes as: discontinuities and variations in thickness (fig. 9, 10, 11, 12).

DISCUSSION

TEM examination completes the data obtained by HE-stained samples examination and reveals changes of the cellular morphologic aspects and the subcellular structures important for establishing the prognosis and the proper therapeutically approach, explaining in the same time the evolution of each particular case.

HE-stained samples examined under the photonic microscope revealed the morphological changes characteristic for malignant transformation, confirming the clinically and imagistic diagnosis of gastric and colorectal adenocarcinoma: in gastric adenocarcinoma, an important desmoplastic reaction, with the invasion of the muscular layer, with glandular outbreaks of different shapes and sizes, invading the characteristic muscular (fig. 1).

In addition to these aspects, the electron microscopy revealed the reversal of the nucleocytoplasmic ratio, reduced quantity and irregular distribution of the chromatin, nuclear envelope with edentulous aspect, elements that completes the histopathological aspects and have particular significance to malignant transformation (fig. 4, 5, 6, 7, 8).

Furthermore, modified cellular coupling areas (vacuolar aspect and disorganization of tight junction architectures) indicate an increased potential for metastasis. These morphological aspects displayed by the examination of the samples in the electron transmission microscopy also suggest changes in the signaling pathways at the cellular level, disruption of the nucleocytoplasmic exchanges and of mechanism of the cellular synthesis responsible for functional perturbation at this level.

So, if the standard histopathological examination misses some specific elements to a malignant transformation, examination in the electron transmission microscopy bring elements to underline the severity of dysplasia, and the changes within the subcellular levels relevant for tumoral staging.

The study of colon samples presents severe cellular lesions in both photon microscopy, but especially in electron microscopy. In addition to the aspects observed in the examination of HE-stained - high, dysplastic, stratified epithelium, sometimes with imprecisely defined boundaries, with large, hyperchromic nuclei, with shape changes; anaplastic tumors with tubular atypical glands, glandular cells with nuclear pleiomorphism and the loss of polarity (fig. 2)-electronomicroscopic changes have been highlighted at both nuclear level and cellular organelles: the presence of hypertrophic nuclei, edentulous and highly dilated perinuclear cisterns; the nucleoli with a disorganized structure, located peripherally to the internal lamina and in some cells, two nucleoli disposed in “glasses” shape, also located peripherally, to the internal lamella – which are characteristic aspects of advanced malignant transformation that could not be revealed by photon microscopy (fig. 9, 10, 11, 12).

Besides, perinuclear cytoplasmic vacuolization was observed the disorganization

of the organelles structure, with particular emphasis on advanced mitochondrial degeneration, changes at the basal membrane level (their detachment from the epithelial cells, the presence of the residual material in their own lamina). These morphological alterations revealed by the TEM also indicate the existence of important molecular changes: disturbances of intercellular communication pathways, ATP synthesis deficiency with significant functional repercussions. Photonic microscopy images have showed a secretion penetrating the intestinal wall layers, which favors the extension of the malignant process and at the same time, explains the severity of the disruption in the electron microscopic study.

The studies support the link between the ultrastructural aspects of different cellular components and the secondary phenomena of the tumorigenesis process. Thus, Mitmaker and colleagues argue in a study that the ratio of nucleus to cytoplasm may suggest aggression of neoplasia and an unfavorable prognosis (16). Also, elliptic nuclei are found in the mucosa of a well-differentiated gastric carcinoma, whereas spherical nuclei in the mildly differentiated mucosa (17).

It is known that in malignant transformation, nuclei undergo important changes, visible both by photon microscopy and especially by electron microscopy (18). Nuclear chromatin in tumor cells undergoes changes in aggregation and mood, being denser and asymmetrically aggregated independent of cell cycle progression – there aspects are identified as well in our case studies. Also, studies conducted by Dakubo *et al*. (19) and Damania *et al*. (20) describe nuclear changes in patients diagnosed with colorectal adenocarcinoma if compared to cell nuclei present in normal mucosa. They describe the so-called phenomenon of carcinogenesis which represents the concept of modified genetic or epigenetic microclimate that creates fertile ground and allows the development of focal tumors. Thus, colorectal cancer is one of the focal points in which in vivo cancer inoculums have to be studied as well as the study of cells at different stages of evolution are crucial in order to identify modifications at the earliest stages.

The electronomicroscopic study of the tumors reveals the increased prevalence of important tumor-specific ultrastructural changes, thus highlighting their severity and major potential for dissemination. It also highlights the severity of morphological changes in the subcellular compartments in case of colon adenocarcinoma compared to the gastric and rectal levels in the studied cases. This change represents the morphological substrate of the characteristic molecular disruptions of these tumoral types.

CONCLUSIONS

Our study emphasizes the ultrastructural details provided by the electron transmission microscopy for the lesions taken under consideration and completes the information provided by the photon microscopy technique and highlights the value of the electron microscopic examination that is often underestimated or ignored. At the same time, the results of the present comparative study between gastric and colorectal adenocarcinoma, complements the data from the few ultrastructural studies in the literature on this subject, it contributes to a complete and relevant image of the specificity of the morphological context in this tumors which accompany the molecular perturbations and provides important in-

formation for their clinical and therapeutic management for these types of injuries that are a real challenge to global public health systems.

STRESUL TRAUMATIC SECUNDAR, EFECTUL ADVERS AL EMPATIEI CLINICE

Irina Crumpei , I. Dafinoiu
Universitatea "Al. I. Cuza" Iaşi
Facultatea de Psihologie şi Ştiinţe ale Educaţiei
Catedra de psihologie medicală şi psihopedagogie specială

SECONDARY TRAUMATIC STRESS, THE SIDE EFFECT OF CLINICAL EMPATHY (Abstract) : There is growing clinical evidence that a second category of trauma victims can result from working with traumatized populations. This article introduces the concept of secondary traumatic stress (STS) and analysis its impact and relevance in the particular situation of medical staff. In the second part we discuss medical workers' empathy as an important factor associated with clinical competence and patient outcomes on one side, and as a recognized risk factor for STS on the other side. Finally, we conclude that the paradox of the clinical relationship needs further attention and study, to find a mutual beneficial solution. Assessment has to be connected to prevention and intervention efforts to ensure effective management of STS among medical workers. **Key words** : SECONDARY TRAUMATIC STRESS, EMPATHY, MEDICAL STAFF

Stresul ocupaţional este o problemă recunoscută printre specialiştii din sănătate. Personalul medical este considerat a reprezenta un risc semnificativ, înregistrând rate crescute de *burnout*, epuizare emoţională, depresie (1,2,3). Mai ales în unele specializări, angajaţii se confruntă cu provocări caracteristice cum ar fi : o cantitate de muncă imprevizibilă, resurse limitate, expunerea repetată la evenimente traumatogene, evenimente violente posibile, şi luarea de decizii critice având adesea la bază doar informaţii incomplete. Contextul economic naţional adaugă deficienţe grave în infrastructură, salarizare şi resurse umane. Personalul medical se confruntă zilnic cu dramele şi traumele a numeroşi pacienţi. Este de aşteptat ca particularităţile îngrijirii medicale în spaţiul Românesc să fie caracterizate de manifestări specifice ale stresului ocupaţional. În acest sens, articolul de faţă îşi propune să evidenţieze vulnerabilitatea cadrelor medicale faţă de stresul traumatic secundar. Această tulburarea afectează global viaţa specialistului, periclitând în acelaşi timp relaţia clinică pacient – cadru medical, precum şi demersul terapeutic.

DE LA TRAUMĂ PRIMARĂ LA STRES TRAUMATIC SECUNDAR

În societatea actuală trauma îşi multiplică ipostazele prin războaie, atacuri teroriste, dezastre naturale şi violenţe de tot felul. Expunerea la evenimente copleşitoare şi traumatice este răspândită în rândurile populaţiei la nivel global. Statisticile arată că în jur de 90% din cetăţenii Statelor Unite sunt supuşi la măcar un eveniment traumatic ce le-a pus existenţa în pericol, de-a lungul vieţii (4). Manualul de diagnostic şi statistică a tulburărilor mentale (DSM) susţine că sindromul de stres posttraumatic se poate instala ca urmare a unei situaţii în care persoana a trăit sau a asistat la un eveniment ce a reprezentat un pericol pentru viaţa sau securitate sa (sau pentru viaţa sau securita-

tea celor din jur) şi a resimţit sentimente de frică intensă, de neputinţă şi oroare (5). Meichenbaum consideră că repercusiunile evenimentului traumatogen pot fi diferenţiate pe patru planuri : consecinţe în plan afectiv : şoc, teroare, culpabilitate, anxietate, ostilitate, depresie ; în plan cognitiv : slăbirea sau diminuarea capacităţilor ; în plan somatic : perturbări ale somnului, coşmaruri, simptome psihosomatice ; consecinţe comportamentale : evitarea, retragerea socială, stresul interpersonal, abuzul de substanţe (6). Situaţiile traumatogene pot fi multiple : un accident rutier sau alt tip de accident grav, o agresiune fizică sau sexuală, războiul sau tortura, catastrofe naturale, cutremure, incendii, inundaţii. Grabmeier arată că şi diagnosticarea unei maladii grave, ca de exemplu cancerul, poate provoca un sindrom de stres posttraumatic. Criteriile de diagnostic oferite de DSM nu explică în totalitate varietatea de răspunsuri umane la traumă. Van der Kolk şi McFarlane atenţionează că „în ciuda eforturilor de a surprinde esenţa răspunsului indivizilor la traumă, diagnosticul sindromului de stres postraumatic nu reuşeşte să descrie complexitatea felului în care oamenii reacţionează în faţa evenimentelor copleşitoare”(7).

McFarlane şi Girolama sugerează că având în vedere varietatea solicitărilor ce cuprind o persoană în funcţie de traumă, şi diversitatea capacităţilor de a pune în practică diverse comportamente adaptative între diferite persoane precum şi în cazul aceleiaşi persoane în momente diferite, reacţiile de stres posttraumatic sunt mult mai complexe decât criteriile DSM o arată (8). Evenimentele traumatogene pun sub semnul întrebării relaţiile umane de bază şi pot rupe ataşamentele din familie, prietenie, dragoste şi comunitate. Zguduie constructul sinelui care s-a format şi este susţinut în relaţie cu ceilalţi. Ele slăbesc sistemele de credinţe ce oferă înţeles experienţei umane. Violează credinţa persoanei într-o ordine divină sau naturală şi izolează victima într-o stare de criză existenţială (9). Unul dintre efectele cele mai profunde în a trăi o traumă îl reprezintă distrugerea credinţelor de bază despre sine şi lume. Janoff-Bluman susţine că expunerea la o experienţă traumatică anulează iluzia de invulnerabilitate pe care oamenii o dezvoltă pentru a se proteja de stres şi anxietate, credinţa lor într-o lume sigură, dreaptă şi plină de sens este pusă sub semnul întrebării (10). În plus, victimele unei traume se întreabă despre rostul şi valoarea lor ca oameni cât şi despre încrederea pe care o pot acorda celorlalţi (11).

Ultimii ani au adus cu sine dezvoltarea domeniului traumatologiei iar conceptul de stres traumatic s-a bucurat de o atenţie sporită. În acest context studiile ce se concentrau firesc pe reacţiile victimei în urma evenimentului traumatic, au descoperit treptat că momentul de criză nu afectează doar pe cei ce sunt de faţă iar victimele se pot multiplica în timp, chiar mult după ce evenimentul marcant a luat sfârşit. Manualul de diagnostic şi statistică a tulburărilor mentale marchează această schimbare de perspectivă adaptând criteriile de diagnostic pentru stresul posttraumatic în cea de-a patra ediţie. Acestea includ acum condiţia în care persoana se confruntă cu un eveniment sau evenimente traumatice care au implicat ameninţări cu moartea, moartea efectivă, vătămarea serioasă sau ameninţarea integrităţii corporale proprii ori a altora (5). Având în vedere că unele categorii profesionale se confruntă sistematic cu experienţele traumatice ale altora, nu este surprinzător că trăiesc simptome ale stresului posttraumatic. Prin urmare nu doar victima primară este expusă riscului de a dezvolta sindromul de stres posttraumatic ci şi martorii direcţi la eveniment precum şi persoanele apropiate victimei care află despre ceea ce i s-a întâmplat. Această precizare a complicat şi mai mult încercările de a delimita cât mai clar diverse concepte ce începuseră deja a se

forma pe această temă. Faptul că stresul posttraumatic poate fi contagios este o chestiune discutată şi cercetată de mai bine de două decenii. În 1988 Figley observă cum familia victimei este afectată de suferinţa acesteia şi adună simptomele constatate sub numele de „victimizare secundară" (12). În ciuda actualizării criteriilor de diagnostic, sindromul de stres posttraumatic aşa cum este el conceput de Asociaţia psihiatrică americană (5), pare a nu acoperi exhaustiv posibilităţile de propagare a simptomelor descrise. Munca sistematică în slujba pacienţilor ce au suferit traume riscă să afecteze în timp pe unii dintre profesionişti. Courtois vorbeşte în acest sens despre „victimizare de contact" (13) iar Mollica, în acelaşi an sugerează că specialiştii se "infectează" cu deznădejdea celor pe care încearcă să îi ajute (14). În ultimii ani etichete cum ar fi epuizare empatică (compassion fatigue), traumatizare vicariantă sau stres traumatic secundar încearcă să împartă şi să clarifice diversitatea simptomelor ce pot apărea în cazul celor expuşi interacţiunii cu victime ale unor evenimente traumatice. Termenul de epuizare empatică a fost introdus pentru prima dată de Joinson in anul 1992 în articolul său despre sindromul de *burnout* la asistente medicale (15). Doi ani mai târziu Figley introduce conceptul de stres traumatic secundar pe care îl descrie ca fiind sinonim cu epuizare empatica. Stresul traumatic secundar apare când un individ este indirect expus la traumă prin intermediul unei descrieri personale sau prin povestirea unei experienţe traumatice (16). Figley defineşte conceptul ca emoţiile şi comportamentele ce rezultă natural atunci când individul află dintr-o descriere personală sau printr-o povestire despre un eveniment traumatic trăit de o persoană semnificativă (17). În continuare Figley susţine că anumite categorii profesionale, cum ar fi de exemplu terapeuţii ce lucrează cu victime, specialiştii ce intervin în situaţii de urgenţă, poliţiştii etc. prezintă un risc crescut de a dezvolta acest tip de stres pentru că ei intră regulat în contact cu istorisiri despre evenimente traumatice. El arată că indivizii pot fi traumatizaţi fără a fi răniţi fizic sau ameninţaţi în mod direct. Atât retrăirea realistă a traumei de către victimă, cât şi interpretarea cognitivă sau emoţională a evenimentului realizată apoi de specialist, pot provoca simptome similare celor din sindromul de stres posttraumatic (hiperexcitaţie, simptome intruzive, evitare, anxietate). În acest caz, persoana afectată nu este rudă sau prieten apropiat cu victima, dar încercarea de a ajuta şi deschiderea empatică o expun aceloraşi simptome. O'Halloran susţine că persoanele care se confruntă cu material traumatic sau lucrează cu persoane traumatizate pot fi afectate profund de experienţele trăite la nivel cognitiv prin capacitatea redusă de concentrare, emoţional prin stări de distres sau spiritual prin revoltă împotriva divinităţii (18). Sindromul de stres traumatic secundar este identic în simptomatologie cu stresul posttraumatic cu excepţia faptului ca în primul caz evenimentul traumatic nu este trăit direct de persoana afectată, ci aceasta află despre ceea ce s-a întâmplat din povestirile unei alte persoane. Simptomele trăite vor fi de evitare, intruziune şi hiperexcitaţie. La fel ca în stresul posttraumatic, în cazul simptomelor intruzive specialistul va retrăi la nivel imaginar evenimentul traumatic ce a afectat victima. Stresul traumatic secundar se află în strânsă legătură cu evoluţia persoanei suferind de stres posttraumatic, pentru că ameliorarea victimei primare va ajuta ameliorarea suferindului secundar (17). Factorii de risc identificaţi de Figley sunt : răspunsul empatic, istoricul traumatic personal, reactualizarea problemelor personale nerezolvate prin ascultarea traumei victimei, lucrul cu populaţii vulnerabile. Dincolo de simptomatologia specifică, persoanele afectate pot resimţi modificări ale credinţelor de bază, ale aşteptărilor şi atitudinilor faţă

de viaţă. Dutton şi Rubinstein susţin că specialiştii pot resimţi sentimente de vină atunci când se surprind bucurându-se de viaţă, gândindu-se la dificultăţile pacienţilor în lupta lor cu trauma (19).

MODELE TEORETICE ALE STRESULUI TRAUMATIC SECUNDAR

Având în vedere similaritatea dintre simptomatologia stresului traumatic secundar şi cea a stresului posttraumatic, şi modelele explicative pentru cele doua patologii vor fi în parte similare. La fel ca şi cei suferind de stres posttraumatic, indivizii care sunt expuşi secundar la stresori traumatici, pot suporta episoade de gândire intruzivă şi etape de evitare, apatie sau excitaţie persistentă. Conform lui Yassen stresul traumatic secundar poate afecta persoana : cognitiv (concentrare diminuată, stimă de sine scăzută, imagerie legată de traumă), emoţional (apatie, depresie, hipersensibilitate), comportamental (tulburări de somn, răspuns exagerat de tresărire, abuz de alcool sau alte substanţe), spiritual (furie împotriva divinităţii, pierdere de semnificaţie şi sens, disperare persistentă), interpersonal (interes scăzut în intimitate, izolare faţă de prieteni, lipsă de încredere), fizic (reacţii somatice, sistem imunitar afectat, dureri) (20).

Modelul neurobiologic

Din punct de vedere neurobiologic, asistând la trauma trăită de pacienţii lor, specialiştii în cauză se confruntă cu varietatea de posibilităţi de boală, ameninţare şi vătămare pe care oamenii o pot întâlni. Când ascultă despre răul ce a survenit altora, este un proces natural ca persoana să evalueze periculozitatea ameninţării pentru propria persoană. Pentru că sarcina principală a creierului uman este de a promova supravieţuirea (21), creierul este setat biologic să caute şi să îşi amintească datele de supravieţuire. Informaţia venită de la pacient, percepută ca fiind potenţial ameninţătoare, nu poate fi ignorată de procesele de căutare de informaţie din creier. Cu alte cuvinte, sistemul limbic al specialistului poate fi activat prin simpla interacţiune cu pacientul. Creierul este de asemeni setat să reţină mai bine acele amintiri cărora le este ataşată semnificaţie emoţională. Astfel, de-a lungul timpului, specialistul poate dezvolta o serie întreagă de amintiri ameninţătoare semnificative emoţional, care pot de asemeni contribui la a activa sistemul limbic când informaţia primită este asociată cu o ameninţare precedentă. În acest fel, expunerea cronică la stresori traumatizanţi poate deteriora sistemul imunitar al persoanei, rezultând într-o varietate de simptome fizice serioase (22).

Modelul de transmitere a traumei

Figley a dezvoltat un model de transmitere a traumei constând din două componente : stresul empatic (compassion stress) şi epuizarea empatică (compassion fatigue) care îşi propune să explice procesul de transmitere a traumei şi oferă o explicaţie plauzibilă pentru motivele pentru care unii indivizi dezvoltă epuizarea empatică iar alţii nu. Acest model susţine că specialiştii încearcă să înţeleagă experienţele pacienţilor identificându-se cu aceştia şi în acest proces specialistul însuşi ajunge să trăiască dificultăţi similare cu pacientul. Prima componentă a modelului descrie instalarea stresului empatic ca o funcţie a interacţiunii dintre şase variabile. Aspectul cheie al acestui model este empatia şi Figley împarte empatia în trei tipuri : abilitate empatică, grijă empatică şi răspuns empatic. Abilitatea empatică se referă la capacitatea specialistului de a recunoaşte durerea celorlalţi, de a oferi necondiţionat o imagine pozitivă şi autentică. Astfel conceptul de empatie este legat de cel de grijă care constituie motivaţia principală de a răspunde pacientului. Literatura de specialitate susţine că abilităţile empatice ale cadrelor medicale reprezintă calităţi cheie pentru ca ei sa poată avea o minte deschisă faţă de pacienţii lor. Fără această

calitate abordarea clinică ar putea avea de suferit semnificativ. Răspunsul empatic este combinaţia dintre abilitatea empatică a specialistului şi grija empatică. Măsoară nivelul de efort investit de specialist pentru a asista pacientul în gestionarea traumei (17). Contagiunea emoţională pe care Figley o defineşte ca fiind trăirea sentimentelor suferindului ca o funcţie a expunerii la suferind, este conectată la abilitatea empatică şi astfel determină stresul empatic. Totuşi dacă specialistul se poate dezangaja din relaţia sa cu victima, el/ea va resimţi un sentiment de satisfacţie prin relaţia de ajutorare, în loc să trăiască efectele stresante ale muncii cu materialul traumatic al clientului. În partea a doua a modelului de transmitere a traumei, Figley susţine că dezvoltarea stresului traumatic secundar este rezultatul interacţiunii a patru variabile : nivelul stresului empatic, expunerea prelungită la victimă, amintirile traumatice şi nivelul de tulburare a propriei vieţi. Figley arată ca expunerea prelungită la materialul traumatic apare ca urmare a sentimentului specialistului că trebuie sa aibă grijă neîntreruptă de pacient şi că este responsabil pentru acesta. Specialistul se simte unicul responsabil pentru pacient şi nu reuşeşte a-şi diminua stresul empatic. În plus, amintirile provoacă simptome secundare şi alte asemenea răspunsuri din partea specialistului. Figley susţine că epuizarea empatică devine un fenomen natural când există aceste circumstanţe.

Un cadru ecologic al traumei

Dutton şi Rubinstein încearcă de asemenea să ofere un cadru teoretic pentru stresul traumatic secundar. Modelul lor, un cadru ecologic al traumei, integrează aspecte ale modelului de transmisie a traumei propus de Figley (17). Conform lui Dutton şi Rubinstein gama de reacţii pe care specialiştii o pot trăi ca urmare a interacţiunii lor cu victime ale unor evenimente traumatice poate fi împărţită în trei arii. Prima categorie se referă la simptomele detresei psihologice, cum ar fi comportamentul de evitare, imageria intruzivă, acuzele somatice sau apatia psihologică. O a doua categorie de reacţii se referă la schimbări în credinţe şi impresii despre lume (10). Indivizii îşi situează presupunerile şi credinţele la un nivel preconştient, ceea ce le permite să îşi stabilească obiective, să plănuiască activităţi şi să îşi ghideze comportamentul. Se crede că aceste credinţe sunt alterate prin expunerea directă sau indirectă la traumă, ceea ce determină stres psihologic şi formarea simptomelor. Ultima categorie care este perturbarea relaţională, poate apărea ca urmare a expunerii secundare, relaţiile specialistului (personale si profesionale) putând avea de suferit. Sensibilitatea lor la întâmplări similare în viaţa personală poate cauza dificultăţi în relaţiile lor şi se pot izola la locul de munca (19). Astfel modelul lui Dutton şi Rubinstein pentru stresul traumatic secundar a propus patru componente : evenimentul traumatic la care specialistul este expus ; strategiile de *coping* ale specialistului ; reacţiile posttraumatice ; factorii personali şi de mediu. Autorii susţin că expunerea la materialul traumatic este unică pentru fiecare specialist în parte şi oferă cinci motive pentru aceasta : materialul traumatic diferă în grad de severitate de la un pacient la altul ; specialistul nu este expus doar materialului traumatic, dar şi emoţiilor pe care clientul le resimte în legătură cu evenimentul ; specialistul este expus revictimizării clientului care poate interveni ca urmare a sistemelor sociale ; specialistul este expus evidenţei faptului că acel tip de traumă există ceea ce îi poate pune sub semnul întrebării credinţele cognitive, şi în ultimul rând specialistul poate avea a face faţă traumei anterioare a clientului ce ar putea reapărea. Pentru că natura expunerii este unică fiecărui specialist, acest model direcţionează cercetarea către toate aceste particularităţi ale recepţionării materialului traumatic la care specialistul are acces. A

doua componentă se referă la strategiile de *coping* despre care autorii susţin că afectează dezvoltarea şi parcursul stresului traumatic secundar. Există două tipuri de strategii de *coping*, personale şi profesionale şi aceste strategii sunt legate de reţeaua socială de suport a persoanei. Autorii arată în continuare că factorii individuali şi de mediu pot fi mediatori ai stresului traumatic secundar. Factorii individuali includ forţa internă a specialistului, resursele sale, vulnerabilităţile şi nivelul de satisfacţie cu viaţa sa personală şi profesională. Dutton şi Rubinstein consideră că factorii de mediu cum sunt suportul social, locul de muncă, factorii culturali, sociali şi profesionali sunt importanţi în influenţarea reacţiilor la materialul traumatic.

EMPATIA, RISC NECESAR ÎN RELAŢIA CLINICĂ

„În mod ironic (…) cei mai eficienţi specialişti sunt cei mai vulnerabili la efectul de oglindire sau contagiune. Cei care dispun de capacităţi enorme de a simţi şi de a exprima empatie tind să fie mai expuşi stresului traumatic secundar”(17). Numeroase studii confirmă importanţa empatiei în profesiile care implică interacţiunea cu oameni. Capacitatea de a-l înţelege pe cel care are nevoie de ajutor este esenţială pentru un bun profesionist. Aceeaşi capacitate însa poate expune persoana unor consecinţe nocive asupra sănătăţii sale fizice şi psihice. Carl Rogers se află printre primii care a vorbit despre importanţa empatiei în lucrul cu oamenii aflaţi în suferinţă. El propune empatia ca mod de a fi, ca formă de comunicare ce implică a îngriji de celălalt, a asculta, a observa, a înţelege, şi a răspunde îngrijorării sale cu respect profund şi autenticitate (23). Cea mai mare parte din comunicare, din ceea ce transmitem celorlalţi se face pe cale nonverbală. Empatia presupune a fi conştient de celălalt şi de ceea ce vrea sa spună prin contact vizual, prin limbajul corporal, prin tăcerile sale, tonul vocii, gesturi, expresii faciale, folosirea spaţiului fizic şi prin multe alte metode. De la Rogers până în zilele noastre abordările terapeutice şi perspectiva asupra interacţiunii cu pacientul s-au modificat, devenind mai complexe, mai diverse, dar importanţa empatiei în profesiile sociale nu a fost niciodată contestată. Este instrumentul principal în construirea unei relaţii de încredere autentică şi durabilă care să garanteze aderarea pacientului la tratament, încrederea lui în reuşita demersului întreprins şi continuarea vizitelor la specialist cu frecvenţa necesară. Una dintre cele mai discutate operaţionalizări ale empatiei, îi atribuie trei dimensiuni. Contagiune emoţională se referă la capacitatea de a împărtăşi suferinţa unei alte persoane. De a trăi alături de cel îndurerat sentimente de tristeţe asemănătoare. Grija empatică arată preocuparea pentru starea celuilalt, îngrijorarea pentru cum va evolua şi dorinţa de a-l sprijini. A treia dimensiune este disponibilitatea de a comunica. Abilitatea de a comunica eficient cu ceilalţi despre subiecte sensibile şi emoţionale (24). Toate cele trei variabile au fost studiate în timp şi s-au arătat a fi benefice pentru interlocutor, dar dintre ele se pare că o importanţă deosebită o are contagiunea emoţională care determină mai multe răspunsuri pozitive. A simţi alături de celălalt, a-i împărtăşi durerea, îl ajută pe cel aflat în suferinţă să se simtă înţeles. Stările emoţionale îi sunt validate de răspunsurile celeilalte persoane şi nu se mai simte însingurat. Empatia este adesea greşit înţeleasă, pentru că a comunica empatic nu înseamnă doar a compătimi pe cel care îşi povesteşte neliniştile ci a-l înţelege şi a-i arăta susţinere. Partenerul empatic trebuie să fie activ în interacţiune şi conectat deplin cu interlocutorul său. A asculta cu atenţie şi a simţi nevoile şi dorinţele celeilalte persoane constituie elementul central al oricărei relaţii centrate pe client.

Hojat, Gonnella, Nasca şi colab. raportează despre importanţa empatiei pentru medici în particular subliniind efectele ei benefice în relaţia cu pacientul şi în rezultatele clinice. Susţin că în ciuda recunoaşterii ei ca element de bază, prea puţine studii s-au ocupat de acest subiect (25). Există însă şi o parte întunecată a implicării empatice pe măsură ce specialistul pătrunde cu înţelegere şi implicare în universul interior al unei persoane tulburate sau traumatizate. Unele dintre experienţele şi emoţiile pacientului pot fi distorsionate pe măsură ce sunt asimilate de către interlocutor şi potrivite în schemele cognitive şi credinţele sale despre lume. În acest sens, Miller şi colaboratorii au investigat rolul empatiei ca precursor al *burnout*-ului asupra unui eşantion de 417 cadre medicale. Rezultatele obţinute arătau cum grija empatică favorizează disponibilitatea comunicaţională, dar contagiunea emoţională duce la o scăderea a acesteia. Disponibilitatea de a comunica pe de altă parte s-a dovedit a fi un predictor important pentru toate cele trei dimensiuni ale *burnout*-ului propuse de Maslach (depersonalizare, reducerea împlinirii personale şi epuizare emoţională) (26). Omdahl şi O'Donnell au realizat un studiu similar centrându-se doar pe situaţia asistenţilor medicali. Autorii au analizat rolul variabilelor ce ţin de empatie în stresul profesional şi în angajamentul ocupaţional la asistenţi medicali. Stresul a fost exprimat prin modelul tridimensional al *burnout*-ului propus de Maslach. Rezultatele au arătat că cele trei variabile ale empatiei explică în proporţie semnificativă varianţa tuturor celor trei dimensiuni ale stresului. Lipsa grijii empatice şi a disponibilităţii comunicaţionale explică mare parte din varianţa factorului depersonalizare, în timp ce lipsa grijii empatice, lipsa disponibilităţii comunicaţionale şi contagiunea emoţională ridicată contribuie semnificativ la reducerea sentimentului de realizare personală. Contagiunea emoţională pare a fi o cauză importantă a epuizării emoţionale, fiind implicată şi în scăderea angajamentului ocupaţional (24). În afara tuturor acestor efecte nefaste ale implicării empatice, Figley, identifica empatia ca factor de risc asociat în sindromul de stres traumatic secundar. El sugera că profesioniştii implicaţi în servicii de ajutorare a celor aflaţi în suferinţă, trebuie sa rămână obiectivi şi să păstreze o anumită distanţă faţă de client atunci când încearcă să îi vină în ajutor. Consemnul este de a asculta empatic, făcând însă abstracţie de trăirile şi părerile personale pentru garantarea unei analize obiective, pentru alegerea tratamentului potrivit şi pentru desfăşurarea intervenţiei în cele mai bune condiţii. Abordarea clinică se plasează cumva într-un context paradoxal care stabileşte compasiunea şi empatia ca fiind esenţiale pentru o relaţie terapeutică oportună, cerând în acelaşi timp detaşare şi obiectivism (27).

CONCLUZII

Există studii care să evalueze nivelul de stres ocupaţional, satisfacţia în muncă, epuizarea emoţională, *burnout*-ul, dar dincolo de stresul resimţit în forma lui generală, personalul medical este zi de zi martor la mari suferinţe, drame şi traume. Stresul traumatic secundar ar putea fi o potenţialitate sumbră în acest caz. Dăruirea, promptitudinea şi eficienţa absolută sunt exigenţe constante pentru personalul medical. Mai mult decât în alte profesii ezitările şi greşelile pot fi ireparabile. Empatia este un element necesar pentru garantarea de servicii medicale competente, pentru o bună relaţie cu pacienţii, pentru obţinerea de rezultate pozitive. În acelaşi timp empatia vulnerabilizează cadrele medicale în faţa stresului în formele sale particulare, ceea ce ameninţă tocmai relaţia cu pacienţii şi calitatea serviciilor oferite. Este dificil de stabilit calea optimă şi studii suplimentare sunt

necesare în această direcţie. Din această cauză evaluarea şi prevenirea unei simptomatologii atât de marcante psihic cum este cea din stresul traumatic secundar, sunt o necesitate.

NOUTĂŢI

Efectele SUBSTITUIENŢILOR SALIVARI asupra statusului oral la pacienţii cu diabet zaharat de tip 2

Un grup de cercetători italieni a evaluat statusul oral la un lot de pacienţii cu diabet zaharat tip 2, înainte şi după terapia cu substituienţi salivari şi la un lot de pacienţi diabetici care nu a urmat terapie cu înlocuitori de salivă. În studiu au fost incluşi 134 de pacienţi cu diabet zaharat de tip 2, având vârsta medie de 47,9 $\pm$ 2,9 ani, cărora li s-a determinat rata fluxului salivar. Media ratei fluxului salivar a fost semnificativ mai scăzută în comparaţie cu lotul martor. Lotul de 134 de pacienţi a fost împărţit aleator în două grupuri a câte 67 de persoane fiecare. Un grup a primit substituienţi salivari imunologic activi timp de 6 luni, celălalt grup neavând nimic administrat. Fiecare pacient din cele două grupuri a fost supus unui examen dentar si parodontal la începutul studiului şi 6 luni mai târziu. Rezultatele studiului arată că, în ceea ce priveşte leziunile carioase şi pierderea dinţilor, nu au existat diferenţe statistice între primul grup, după 6 luni de tratament cu substituienţi salivari şi grupul de control ($P > 0,01$). Înlocuitorii salivari nu au redus în mod semnificativ boala parodontală ($P > 0,01$). În grupul tratat cu substituienţi salivari, după 6 luni de tratament, media indicelui de placă dentară a scăzut de la 2,3 $\pm$ 0,73 la 1,6 $\pm$ 0,56, la pacienţii cu gingivită a scăzut de la 66% la 43%, iar la pacienţii cu o infestare fungică semnificativă, numărul a scăzut de la 60% la 37%. Aceste diferenţe au fost semnificative statistic ($P < 0.01$). În concluzie, la pacienţii cu diabet zaharat de tip 2, în caz de hiposalivaţie, tratamentul cu substituienţi salivari imunologic activi poate fi util în reducerea cantităţii de placă, gingivitei şi infestării fungice (Montaldo L, Montaldo P, Papa A, Caramico N, Toro G. Effects of saliva substitutes on oral status in patients with type 2 diabetes. *Diabet Med* 2010 ; 27 (11) : 1280–1283).

A COMPARATIVE STUDY OF PERSONALITY PROFILES BETWEEN TWO POPULATIONS OF STUDENTS FROM TIMISOARA, ROMANIA AND CHISINAU, REPUBLIC OF MOLDOVA (Abstract): The aim of this study was to compare personality profiles between two populations of students from Timisoara, Romania and Chisinau, Republic of Moldova. The study was performed on two samples of students at Medicine in the 2nd year of study: 172 students from Timisoara (72.67% male, 27.33% female, aged 19-22 years), and 418 from Chisinau (75.84% girls and 24.16 boys, aged 19-22 years). The study conducted was a cross sectional one and it consisted in applying a Freiburg Personality Inventory (FPI) (212 items, Cronbach`s α index 0.753 for Timisoara and 0.695 for Chisinau samples). Individual FPI profiles (12 personality traits with 9 ranks of intensity) were built using an Excel 2003 Program. FPI profiles (median) of the samples indicated the same level of intensity in both samples for 6 personality traits (Aggressiveness, Sociability, Calm, Sincerity, Extraversion, Masculinity) and different levels for the other 6 (Nervousness rank 7, Depression, Excitability, Domination, Inhibition, Emotional lability). Personality profiles of female-students were similar with personality profiles of entire samples (except Depression in Timisoara, and Calm in Chisinau). Personality profiles of students aged 20 years were similar with personality profiles of entire sample (except Domination in Timisoara). Only Nervousness (rank 7) was outside etalon interval (ranks 4-6) in the Chisinau sample and it was higher than in the Timisoara sample with 1 rank for all personality profiles. In conclusion personality profiles of both samples presented equally similarities and differences and are specific for female-students aged 20 years in the 2nd year of Medicine school. **Keywords:** PERSONALITY PROFILES, STUDENTS, TIMISOARA AND CHISINAU, CROSS SECTIONAL STUDY.

Personality traits of individuals from different countries have become a subject of growing interest (1). The Banat with the capital in Timisoara and Bessarabia with the capital in Chisinau were in the past (1918-1940) two historical provinces of Romania. In the meantime (1940-2018) they became two regions in two different countries (Romania and Republic of Moldova). Personality traits found in certain populations indicate heritage or/and environmental influence (2). Personality profiles of cultures can be operationalized as the mean trait levels of the members of a

culture (3). The aim of this study is to compare personality traits (prevalence and profiles) between two populations of students in the 2nd year of study at the Medicine Faculty, from Timisoara and Chisinau.

MATERIAL AND METHODS

A cross sectional study was performed on two samples of students in the 2nd year of study at Medicine Faculty from Timisoara (Romania) and Chisinau (Republic of Moldova). It consisted in a Freiburg Personality Inventory (FPI, 212 items) applying (4). Sample structure, statistic and reliability of method for Timisoara and Chisinau are presented in first table.

The questionnaire, standardized for Romanian population, and measuring 12 personality traits (Nervousness (Nrv), Aggressiveness (Agr), Depression (D), Excitability (Exc), Sociability (Soc), Calm (Clm), Domination (Do), Inhibition (Inh), Sincerity (Snc), Extraversion (Exv), Emotional lability (Lbl) and Masculinity (M)) was applied individually and anonymously, in a one-hour session. The ethical approval of the Ethical Committees of both Universities and the informed consent of each student to participate were asked for and obtained. FPI individual profiles were built using an Excel 2003 Program. Statistical work was performed using a SPSS Statistics 20. Prevalence (%) and personality profiles (median trait levels) of both samples were performed. Samples size, gender and age were carefully considered.

TABLE I

Samples structure and reliability of the method

	Timisoara[1]						Chisinau[2]					
	All sample		Females		Males		All sample		Female		Males	
Age	N	%	N	%	N	%	N	%	N	%	N	%

Note: [1] - 26 excluded students from the original sample;

[2] – 42 excluded students from the original sample; N-number of students; % - percent.

RESULTS

In comparing the Timisoara and the Chisinau entire samples, the highest students` prevalence was at the same levels of intensity for 7 personality traits (Nrv, Agr, D, Clm, Inh, Snc, Exv) and at the different

intensity levels for 5 traits (Exc, Soc, Do, Lbl and M) (tab. II). Personality profiles (median level of the traits intensity) of the entire samples indicated 6 personality traits (Agr, Soc, Clm, Snc, Exv, M) at the same level of intensity and 6 traits (Nrv, D, Exc, Do, Inh, and Lbl) at different levels of intensity (fig. 1).

Note: T – Timisoara; C –Chisinau; 1…9 – ranks of intensity for each personality dimension.

The median age for both samples was 20 years (tab. I). Personality profiles of students aged 20 were identical to with personality profiles of the entire sample (except Do in Timisoara). From the entire sample 72.67% (125) in Timisoara and 75.84% (317) in Chisinau were female-students (tab. I). The female students` profiles were identical to (except D in Timisoara and Clm in Chisinau) with the entire samples profiles. The male-students' profiles were different from the entire sample, students aged 20, and the female-students' profiles. Nevertheless, the similarities between Timisoara and Chisinau were higher (8 personality traits at the same rank) than all the others (fig. 1). Nervousness (rank 7) was outside etalon interval (ranks 4-6) for all analyzed profiles in Chisinau sample.

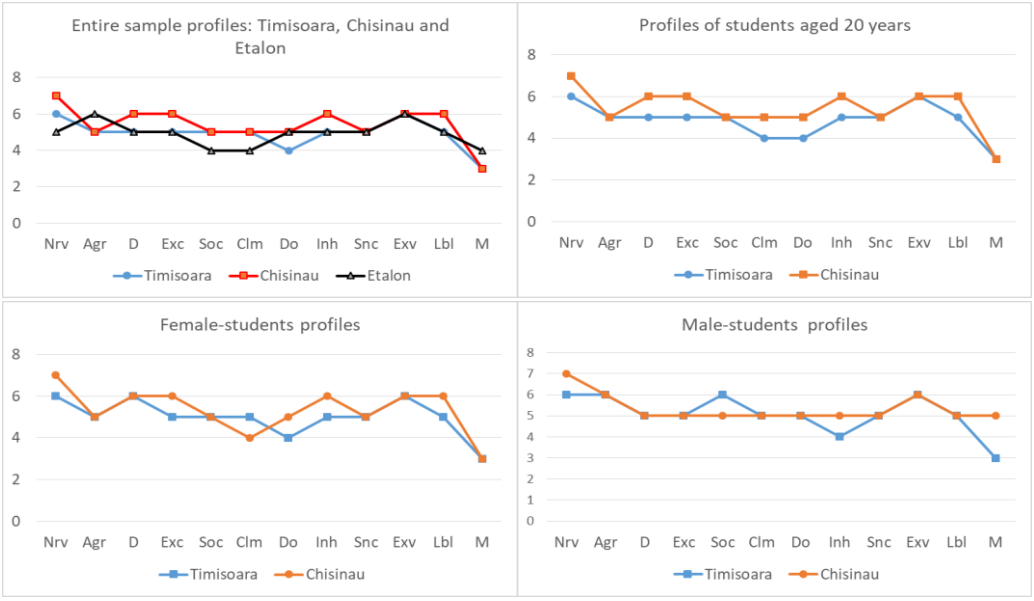

Fig. 1. Personality profiles built for entire samples, students aged 20, female- and male-students samples in Timisoara and Chisinau

DISCUSSION

Real differences in personality traits across countries found in past research and the difficulty in establishing a relationship between personality traits and culture in present studies (1) let the question "Is it a relation between personality profile and culture?" still open. In the performed study we found similarities and differences of personality profiles between the two cities, and a powerful influence of gender and age on personality profiles of students in the 2nd year of study at Medicine from Chisinau and Timisoara. Aggregate personality profiles provide insight into cultural differences (3) and similarities between cultures into segregated cultures. FPI tool offered us the possibility to pinpoint interesting cultural, gender, age and professional contribution (5, 6) to personality profiles in 2 populations with common cultural elements. A limit of this study is that it is an

observational one and future investigation needs to be done.

CONCLUSIONS

Personality profiles of both samples (Timisoara and Chisinau) present equally, similarities and differences and are specific for female-students aged 20 years in the 2nd year at Medicine Faculty. Nervousness (rank 7) is outside etalon interval in the Chisinau sample and is higher, with 1 rank, than in the Timisoara sample for all personality profiles.

NEWS

LIQUID BIOPSIES COULD REVOLUTIONISE CANCER MEDICINE

Tumor biopsies are the current standard for cancer diagnosis and the preferred method for molecular testing to guide the selection of precision therapies. Liquid biopsies, mostly those involving cell-free DNA (cfDNA) from plasma, are rapidly emerging as an important and minimally alternative approach. Liquid biopsy is becoming a valuable tool for molecular testing for new insights into tumor heterogeneity, and for cancer detection and monitoring. Although liquid biopsy has most often referred to the analysis of cfDNA from peripheral blood, this term also refers to the isolation and analysis of tumor derived material from blood or other bodily fluid like cerebrospinal fluid, saliva, pleural fluid, ascites, stool and urine. Although more prospective studies are needed liquid biopsies have the potential to revolutionize cancer medicine (Corcoran RB, Chabner BA. Application of cell-free DNA analysis to cancer treatment. *N Engl J Med* 2018; 379(18): 1754-1765).

THE ROLE OF DYSFUNCTIONS AND PARAFUNCTION HABITS IN THE DEVELOPMENT OF MALOCCLUSIONS

THE ROLE OF DYSFUNCTIONS AND PARAFUNCTION HABITS IN THE DEVELOPMENT OF MALOCCLUSIONS (Abstract): The aim of this study was to find any correlations between dysfunctions and parafunction habits in mixed dentition children and malocclusions prevalence. **Material and methods**: A number of 50 children were included in this study, 27 girls and 23 boys, aged between 6 and 8 years old. They were examined by an orthodontist regarding the presence of malocclusions: overjet, overbite, anterior or posterior crossbite, anterior open bite and canine and first molar relationship. A statistical test was used to find the correlation strength between bad habits and malocclusions. **Results:** An increased overjet was correlated with long time artificial feeding and a deep overbite was associated with baby pacifier habits. Canine and molar class II were associated with thumb sucking habits and artificial feeding. **Conclusions:** The presence of bad habits was directly associated with the presence of malocclusions and the malocclusion prevalence was higher at children with bad habits. **Keywords**: DYSFUNCTION, PARAFUNCTION, HABITS, MIXED DENTITION, MALOCCLUSION.

Malocclusion is a development deviation from the orofacial equilibrium having consequences on dental health and psychological comfort of the patient.

Malocclusions prevalence depends on the interaction of different factors: genetic, environmental, neuromuscular and pathological changes in primary or early mixed dentition (1). The etiology of malocclusion is numerous, and the risk factors can be divided in three categories: general causes (heredity, endocrine disorders, harmful habits and disorder of physiological functions), local causes (number, form or position abnormalities, premature loss of primary teeth), dento-alveolar disharmony (crowding) (2).

Another author divides the dento-maxillary pathological functions in two groups:

- Dysfunction habits: artificial feeding, oral breathing, tongue-thrust habit, bad phonation;
- Parafunction habits: sucking habits, tics and bruxism (3).

Artificial feeding has been associated with malocclusions especially in primary dentition. Some studies revealed that 53% of artificial-fed children developed myofunc-

tional disorders with tongue resting on the mandibular arch or between dental arches, because of muscle hypotonicity (4). Alteration of oral muscles caused by artificial feeding can affect many functions: deglutition, mastication, breathing and speech-sound pronouncement (5). Several authors affirmed that bottle-fed children can easily develop a nonnutritive-sucking habit (6, 7).

Both types of sucking habits are associated with an atypical swallowing pattern, with tongue thrusting, which can be related to the development of posterior crossbite malocclusion (8).

Also, oral breathing, which is frequently found during the night, is a risk factor for malocclusion developing, especially open bite or class II/1 with an increased overjet. Mouth-breathing is often associated with the presence of enlarged adenoids and nasopharyngeal airway obstruction. Several studies associated these dysfunctions with the development of skeletal and dento-alveolar malocclusions (9, 10).

Tongue thrust or immature deglutition is a harmful habit which can favor the appearance of some dento-maxillary abnormalities. Kydd *et al.* found that patients with tongue thrust put more pressure on the upper anterior teeth than those with normal deglutition (11). Neff and Kydd established that deglutition frequency is double on those with normal deglutition than children with tongue thrust (12). Whitman *et al.* showed the lack of pharyngeal reflex on those with immature deglutition (13).

Thumb sucking behavior was recognized by many authors as affecting occlusion and characteristics of dento-alveolar arches. Farsi and Salama affirmed that thumb sucking children have frequently dental class II on molars and canines and an increased overjet (14).

The aim of the present study is to assess the relationship between different dysfunction habits and the prevalence of malocclusions in children with mixed dentition.

MATERIAL AND METHODS

This prospective study was performed on 50 children from a public school from Tirgu-Mures, 27 girls and 23 boys, aged between 6-8 years old. The children were examined regarding the presence of malocclusions: overjet and overbite measurement, presence or absence of anterior or posterior crossbite, presence or absence of anterior open bite and canine and first molar relationship. Examination was made in the school medical office by an orthodontist using single use examination kits keeping the intercuspation relationship (fig. 1). The information about history and duration of habits has been taken from parents, who answered to a questionnaire and signed a consent for children examination.

The habits that were analyzed were: thumb sucking, oral breathing, tongue thrust, artificial feeding and baby pacifier. The collected data were statistically analyzed using Spearman's test, detecting the correlation between multiple habits and the presence of malocclusions.

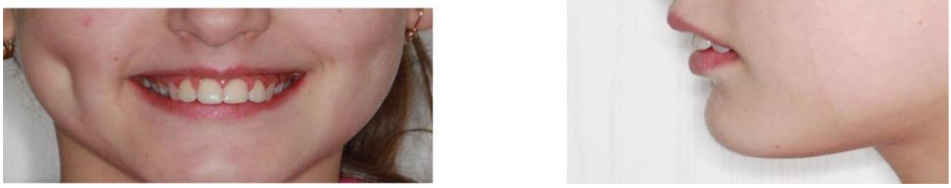

Fig. 1. Female patient; Class II/1 malocclusion; thumb sucking habit followed by oral breathing

RESULTS

An increased overjet can be caused by a long-time artificial feeding habit, a weak correlation has been found between those two. An increased overbite is weakly correlated with baby pacifier habits, but also with natural feeding, and a decreased overbite is weakly correlated with thumb sucking habit. A canine and molar class II can be associated with a thumb sucking habit, with a moderate correlation, and also with artificial feeding, but having a weak correlation. On the other hand, Class III relations were found on children with pacifier sucking habit. A crossbite occlusion can be associated with a long-time pacifier sucking habit with a moderate correlation between them. None of dysfunction habits has been correlated with crowding or spacing incongruence (tab. I).

	N	26	26	26	26	26

*. Correlation is significant at the 0.05 level (2-tailed). **. Correlation is significant at the 0.01 level (2-tailed).

The prevalence of malocclusions was: 8 children presented an increased overjet; 15 children presented a deep overbite, 11 children had edge to edge anterior bite and only 2 children had an open anterior bite. The posterior crossbite was found in only 3 cases. The canine and molar relations were: dental class II was the most frequent on canine and molar, both present on 7 cases and 6 cases having only the canine in class II. Crowding and spacing incongruences were found: 13 crowding cases and 15 spacing cases.

DISCUSSION

The study design is similar with other studies in the literature being based on cause-effect relation. It was observed that a long time of bad habits increase malocclusions. Also, in the Elton *et al.*, study has been showed that children with a prolonged pacifier-sucking habit after 2 years of age had greater chances of malocclusion than normal children (15).

Also, other authors, like Farsi and Salama, found that nonnutritive sucking habits determine distal molar and canine relationships and larger overjet (14). Warren and Bishara study were similar with our study regarding an increased overjet on children with artificial feeding habit. They also found a reduced overbite on this patient, but our results are no significant regarding this (16).

A Slovenian study demonstrated that thumb or pacifier sucking habit and artificial feeding practiced after the age of 5 are correlated with an atypical deglutition at the age of 6-9 years and with the presence of a malocclusion after 12 years (17).

Suzely *et al.* study showed that pacifier sucking habit practiced for 12-30 months is associated with an increased overjet and open bite but practiced for more than 30 months can be associated with an overbite (18). In our study the pacifier sucking habit is weakly correlated with an increased overjet and moderate correlated with crossbite malocclusion.

The prevalence of malocclusion from our study is 19.6 %, lower than other studies: 32.5% in Brazil on a 381 children sample or 70% from an 80 children sample (6).

The highest percentage among dysfunctions was the artificial feeding more than 12 months- 40 %, followed by pacifier-sucking more than 2 years - 20 %, which are similar with other studies percentages: artificial feeding - 90% and pacifier sucking - 38% (19).

According to World Health Organization, breast feeding should be exclusive till the age of 6 months and additional till the age of 2. In this study 8% of children haven't ever been breast fed and 24% have been fed more than 12 months. The insufficiency of natural alimentation can be correlated with an undeveloped facial muscles, atypical deglutition, bad sucking habits and oral breath.

Premature loss of temporary teeth can also be the reason of underdeveloped bones and secondary open bite, which can cause deviation from normal function. The use of space maintainers after premature loss of the second upper temporary molar is a last solution in preventing tridimensional lesions in the dental arch and occlusion (19).

The limit of our study is the small number of patients, especially those diagnosed with oral breathing and atypical deglutition, the reason of the absence of correlations between these dysfunctions and malocclusions development.

CONCLUSIONS

The presence of bad habits was directly associated with the presence of malocclusions.

The malocclusion prevalence is increased on children with dysfunctions and

parafunctions.

Children artificial fed had greater chances to an increased overjet and molar class II.

Thumb sucking habits at children were weakly correlated with a decreased overbite and an increased overjet and moderate correlated with molar and canine class II.

The high frequency of bad habits seems to be a real problem for the development of dento-maxillary system, and it needs more attention from dentists and also from parents.

Using the baby pacifier for a long time can increase the overbite and the prevalence of crossbite malocclusion.

It is a bit difficult to find statistical correlations between dysfunctions and malocclusions given a smaller number of children, but the cause-effect relationship is clearly demonstrated in literature.

STUDY ON CORRELATION BETWEEN CERVICAL VERTEBRAE MATURATION, DENTAL AGE AND ACTUAL AGE OF CHILDREN (Abstract): The study **aim** was to provide a version of the cervical vertebral maturation index (CVM) method for evaluating maxillary and mandibular skeletal maturation for each patient in the study group. **Material and methods:** The morphology of the three cervical vertebrae, the presence of concavities on the lower vertebral border and the form of the vertebral body at CS 2, CS 3 and CS 4 was evaluated by visual inspection of lateral cephalograms by two evaluators. The percentage of concordance among examiners was 96.7% For the study of the correlation the 2 evaluators examined 60 panoramic radiographies and analyzed the dental age using the Demirjian Index. **Results**: The descriptive indicators of the study group show an average age of 12.65 years. The average CVM score awarded in the study group is 3.133. The most frequently score is CVSM 2 ,anatomical feature that identifies the stage immediately ahead of the mandibular growth peak. For the correlation the dental age was determined with the better known Demirjian Index using scores calculated on the reference teeth 33, 34, 37 on the panoramic radiographies in the study group. **Conclusions**: The results of visual cephalometric analysis required a relatively short time and are consistent with the CVM method in published studies, the reproducibility of CVM steps being equally high. **Keywords:** VERTEBRAE, FORM, CEPHALOGRAMS, CVM SCORE, DEMIRJIAN INDEX, DENTAL AGE.

The fundamental concept of dentofacial orthopedics is to achieve maximum, three-dimensional effects in the optimum mandibular growth period. Treating inaccurately before puberty gives the impression that functional appliances do not work although they are only used in a biologically unfavorable moment .

There are few studies in our country that include information on skeletal maturity in patients treated with functional appliances, and for the most part, the biological growth indicator is the supplementary analysis of hand-wrist X-ray or Demirjian analysis on panoramic radiographs (1, 2).

The Baccetti CVM method considers that maximal mandibular growth time is associated with CVM 3 - CVM 4 stage not in temporary or mixed dentition but prepuberty (3, 4, 5, 6, 7) Recently, cervical vertebral maturation index CVM has gained maximum attention in the literature as an alternative to evaluate skeletal maturity in the office, replacing an additional radiological exam (hand-wrist radiograph) in the conditions where conventional cephalogram is recommended for diagnosis, and the majority of orthodontists are trained and familiar with its interpretation.

AIM

In this study we intended to provide a version of the cervical vertebral maturation index CVM method for evaluating maxillary and mandibular skeletal maturation for each patient, we made the analysis of the morphological characteristics of C2, C3 and C4 cervical vertebrae on lateral cephalograms and determined the correlation with the values of the Demirjian Index evaluated on panoramic radiographs.

MATERIAL AND METHOD

Visual analysis - 2 evaluators examined the morphology of the three cervical vertebrae by visual inspection on lateral cephalograms. The proportion of concordance among examiners was 96.7%.

Visual analysis - 2 evaluators examined the panoramic radiographs and the Demirjian Index was determined. The percentage of concordance among examiners was 96.7%;

60 lateral cephalograms and panoramic radiographs were realized with the same FONA radiological equipment was selected for the study: 29 girls and 31 boys were selected for the study. The distribution was almost equal - 47.5% girls and 50.8% boys. The age distribution of the study group is heterogeneous: 12-year-old children predominate 26.2%, followed by 11-year-olds and 13-year-olds, the smallest 15-year-old (3.3%) (tab. I).

TABLE I

Distribution of the study group by age

	Frequency	Percentage	Valid percentage	Cumulative percentage
10.00	8	13.1	13.3	13.3
11.00	11	18.0	18.3	31.7
12.00	16	26.2	26.7	58.3
13.00	10	16.4	16.7	75.0
14.00	3	4.9	5.0	80.0
15.00	2	3.3	3.3	83.3
16.00	10	16.4	16.4	75.0
TOTAL	**60**	**100.0**		

The statistical descriptive parameters of the study group show an average age of 12.65 years, average Demirjian Index of 7.43 for the lower canine, 7.35 for the lower first premolar, 6.88 for the lower second premolar, 9 for the lower second molar.

The average cervical vertebral maturation index CVM score in the study group is 3.133 with a standard deviation of 1.52 (tab. II).

TABLE II

Statistical descriptive parameters in the study group

	N	Minimum	Maximum	Medium value	Standard Deviation
Age	60	10.00	16.00	12.6500	2.08160
DI 33	60	6.00	8.00	7.4333	0.67313
DI 34	60	5.00	8.00	7.3500	0.75521
DI 35	60	6.00	8.00	6.8833	0.82527
DI 37	60	5.00	8.00	6.9000	0.72952
CVM	60	1.00	6.00	3.1333	1.52345

RESULTS AND DISCUSSION

The first examiner gave cervical vertebral maturation index CVM scores between 1 and 6 with an average of 3. The second observer gave cervical vertebral maturation index CVM close but less expressive CVM with a mean greater than 3.5, bringing the patients to the maximum value of the CVM score (tab. III).

The first examiner gave cervical vertebral maturation index CVM 1 scores in 8% cases; CVM 2 in 40% cases; CVM 3 score in 18%;CVM 4 score in 16% cases; CVM 5 score in 14% cases and CVM 6 score in 4% of cases. The second examiner gave CVM 1 scores in 12% cases; CVM 2 in 28% cases; CVM 3 score in 24% cases; CVM 4 score in 16% cases; CVM 5 score in 12% cases and CVM score 6 in 4% cases.

TABLE III

The CVM scores calculated in the study group

Age	N	Medium value	Standard Dev.	Medium Error
	60	12.65	2.08160	0.84728
CVM scores Observer 1	60	3.0000	1.35526	0.19166
CVM scores Observer 2	60	3.5400	4.47765	0.63324

In the study group, cervical vertebral maturation index CVM 1 scores were seen in 13.1%. lateral cephalograms; CVM 2 scores were seen in 27% examinations.; CVM 3 scores were seen in 19.7% examinations; CVM 4 scores were seen in 18% examinations and CVM scores 5 and 6 were seen in 10% examinations (tab. IV).

The cervical vertebral maturation index CVM score most often accorded is CVM 2 which has the highest percentage distribution as in Howell's studies (8). In this stage of skeletal development, vertebrae C2 and C3 are trapezoidal or rectangular in shape and have concavities on the lower edge of the vertebral body.

General tendency is that the skeletal age is lower than the chronological age, which leads to the conclusion that these children tend to late mature as the Arab children in the study of Alhadlaq (9), the Turkish children in the study of Uysal (10, 11) and different from Thai children with early maturation from Kumar's study (12).

TABLE IV

CVM scores in the study group

CVM				
	Frequency	Percentage	Valid Percentage	Cumulative percentage
1.00	8	13.1	13.3	13.3
2.00	17	27.9	28.3	41.7
3.00	12	19.7	20.0	61.7
4.00	11	18.0	18.3	80.0
5.00	6	9.8	10.0	90.0
6.00	6	9.8	10.0	100.0
TOTAL	60	100.0		

For the correlation of age identified using the cervical vertebral maturation index CVM stages on the lateral cephalograms Demirjian scores on the reference teeth 33, 34, 37 were calculated on panoramic radiographs of the patients in the study group (13, 14).

The score for the lower canine was 6 for 9.8% of patients; 7 for 36.1% and 8 for half of the patients in the study group, the lower canine being in stage G or H of dental development after Demirjian. This stage is reached 0.4 years before the pubertal growth peak in girls, and in boys 1.3 years earlier.

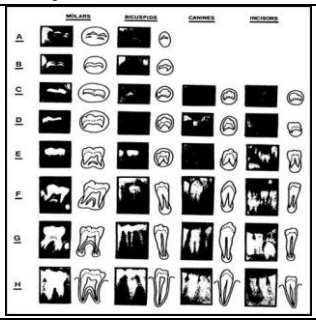
The Demirjian score for the first lower premolar was 5 for 3.3% of patients; 6 for 6.6%, 7 for 41%; and 8 for 41% of the patients in the study group, the lower canine being in stage G or H of development after Demirjian.

This stage is reached 0.4 years before puberty growth peak in girls and in boys with 1.3 years previously. The score for the lower second molar was 5 for 3.3% of patients, 6 for 21.3%, **7** for 55.7% and 8 for 18% of the patients in the study group, the lower molar being in stage F, G or H dental development after Demirjian Index. Stage F marks the onset of pubertal growth peak in girls (tab. V) (15).

TABLE V

Values of the Demirjian Index on panoramic radiographies at 33, 34 and 37 in the study group. Imaging with the Demirjian Index by Maniar *et al.*

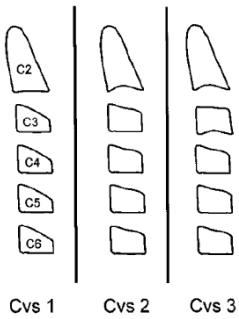
		Demirjian Index 33	Demirjian Index 34	Demirjian Index 37
		Frequency	Frequency	Frequency
F	5.00	6	2	2
G	6.00	22	4	4
G	7.00	32	25	25
H	8.00	61	29	29
TOTAL		60	60	60



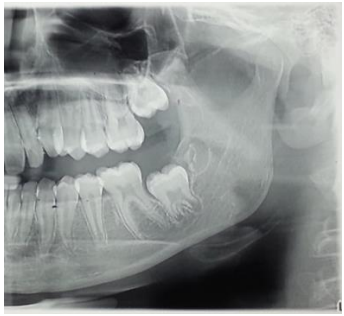
For the 11-year-old CE diagnosed with Class II / 1 Angle Malocclusion, lateral cephalogram and panoramic radiography were analyzed, a maximum increase at 11 years old was identified and a functional appliance treatment was initiated with a Klammt elastic activator that corrected the overjet and class II molar relation in 6 months (figs. 1, 2, 3).

Fig. 1. Initial intraoral aspects

Fig. 2. Intraoral image after 6 months treatment with Klammt elastic activator-normal overjet and molar occlusion



Stage CVM 2 Lower margins of vertebrae C2, C3 have a visible concavity on the lower edge, vertebrae C3 and C4 are rectangular in shape and the mandible will have a maximum increase in one year.



Stage G of the Demirjian Index, in which the limiting walls of the 33,34 apex are parallel, and the distal roots of the molars, especially the distal one is open

The Klammt activator used for patient CE in the optimal CVM 2 stage who corrected the occlusion in 6 months

Fig. 3. CVM score, Demirjian Index and the functional appliance for the patient CE

CONCLUSIONS

Changes in the size and shape of cervical vertebrae seen in growing children are of major concern as individual skeletal maturation indicators.

The results of visual cephalometric analysis require a relatively short time and are consistent with the CVM method in published studies, the reproducibility of CVM steps being equally large.

The appearance of a concavity on the C3 cervical vertebrae represents the anatomical characteristic that identifies the stage immediately before the peak of mandibular growth.

Correspondence between the records of the two examiners is maximum.

For correlation of age identified with CVM stages on cephalograms Demirjian scores on reference teeth 33, 34, 37 were

calculated on panoramic radiographies of patients in the study group. The score for the lower canine was 6 for 9.8% of patients, 7 for 36.1% and 8 for half of the patients in the study group, the lower canine being in stage G or H of dental development after Demirjian. This stage is reached 0.4 years before the pubertal growth peak in girls, and 1.3 years earlier in boys .

CVM score more often granted is CVSM 2 which has the highest percentage distribution.

The general tendency is that the skeletal age is lower than the chronological one, which leads to the conclusion that these children tend to late mature as the Arab children, Turkish children and different from Thai children with early maturation.

3. Clinica a II-a Pediatrie

KOSTMANN DISEASE IN CHILDREN (Abstract) : Kostmann's disease (KD) is a severe congenital neutropenia, a rare autosomal recessive disorder of neutrophil number. Complete blood count with differential reveals an ANC less than 500/mm^{3,} as seen in classic cases, monocytosis and eosinophilia. Bone marrow aspiration or biopsy reveals an arrest of neutrophil precursor maturation at the promielocyte or myelocyte level. KD results in an increased susceptibility to frequent bacterial infections. In the absence of medical intervention with granulocyte colony-stimulating factor (G-CSF), bone marrow transplantation, the mortality rate is 70% within the first year of life. We present three cases to illustrate this rare entity, the difficulty of diagnosis, but also to underline the importance of correct treatment. **Key words** : SEVERE CONGENITAL NEUTROPENIA, KOSTMANN DISEASE

Boala Kostmann (KD) sau neutropenia congenitală severă este o entitate rară (1-2 cazuri/1 milion de persoane) (1), cu transmitere autosomal recesivă (4), având drept caracteristică scăderea numărului absolut de neutrofile (ANC) $< 500/mm^3$(3), ce se reflectă clinic în creşterea susceptibilităţii la infecţii bacteriene în special, apărute la scurt timp după naştere. Biopsia sau aspiratul de măduvă osoasă (MO) relevă oprirea în maturare a precursorilor neutrofilici în stadiul de promielocit sau mielocit (4).

Tratamentul medical vizează antibioterapia în infecţiile bacteriene şi stimularea producţiei de neutrofile (cu factor de creştere a coloniilor granulocitare G-CSF în administrare zilnică, pe termen lung pentru a obţine beneficiu clinic) (4,5), iar cel chirurgical implică drenarea eventualelor abcese. Splenectomia nu este eficientă (4).

În absenţa intervenţiei medicale cu factor de creştere a coloniilor granulocitare (G-CSF), rata mortalităţii este mare (70% în primul an), rămânând de luat în considerare transplantul de MO (2) la pacienţii nonresponsivi la G-CSF sau la cei cu transformare leucemică (KD fiind apreciat ca stare preleucemică) (4,5) .

Vă prezentăm o suită de 3 cazuri, două surori (P.C.E. şi P.P.M.) şi un băieţel (T.V.D.), diagnosticate, îngrijite şi monitorizate în serviciul nostru.

CAZUL I

Pacienta P.C.E., în vârstă de 7 ani, din mediul rural, se internează pentru cura chirurgicală a unor multiple flegmoane la nivelul ambelor coapse şi faţa externă a genunchiului drept, colecţii tratate cu oxacilină 5 zile şi care au fistulizat spontan. Din ante-

TABELUL I
Aspirat de măduvă osoasă

	Mieloblast	Promielocit	Mielocit N	Mielocit E	Metamielocit	N nesegm
02.09.04	2%	49%			23%	3%
14.09.04	3%	19%	18%	17%	6%	2%
02.10.04	1%	31%	12%	5%	14%	2%

cedente se remarcă numeroase infecţii respiratorii şi cutanate, spitalizate. La examenul clinic se remarcă cicatrici multiple la nivelul întregului corp, markeri ai infecţiilor cutanate numeroase din antecedente. Biologic se constată: neutropenie (NP) (GA $=5.000/mm^3$, PN=6%, ANC=$300/mm^3$), limfomonocitoză şi eozinofilie, sindrom anemic important, hipocrom microcitar (Hb =7,4 g/dL), reactanţi de fază acută marcat crescuţi. Din puroiul recoltat s-a izolat Stafilococ coagulazo-negativ. Prezenţa bicitopeniei a impus efectuarea aspiratului de MO: măduvă polimorfă, bogat celularizată, granulopoieză cu blocaj maturativ şi cu asincronisme de maturaţie, eritropoieză cu semne morfologice de carenţă mixtă, mega-cariopoieză plachetogenă, eozinofilie 40%, plasmocitoză 10%, macrofagie. LDH în limite normale, electroforeza proteinelor serice: α – 2globulinele $\uparrow$, γ – globulinele $\uparrow$. Testul HIV negativ, imunograma a relevat Ig A $\uparrow\uparrow$ şi Ig M $\uparrow$, cu Ig G normale. Sub triplă combinaţie de antibiotice, transfuzii de sânge, evoluţia a fost lent favorabilă. Investigaţiile vizând NP au fost aprofundate în secţia Hemato-Oncologie. Evolutiv (tab. I, fig. 3.) NP s-a menţinut severă ($<500/mm^3$, în repetate rânduri chiar până la valoarea 0), timp de 8 săptămâni, cu limfomonocitoză >60%, eozinofilie > 20%, liniile GR şi ale TR fiind normale. Aspiratul de MO, în mod repetat a evidenţiat blocaj maturativ la nivel de metamielocit.

S-a iniţiat urgent tratament cu Neupogen (G-CSF), având în vedere infecţia severă cu risc de diseminare septicemică.

Diagnosticul de Boală Kostmann a fost pus prin coroborarea datelor anamnestice (antecedente de infecţii tegumentare şi respiratorii, fără istoric de boli infecto-contagioase recente, sau de consum de medicamente în ultimele 7-10 zile, cu potenţial de a provoca reacţii idiosincrazice), a datelor clinice (evoluţie lentă a unei infecţii tegumentare, corect tratată medical şi chirurgical), şi a datelor paraclinice - NP severă ($<500/mm^3$), obiectivată pe o perioadă de >14 zile, fără pancitopenie, cu aspect al MO de blocaj maturativ la nivel de promielocit, cu hiperplazie pe linia eozinofilelor, monocitelor şi prezenţa în număr $\uparrow$a plasmocitelor.

Au fost excluse în cadrul diagnosticului diferenţial NP de cauză extrinsecă (medicamentoase, postinfecţioase, cele secundare infiltrării medulare), NP benignă familială (dar mama şi tatăl au avut ANC în limite normale), NP ciclică (dar nu s-au înregistrat oscilaţii ale PN timp de 8 săptămâni şi răspunsul a fost dificil la administrarea de G-CSF), mielokathexis (dar morfologia PN şi aspectul MO au fost normale), NP intrinsecă din cadrul sindromului Schwachmann, diskeratoza congenitală, sindromul Chediak-Higashi; NP extrinsecă autoimună (exclusă pe baza AAN, celule lupice şi FR negativi) şi NP benignă cronică (sindromul „leucocitelor leneşe"). Pentru realizarea acestui ultim deziderat, ar fi fost necesară determinarea Ac anti neutrofilici (NA1, NA2, NB1, ND1, NE1), care nu a fost posibilă însă. S-au efectuat evaluări paraclinice indirecte şi anume testul la dexametazonă şi testul la epinefrină (ambele fiind negative).

Tratamentul a fost efectuat cu Neupogen (G-CSF), 7 $\rightarrow$ 60 μg/kg/zi, (cu răspuns pozitiv obţinut după 8 săptămâni), antibioterapie şi tratament chirurgical local în continuare.

Particularitatea cazului: s-a crezut iniţial că este o formă particulară de boală cu

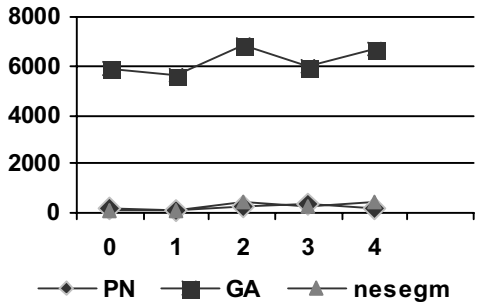

Fig. 1. Testul la epinefrină

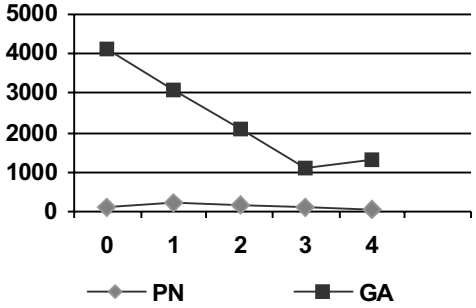

Fig. 2. Testul la dexametazonă

receptor mutant pentru G-CSF, datorită răspunsului negativ în prima săptămână de tratament şi, de asemenea, supravieţuirii până la vârsta de 7 ani, deoarece apărarea umorală, celulară şi macrofagele tisulare au jucat un rol critic.

CAZUL II

Pacienta P.P.M., în vârstă de 9 luni este investigată şi ea având în vedere antecedentele heredocolaterale (sora sa P.C.E., diagnosticată cu boală Kostmann) şi anamneza cu foarte frecvente infecţii (digestive, cutanate, respiratorii, sferă ORL- otite medii repetate) şi diagnosticată cu KD. Sub tratament cu Neupogen si multiple asocieri de antibiotice s-a obţinut vindecarea infecţiilor, unele dintre ele de gravitate mare dat fiind ANC $<200/mm^3$ şi riscul de diseminare septicemică.

CAZUL III

Pacientul T.V.D., în vârstă de 10 ani, din mediul rural, care se internează pentru conduita chirurgicală a unui flegmon situat în spaţiul popliteu drept. Din antecedente se remarcă, încă de la naştere, numeroase infecţii cu piogeni (adenoflegmoane operate, angine, abcese dentare), hipoacuzia bilaterală de gravitate medie, secundară multiplelor infecţii otice, pneumonie cu pleurezie, duplicitate pielo-caliceală bilaterală .Sub tratament cu asociere de antibiotice evoluţia a fost favorabilă şi copilul a fost transferat în Secţia de Hemato-Oncologie pentru aprofundarea investigaţiilor şi conduită terapeutică adecvată. Examenul obiectiv la internare releva stare generală influenţată, hipotrofie staturo-ponderală, numeroase cicatrici postinfecţioase cutanate, flegmon la nivelul 1/3 inferioare faţa posterioară a coapsei drepte şi spaţiului popliteu drept (fig. 4.), cu impotenţă funcţională la nivelul articulaţiei genunchiului drept, micropoliadenopatie generalizată, hipotrofie musculară, dentiţie întârziată, hipoacuzie bilaterală.

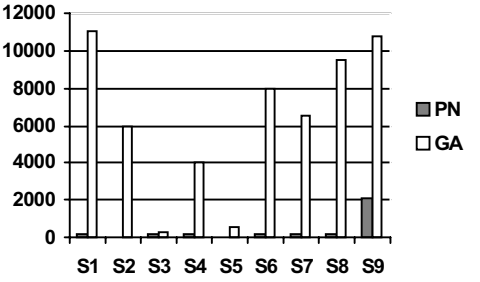

Fig. 3. Supraveghere clinică – curba GA, PN/G-CSF

Paraclinic, prezenta HLG cu GA normale / ↓, dar cu PN în FL de 3%, cu limfomonocitoză şi eozinofilie, seriile GR şi TR normale. Aspectul aspiratului de MO a fost de granulopoieză uşor hiperplazică, cu predominenţa stadiilor de promielocit, mielocit şi metamielocit şi rare elemente neutrofile finale, hipereozinofilie, plasmocitoză importantă, celelalte serii normale.

S-a efectuat tratament chirurgical, antibioterapie conform anti-biogramei şi tratament

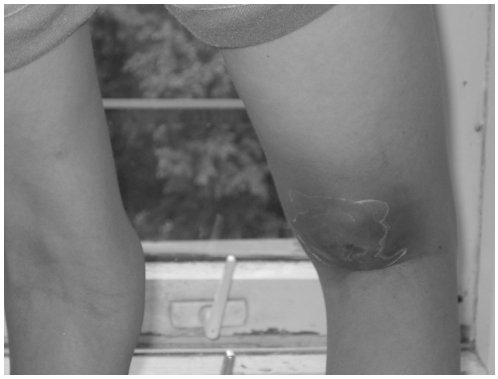

Fig. 4. Flegmon 1/3 inferioară faţa posterioară a coapsei

cu Neupogen, cu evoluţie lent favorabilă.

Cei trei copii cu KD sunt în viaţă la momentul redactării acestui material, cu stare generală şi calitate a vieţii bună - indice Karnovski 100%, fără complicaţii ale tratamentului cu Neupogen şi fără o maladie secundară.

DISCUŢII

Prognosticul în KD este rezervat. Introducerea tratamentului cu G-CSF produce o creştere semnificativă şi susţinută a ANC, rezultând în infecţii febrile de scurtă durată .Altă complicaţie redutabilă este LAM, care se poate dezvolta la 5-7% din bolnavi, KD fiind recunoscută ca stare preleucemică. Complicaţiile pe termen lung cu G-CSF nu sunt de neglijat : durerile osoase şi fracturile (la 50% din bolnavi – se datorează ↑ resorbţiei osoase), osteopenie, fibroza MO. În caz de epuizare a efectului G-CSF, singura resursă terapeutică rămâne transplantul de MO.

CONCLUZII

KD este o boala rară, care atrage atenţia prin frecvenţa infecţiilor, în special bacteriene. Tratamentul cu G-CSF prelungeşte evoluţia şi ameliorează prognosticul bolnavului.

FACTORS INFLUENCING DIETARY HABITS AMONG MEDICAL STUDENTS AND DOCTORS. A THEORETICAL APPROACH (Abstract): Dietary habits are strong related to physical and psychological health. During academic years, students are more prone to experience unhealthy food and to develop unhealthy and risky behaviors like smoking, eating fast food, skipping meals, unbalance nutritional dinners, skipping lunches and breakfasts and eating disorders due to stress. Later in their life as doctors, these dietary habits are more and more influenced by professional life, job-related factors like swifts, long working hours with great impact on health. The paper presents risk factors related to dietary habits among medical students and doctors, and their consequences on physical and psychological health. **Keywords**: PHYSICIANS, DIETARY HABITS, MEDICAL STUDENTS, EATING DISORDERS, STRESS.

The World Health Organization defines health as a state of complete physical, mental and social well-being and not just the absence of disease or infirmity (1). A healthy lifestyle that includes regular physical activity, a balanced diet and avoiding smoking as well as excessive alcohol consumption has been shown to reduce the alarming overall mortality caused by non-communicable diseases (NCDs), which annually, represents 36 million deaths worldwide (2). Moreover, healthy eating has an influence on motor concentration (3), memory and performance (4), mood and fatigue (5) - the latter being associated with cognitive and motor disorders, injuries and mistakes (6).

Medicine, which involves long hours of work, emotional stress and high volume of tasks, is an example of demanding activity, both physically and mentally, which requires high levels of cognitive and motor performance (7). The pre-existing patterns of unhealthy behavior established during the student's years of medical training can continue to develop during adult life, transforming into behaviors that will shape the future related to the health of the young doctor (8-10). Thus, it is important to first explore the lifestyle (nutrition, exercise, alcohol and tobacco use) and certain aspects of medical students' mental health, and then to see what impact the medical profession has on the dietary behavior of physicians.

Unhealthy eating habits among students

The transition in university education is significant because during this period young

adults experience greater freedom to make choices regarding food behavior and lifestyle (11). Rapid changes in mental growth and development place these young adults in a group of nutritionally vulnerable people with poor eating habits who are unable to meet their dietary requirements. The most common unhealthy food choices among students seem to be omitting the main meals, frequent meals in the city, increased consumption of snacks and fast food (12). According to studies conducted at US universities, significant increases in fat intake and alcohol intake have been reported in these students, so that unhealthy eating and excessive alcohol consumption make a significant contribution to energy intake and, therefore, may facilitates the student's weight gain. Also, the same pattern of weight gain in students is under development in Europe (13).

In European countries, the consumption of snacks is very widespread, proving that the most common contexts for serving snacks among young people are after courses (4,6 times a week), while watching TV (3.5 times a week) and while staying with friends (2.4 times a week) (14). Also, environmental factors (through the emergence of malls, shops, vending machines and fast food markets) contribute to the adoption of unhealthy eating habits among students. They have a lack of nutritional knowledge and tend to make their own food choices based on the cost of food and the availability of fast food, and this can negatively affect their nutritional status (12).

Excessive alcohol consumption among students is a widespread problem in several university campuses, with studies indicating an increased prevalence of a desire to drink among students (drinking five or more alcoholic drinks at a single meeting). Alcohol consumption among students was also associated with other unhealthy behaviors including smoking, risky sexual behaviors, contact with multiple sexual partners, injuries, and failure to use the seat belt in the car. Smoking is also widespread among students worldwide given the fact that a quarter of all or even more US students smoke and 75% of them continue to smoke into adulthood, placing future adults at greater risk of developing lung cancer and cardiovascular disease (15). In addition, students often fail to meet dietary recommendations and physical activity requirements, the highest rate of physical activity decline being recorded in the early maturity period, between 18 and 24 years old (16).

Students from later university years show a higher prevalence of drinking, smoking, and their consumption of fruit and vegetables decreases with each completed semester (17, 18). The academic environment can affect students' mental health; for example, academic overload can lead to stress, anxiety and depression, and in addition, contact with patients with poor health can be a unique stressor in medical school (10).

Medical students were supposed to practice healthier eating habits compared to non-medical students, but some studies have found the opposite. A previous study in China revealed that medical students presented risk factors for early chronic disease due to poor eating habits. It was found that although medical students had enough knowledge of healthy eating habits, they failed to apply this knowledge in practice (12). Also, another study conducted in Poland shows that medical students are aware of the benefits of a balanced diet and an active lifestyle on health, but nevertheless fail to turn theory into practice (19). Therefore, the fact that many medical stu-

dents apparently do not meet the criteria for a healthy lifestyle, despite knowing in theory these notions unlike non-medical students, is a very serious health problem. Thus, raising awareness of this issue among students should become a high priority for medical universities.

A study conducted in China shows that the prevalence of regular breakfast consumption (71.1%) is lower compared to the prevalence recently reported among medical students in Western countries (80% in the United States, 90% in France and 72,5% in Australia for example) but is higher compared to Lebanon (52.7%) (20). In Croatia, it seems like students from Zagreb School of Medicine from 1-6 years have an unhealthy diet and lifestyle, and studies in other countries have also reported that young people have developed irregular dietary patterns like skipping meals, snacking between meals and often eating away from home. The reasons for these unhealthy behaviors may be their busy schedules, lectures and different places provided by lectures, lack of experience and time for organizing an economical, fast and healthy meal and more (21).

High prevalence of overweight (24%, N = 36) and obesity (9.3%, N = 14 - out of a total of 150 students) associated with poor dietary practices and low levels of physical activity among medical students included in a study in India is a matter of serious concern. Factors such as fruit intake, duration of physical activity, sleep and sedentary behavior had a significant association with nutritional status. A higher proportion of overweight (47.2%) and obese (50%) had lower fruit intake compared to those with normal BMI (25.9%), and average fruit and vegetable consumption was lower than recommended. Most participants reported the consumption of fruits and vegetables only once or twice a week. These observations show that medical students, despite adequate knowledge, are not sufficiently motivated to change their lifestyle. Students should be encouraged to adopt healthy eating practices and to undertake various outdoor sports activities (22).

Factors that affect eating habits

The stress of university life could be one of the major factors that negatively influence the diet of young adults. It has been found that students in the first years of college are particularly vulnerable to stress (23). Excessive fatigue is often a result of the different challenges of university life (compliance with academic requirements and university standards, weakening family ties, meeting new people) that have an impact on both physical and mental health. In a study in Australia, fatigue proved to be a common health problem among more than half of the participants, being negatively associated with academic behavior (absenteeism or even university dropout). Fatigue has been shown to be associated with a number of health-risk behaviors, especially around alcohol consumption, as well as unhealthy weight loss behaviors. These findings may reflect two types of fatigue in the student population: fatigue related to sleep deprivation (assuming alcohol consumption was associated with less sleep) and fatigue related to illness-most commonly found in this study (24).

Additionally, what causes students to eat unhealthy food is not only the choice of food, but there are structural forces that make it difficult for students to consume healthy foods such as: financial incomes, meals' costs, unhealthy food environment,

nutritional education and health beliefs. Besides these, there are many factors that affect the eating habits among students, among which: the differences of social class, the cost of food, the knowledge of food, the time of food preparation, the family structure, culture and so on, some of these factors can even be multiplied, considering lives of many students (25).

More and more evidence show that a fairly large proportion of young people are experiencing poor physical health and the prevalence of psychological disorders is higher in students than in the general population (non-students) (24). The incidence of mental health problems among medical students can be up to 30%, but most students do not ask for help (26).

Particularities among medical students - eating disorders and nutritional knowledge

Eating disorders are another problem among students. Studies have shown that the estimated prevalence of eating disorders among them has increased from 8% to 20.5%. Alarming is the fact that a significant portion of those who show signs of eating disorders have not been diagnosed and do not want treatment (27). In Romania, previous studies conducted on medical students showed that they had high levels of academic distress which affect sleep and food behaviors and this academic level of distress is correlated with a high score for depression (28).

Sleep is another important component of the lifestyle, having consequences on both physical and mental health. The freshmen students from dental medicine sleep, on average, 6.34 hours per night (29). Thus, shorter sleep duration was associated with higher physical and mental stress, lower academic outcomes, suicide risk, mental and eating disorders (30). Also, high scores of body dissatisfaction were associated with the practice of following a weight loss diet and eating during nights (29). Another study showed that complaints about sleep problems are common in young medical students, the quality of student sleep being assessed as good in less than half of them (40%), excellence at only one third (29%) and satisfactory to less than a quarter (24%). Sleep quality is associated with academic progress and living conditions and daytime sleepiness is a significant problem for students and is associated with both sleep disorders and work while studying (31).

Another aspect that medical students face is nutritional knowledge. Historically, nutrition education has been underrepresented in many medical schools and residency programs. Surveys showed that most medical schools in the United States do not yet provided adequate nutrition education and do not produced graduates with the necessary nutritional skills in medical practice (32). It is noted that students considered that nutrition information is poorly integrated into the curriculum, and more than that, students attended few nutrition counselors during their residency years and the nutrition information that was provided was often outdated or incorrect (33). Improving students' nutrition knowledge is important because this allows medical students to learn about the lifestyle and challenges that patients face, in addition to aspects of the disease (34).

Although the National Academy of Sciences has recommended a minimum of 25 hours of nutrition education, most medical schools offer medical students very little nutrition education or do not offer at all

during university years (33). Physicians, residents and medical students do not feel comfortable, confident or adequately prepared to provide nutritional counseling and clearly need more training and further education in nutrition assessment and intervention (32).

Impact of the medical profession on the dietary behavior of physicians

The culture of medicine promotes the belief that not only students, but also doctors are never sick. Traditionally, doctors have neglected their own health in favor of numerous professional and personal obligations and often consider that attention to their own needs is a sign of weakness. Fortunately, attitudes have changed and nowadays, more attention is paid to the doctor's health. Medical associations are beginning to recognize the potential risks of the health care profession, and many have created programs to meet the health care needs of physicians (35). Furthermore, it is recognized that the health of physicians has a direct impact on the health of the population because numerous studies have established a link between the health behaviors of physicians and their interactions with patients (36).

Physicians have the privilege and responsibility to play a leading role in promoting healthy habits because they consult their patients daily, and studies confirm that physicians' lifestyle tips induce and maintain positive behavioral changes in patients. Physicians' life habits are of particular importance both because they influence the physician's own health and because these habits influence patient consultations, one of the strongest predictors of physicians offering lifestyle advice is the physician's own health behavior. Healthy practitioners are more likely to discuss preventive measures with their patients being credible, while the advice of physicians with unfavorable life habits is forgotten because they do not follow themselves (2).

Most of the researches in the health of the doctor focused on three areas: stress related to work and burning; mental health disorders such as depression and suicide; and substance abuse. In contrast, there was very little research into lifestyle and unhealthy eating habits among physicians. Since not all physicians become depressed or addicted to certain substances, but absolutely all face the challenge of incorporating healthy habits into their busy lives, there should be an increased focus on healthy daily life among physicians who might be able to help to prevent progression to serious health problems, including mental health problems and addiction (35).

Poor living habits among both physicians and the general population of Bahrain reflect rooted cultural patterns present in the population of the Middle East, which can be exaggerated among physicians due to excessive workload and long shifts. In terms of eating habits, less than half of the population eats all three main meals each day, with breakfast being the most commonly overlooked meal during an average week. More than half of the doctors (53.3%, N = 80) reported that they did not eat fast meals during the week, while one third (28.9%) eat fast food once a week. The average daily intake of water was 1.7 L, and carbonated soft drinks are consumed daily by about half of the physicians (47%). Most doctors (86.2%) consume at least one caffeinated beverage daily, and 47% of them followed a diet to reduce weight during the last 6 months, while 6.6% took medicines to help them helps to

lose weight (2). In another study, Canadian physician reports an average daily intake of 4.8 servings of fruits and vegetables, and over half of physicians consume at least five recommended servings (37). Doctors reported reasonably healthy behaviors in relation to alcohol consumption, smoking, diet and exercise. However, daily water consumption, weekly breakfast and weekly aerobic exercises were reduced (7).

Doctors, like the rest of the population, do not consistently meet the recommended recommendations for physical activity (35). In a study conducted in Bahrain, only one-third (29.6%) of physicians reported performing more than 30 minutes of continuous physical activity over a whole week. Of those who do weekly sports, the majority (81%) practiced physical activity for 3 days a week or less, the most frequent activities being walking and swimming. Physicians who were physically active during the week were less stressed and consumed less fat food during the week (2).

While statistics between physicians may simply reflect a larger cultural problem, there may be factors specific to medicines that discourage physical activity. A study of medical students showed that weekly physical exercises decrease during medical training, most likely due to increased workloads and long hospital changes during the clinical years (38). Increasing activity among physicians has the potential to benefit physicians, patients and the overall health care system. British Columbia's "Walk With Your Doc" initiative, involving over 100 physicians and 2000 patients in the province, is an excellent example of a simple program that encourages regular exercise for both physicians and patients and allows physicians to serve as healthy role models in their community (35).

In several European countries (such as Germany, Finland, Estonia) and in the USA, the prevalence of smoking among physicians is now less than 20%. In these countries, the population seems to be well informed about the dangers of smoking, and doctors seem to respond by giving up smoking more frequently than other people which leads to this significant drop in prevalence. An inverse model was found for alcohol consumption, Swiss doctors consuming alcohol more than the general population and only 4% were abstinent (compared to 22% in the general population) (39). Some authors suggest that the higher prevalence of alcohol use among physicians could be explained by their higher socio-economic status (40), while other studies claim that health institutions, medical schools and hospitals do not have effective health promotion programs for prevent alcohol use and abuse among physicians (41). Finally, higher alcohol consumption among physicians may be related to the fact that drinking a small amount of alcohol can protect against cardiovascular disease and is therefore not a risky behavior for health (42).

Sleep deprivation has been shown to affect clinician performance and cognitive scores (43). Although primary care physicians in Bahrain enjoy a more relaxed time frame than most other specialties, the average sleep time reported for physicians in our study is 5.9 hours, with most physicians (86.3%) who reports less than 8 hours of sleep per night. Doctors who sleep longer than 6 hours are less likely to be smokers and are more likely to eat breakfast most days of the week. On average, the level of perceived stress was 6.4/10, and women were significantly more likely to report severe stress levels than men (2). Among

Canadian general practitioners, half of them report difficulty sleeping and almost two thirds complain of exhaustion or drowsiness at least 3 days a week. Chronic sleep deprivation for physicians and residents is alarming, as it has been repeatedly correlated with decreased cognitive performance, increased likelihood of medical error, and higher cases of self-injury, such as prickling with a contaminated needle (44). Other studies have shown that moderate sleep deprivation - the equivalent of about 18 hours without sleep - may be more disabling than being legally drunk (6). Some research has begun to investigate ways to minimize sleep deprivation to the doctor. Nelson (45) focused on emergency department physicians, a group that is typically vulnerable because of work instead, and suggests scheduling models that would reduce sleep deprivation, allowing each doctor at least 4 hours of constant "anchor sleep" per night, a technique that has been shown to maintain a constant sleep and wake cycle and reduce fatigue (46).

The most commonly cited obstacle to following a healthy diet by physicians was the lack of time due to excessive workloads and frequent meeting at noon. Many doctors have mentioned the lack of access to healthy foods, especially those who work outside regular working hours (when the hospital cafeteria is closed, for example). Inadequate food storage, lack of healthy choices and lack of prioritization of physician well-being were also identified as problems (35).

Another study shows that many doctors have considered that their employer and work environment are not compatible with healthy eating. Doctors noticed this because of the lack of breaks, inadequate selection of food and the opening time of the canteen. Most physicians consider that a healthy diet has an important influence on their work performance. Respondents' dissatisfaction with the provision of healthy and vegetarian options suggests that the canteen delivery does not reflect the views of physicians or nutritional expectations. Most hospital canteens are shared by doctors and visitors to the hospital, providing hospital kitchens and catering services for patients. Therefore, poor delivery of canteens and dissatisfaction with canteen services may have a greater impact and relevance than for physicians (7).

Considering the importance of a healthy diet, all the doctors questioned in a study reported that inadequate nutrition had an impact on them at work. Most mentioned emotional symptoms, such as irritability and frustration. Many also mentioned physical symptoms (ease, tremor, nausea) and cognitive effects (difficulty concentrating, making slow / slow decisions) as consequences of inadequate diet. These findings are alarming, given the ubiquity of inadequate nutrition among physicians, which can lead to decreased patient care quality and medical errors (35).

Also, doctors may feel pressure from both patients and their colleagues to seem healthy, as their own physical health is considered an indicator of their medical competence (47). Studies named doctors "notoriously bad patients" considering that one third of Australian residents do not have a family doctor and a large proportion of young Irish doctors have not been in the spotlight for a doctor in the last 5 years which indicates that most physicians engage in self-treatment (48, 49). Furthermore, a significant number of physicians admit to self-prescribing drugs, a practice that is considered unethical by all medical

associations and has been banned by legislation in certain jurisdictions (50). Very often, doctors do not seek help, even though they may realize that they need it; a study showed that only 2% of Canadian physicians who were identified as depressed sought treatment. Therefore, all physicians should have their own family doctor who can provide regular, continuous and effective care; this would avoid the problem of self-prescribing and ensure that physicians take the recommended preventive screening measures (35).

Numerous studies have found that many medical staff are experiencing burnout, a syndrome resulting from work stress, characterized by emotional exhaustion, feelings of cynicism and detachment from patients (depersonalization) and a low sense of personal achievement (51-54).Workplace stressors deplete employees' mental and physical resources and lead to exhaustion and health problems. Thus, burnout was significantly positively associated with higher fast food intake, infrequent exercise, higher alcohol use, and more frequent use of painkillers, regardless of country of residence. Transnational comparisons showed significant differences in exhaustion and health behaviors, with health professionals in Turkey, Greece and Bulgaria reporting the most unfavorable experiences.

Behaviors and health risks among health professionals are important both in the context of the health and well-being of medical professionals, as well as factors contributing to medical errors and inadequate patient safety (55). Other studies found that the level of higher education, work experience and higher status decrease burnout, while working at night on shifts, difficulties in care of the children and in the accomplishment of the household tasks, health problems of the nurse or of their children, the economic difficulties and the difficulties encountered in transport, increases the level of burnout among medical doctors (56-59).

CONCLUSIONS

Studies show significantly higher rates of obesity, poor physical activity and other unfavorable life habits among physicians, which could have a negative impact on physician-patient interaction. A multitude of factors interact to influence the health of physicians in the workplace, including diet, workload, stress, mental health and lifestyle. Other studies show that many doctors do not consider the work environment conducive to healthy eating, which is due to the lack of breaks, the lack of selection of the canteen and the opening hours of the canteen. Let's not forget that medical students are a key demographic for interventions that promote health and well-being. A four-year intervention study showed that medical students who received curricular and extracurricular education in diet, exercise, alcohol and tobacco improved personal health practices compared to controls. Students were more likely to advise patients on healthy living habits.

It is necessary to continuously promote the health of the doctor, to avoid placing their patients' needs before their needs and to dispel the myth that doctors never get sick. The medical culture must move away from its highly competitive, individualistic focus, excessive workloads and extreme self-sacrifice and embrace changes that promote optimal physician well-being to improve patient care. But until such a change occurs, improving the physician's health will be an ongoing upward struggle.

NEWS

GREAT STEP IN WIN THE BATTLE AGAINST CANCER: PTPN2 GENE

A group of researchers from the Blavatnik Institute at Harvard Medical have shown that disrupting a key immune regulator, a gene called PTPN2, boosts anti-tumor immunity and enables cancer clearance in animal models. The work, published in Nature Immunology, demonstrates that deleting the gene from the immune system of mice harboring cancer stimulates the production and fitness of cancer-and-infection-fighting immune cells known as T-killer cells. In one experiment, deleting the PTPN2 gene from the immune systems of mice eradicated colon cancer in all animals. In another, the approach combined with PD-1 checkpoint blockade successfully eliminated a particularly aggressive and treatment-resistant form of melanoma in one-fourth of the mice with this form of cancer. Taken together, these findings identify a promising new target for cancer therapy, but further testing of the approach will be needed (LaFleur MW, Nguyen TH, Coxe MA. *et al*. PTPN2 regulates the generation of exhausted $CD8^+$ T cell subpopulations and restrains tumor immunity. *Nat Immunol* 2019; 20: 1335-1347)

MINIMALLY INVASIVE BRIDGE INLAY-RETAINED - AN OPTION FOR FIXED DENTAL PROSTHESIS. CASE REPORT

MINIMALLY INVASIVE BRIDGE INLAY-RETAINED - AN OPTION FOR FIXED DENTAL PROSTHESIS. CASE REPORT (Abstract): The minimally invasive bridges are considered a common substitute for conventional fixed prosthesis because require a minimal teeth preparation, protection of the pulp vitality and less periodontal irritation. Modern materials currently available on the domain - ceramic systems or zirconium dioxide-allow the realization of such prosthetic constructions, ensuring sufficient strength and longevity over time. The purpose of this article is to describe clinical procedures related to the placement of minimally invasive bridge inlay-retained with a zirconia framework, subsequently veneered with ceramic. Digital CAD-CAM technology greatly reduces working time and allows a high-precision prosthetic device. All these advantages make our therapeutic solution a viable option for restoring the continuity of the dental arch in the posterior area. **Keywords:** MINIMALLY INVASIVE BRIDGE, INLAYS.

Now days different indirect restorations used to replace a single missing tooth in the posterior area, such as traditional full-coverage fixed dental prostheses, implant-supported crowns, and inlay-retained fixed dental prosthesis are available in dentistry (1). The minimally invasive bridges are considered a common substitute for conventional fixed prosthesis, to avoid full crowns applied on the non-affected abutments. This treatment is an efficient method to provide satisfactory aesthetics with minimal loss of dental tissue. The design of these devices is a viable option for treating a single tooth edentation.

Currently, there is a wide range of materials and technologies to solve a reduced partial edentation in the posterior area of the dental arches. When implant therapy is contraindicated or is not possible to be applied, minimally invasive devices becomes an optimal treatment option, because allow a higher preservation of healthy dental structure and the protection of periodontal tissue. There are some advantages of this reconstruction compared to a fixed prosthetic bridge, as the minimal teeth preparation, the protection of the vitality of the dental pulp, less periodontal irritation. In order to ensure an optimal adaptation and a longevity to these prosthetic constructions, a careful evaluation of the clinical situation is necessary. Inlay-retained bridges are indicated for patients with good oral hygiene and low caries susceptibility, with a minimum coronal tooth height of 5

mm, and parallel abutments. Contraindications include extensive crown defects, tooth mobility, parafunctions, the absence of enamel on the preparation margins (2, 3).

Modern materials currently available on the market such as ceramic systems or zirconium dioxide, allow the realization of such prosthetic constructions, with sufficient strength and longevity over time. The precision of these minimally invasive bridges and the variability of the materials and technologies that can be used, make patients to accept them as a treatment solution for reduced edentulous situations (4).

The purpose of this article is to describe clinical procedures related to the placement of minimally invasive bridge inlay-retained with a zirconia framework, subsequently veneered with ceramic.

Prosthetic restorations made of zirconia have a low weight, very good mechanical strength, excellent biocompatibility, appropriate color, close to dental tissues, low thermal conductivity, smooth surface, which is not favorable to adhesion of biofilm. CAD-CAM technology greatly reduces working time and allows a high-precision prosthetic appliance. All these advantages make our therapeutic solution a viable option for restoring the continuity of the dental arch in the posterior area (5).

CASE REPORT

A 32 year old female patient came to the dental clinic with esthetic problems, consequently to second upper premolar loss. After the clinical (fig. 1) and complementary examinations because the patient refused the implant solution, we chose as therapeutic strategy a minimally invasive bridge with inlay crown on the abutment 1.4 and 1.6 and pontic for 1.5.

Fig. 1. Clinical examination of the patient

On the very first stage, a zirconia framework was made, in order to ensure the optimal resistance of the bridge; subsequently ceramic veneered, to restore the aesthetic appearance.

We prepared the inlay cavities- mesio-occlusal, and disto-occlusal, on the abutment teeth and the impressions was registered for the upper and lower arches (fig. 2).

Fig. 2. Upper and lower arches impression registration

The impressions were sent to the dental laboratory, and the technician poured the

working casts. These are properly prepared and introduced into the scanning room. The first step consisted in a highly accuracy optical impression, registered by scanning, in order to gain a digital model (fig. 3). The design of the framework was realized using the software- design component and analyzed from the point of view of the occlusion relationships and of the restoration of morphological elements.

Fig. 3. Working stone casts and scanning

The information were transmitted to the CAM component, in order to manufacture the framework, by milling the zirconia blocks (fig. 4). For the framework VITA YZ HT blanks were used, a solution for precise, efficient and true-to-shade zirconia reconstructions. The prosthetic piece was finished, sandblasted for 10 sec at a pressure of 2.7 bar, with 50μ alumina powder. Then the framework was checked on the model and into the oral cavity and because no adjustments were necessary, the dental technician did the ceramic veneering (fig. 5).

Fig. 4. Milling the framework

Fig. 5. Zirconia framework after finishing

The opperation started with an oxidation in order to clean the framework and to provide a good chemical and mechanical bond of the components. Then the layers for dentin and enamel were applied, and sintered in vacuum (fig. 6). For veneering we used Vita VM 9 (Vita), a highly-esthetic, fine-structure feldspar ceramic, that is perfectly adapted for zirconia framework.

After processing and checking on the working cast and in to the oral cavity, the superficial ceramic layer, the glaze, was applied and sintered in normal atmospheric

conditions (fig. 7).
The final bridge is sent to the dental office for the final adaptation and cementation in to the oral cavity (fig. 8).

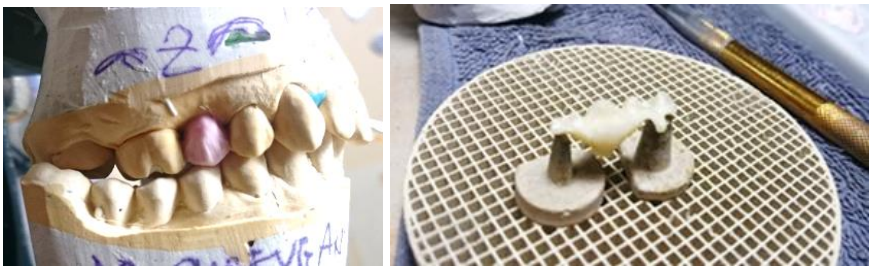

Fig. 6. Application and sintering of ceramic layers

Fig. 7. Checking ang glaze application

Fig. 8. Final adaptation and cementation in to the oral cavity

DISCUSSION

Minimally invasive bridges inlay-retained are considered a conservative therapeutic option, because the use of inlays as retainer element on the abutment teeth allows a minimum sacrifice of dental tissue. Preserving tooth structure is adequate to the overall health of the tooth and periodontal tissues. The use of minimally invasive bonded restoration induce less trauma and superior prognosis (5, 6) In the last years, the demand for esthetics and biocompatibility led to the use of zirconia CAD/CAM materials for fixed prosthodontics (7). New materials, with a very good mechanical behavior, currently available, allow the use of this type of prosthetic restoration on premolars and molars, in mesio-occlusal and disto-occlusal cavities. The realization of these bridges using CAD-CAM technologies has many advantages: the registration of a digital im-

pression and ordering the restoration online, quickly and easily maximum precision for all results combined with easy handling, extremely wide range of applications and material versatility, high flexibility and future security due to open CAD/CAM interfaces, a diversity of possibilities of integration. Minimizing the treatment time and the number of appointments is favorable for the patient, and also precludes the complications and it is possible to achieve the preferred treatment outcomes with expedition of the whole procedure. Another advantage is represented by the leading of an excellent intraoral fit of the prosthetic appliance (8).

CONCLUSIONS

The technique presented in this case report describes a conservative method of rehabilitation of a single-tooth edentation, as an alternative to an implant-supported crown. The mechanical and aesthetic advantages of this type of restoration make our treatment alternative an extremely viable option. Briefly, the advantages of a minimally invasive bridge are conservative, highly aesthetic, strong bonded to teeth support, no discoloration of dental tissues, insulation of the teeth, good suited for large cavities, long lasting (9, 10). Surveying the mechanical properties of materials, their behavior over time, the advantages and disadvantages of the techniques, the causes that lead to failures, as well as the requirements of each patient, we can establish the optimal therapeutic solution for each clinical case.

DIAGNOSTIC VALUE OF A NEGATIVE SINGLE COLOR DUPLEX ULTRASOUND IN DEEP VEIN THROMBOSIS SUSPICION DURING PREGNANCY (Abstract): Objective: to determine whether a negative single complete ultrasound (US) of the lower limbs veins is a safe and accurate diagnostic method to rule out deep venous thrombosis (DVT) in pregnancy. **Material and methods**: We performed a prospective study on 87 consecutive pregnant women with clinical suspicion of DVT in "Dr. D. Popescu" Maternity, Timişoara, between January 2007 and December 2009. All cases were investigated by color duplex ultrasound. Those who were negative but with high clinical probability of DVT underwent MR venography, the rest with negative US findings did not received anticoagulant therapy and US was repeated after seven days. All were instructed about the signs and symptoms of DVT and asked to return at six weeks postpartum when they were questioned if presented any. **Results**: from the 87 women 30 (34.48%) were found positive and two (2.29%) had a high clinical suspicion of DVT. 55 (63.21%) with negative findings repeated the US exam after 7 days which remained negative. Only 43 (78.18%) returned for the 6 weeks postpartum visit and none of them experienced any thromboembolic event during follow-up. **Conclusions**: A single complete color duplex ultrasonography of lower limbs veins appears to be a safe method to rule out the diagnosis of deep venous thrombosis in pregnant women and if negative is safe to withhold heparin therapy. **Key words**: DEEP VEIN THROMBOSIS, PREGNANCY, VENOUS ULTRASOUND

BIOPHARMACEUTICAL CHARACTERISTICS AND *IN VITRO* EVALUATION OF THE REDUCING ANTIOXIDANT POWER OF SOME DICLOFENAC DERIVATIVES

A. Focșa*, Ioana Vasincu, A. Sava, Andreea Iacob, Maria Apotrosoaei, Lenuța Profire
"Grigore T. Popa" University of Medicine and Pharmacy Iasi

BIOPHARMACEUTICAL CHARACTERISTICS AND *IN VITRO* EVALUATION OF THE REDUCING ANTIOXIDANT POWER OF SOME DICLOFENAC DERIVATIVES (Abstract): **Aim**: Biopharmaceutical characterization using the prediction program MedChemDesigner 5.5 and the evaluation of the reducing antioxidant power of some diclofenac derivatives. **Material and methods**: The synthesized compounds (4a-s) were characterized *in silico*, by estimation of octanol/water partition coefficient (OWPC), octanol/water distribution coefficient (OWDC), absorptive capacity at digestive level, and topological polar surface area. The evaluation of antioxidant power was performed using *in vitro* methods: ferric and phosphomolybdenum reducing antioxidant power assays. **Results**: The biopharmaceutical characteristics suggest an optimal pharmacokinetic profile with a lipophilic character of the studied derivatives, which allows both the crossing of cell membranes and digestive tract absorption. In addition, several compounds have demonstrated notable antioxidant capacity, higher than that of diclofenac. The most active compounds were 4s (R=2-Br-3-OH-4-OCH_3) and 4h (R=H). **Conclusions**: The biopharmaceutical study revealed promising characteristics regarding the pharmacokinetic profile of the studied compounds. Moreover, it was noticed that the antioxidant effect increases with concentration and is influenced by the nature of the substituent in the aromatic ring. **Keywords**: BIOPHARMACEUTICAL CHARACTERIZATION, HYDRAZONES, ANTI-OXIDANT CAPACITY.

Lipophilicity is an important parameter in the design of drugs, having a relevant role in the pharmacokinetic profile, including distribution, transport and metabolism of the drugs. If lipophilicity is increased, meaning that the compounds are hydrophobic, they can accumulate in the body and cause possible side effects (1, 2). The lipophilic character of the compounds is assessed using the partition and distribution coefficients in two immiscible phases: water (hydrophilic phase) and n-octanol (hydrophobic phase), which mimics the biological membranes (3-5).

OWPC (log P) is the ratio of concentration of a compound in a mixture of two solvents, octanol and water. If OWPC is higher than 5, the compound is considered to be highly lipophilic, meaning an increased diffusion through the cell membranes, but a reduced intestinal absorption rate due to the lack of solubility in water.

An ideal value of the partition coefficient is considered to be in the range of 0-5. The partition coefficient generally refers to the concentration ratio of un-ionized species of the compound, whereas the distribution coefficient refers to the concentration ratio of all species of the compound (ionized and un-ionized). Compounds that do not undergo an ionization process have a log D (OWDC) value equal to OWPC (6, 7).

MATERIAL AND METHODS

Biopharmaceutical characterization

The diclofenac derivatives with hydrazone structure (**4a-s**) synthesized by our research group (8,9) were characterized *in silico*, using the MedChem Designer™ program by the estimation of OWPC (log P), OWDC (log D), oral absorptive capacity by checking the Lipinski's rule, molar mass (MM), number of acceptor groups and proton donors (M_NO), topological polar surface area (T_PSA), and the number of proton donor groups (HBDH).

Antioxidant assays

Ferric Reducing Antioxidant Power (FRAP) Assay

Stock solutions of 10 mg/mL were prepared by dissolving the tested compounds (**4a-s**) in DMSO. From the stock solution different volumes were measured and DMSO was added up to 0.5 mL to obtain different concentrations (0.045 mg/mL, 0.09 mg/mL, 0.18 mg/mL, and 0.36 mg/mL). To 0.5 mL of sample of each concentration, 0.5 mL of 0.2 M phosphate buffer (pH=6.6) was added. The reaction was initiated by adding 0.5 mL of 1% potassium ferricyanide, after which the samples were incubated at 50°C for 20 min in a water bath and then the reaction was stopped by adding of 0.5 mL of 10% trichloroacetic acid. To 1 mL of this solution, 1 mL double-distilled water and 0.2 mL of 0.1% ferric chloride were added. The resulting mixture was stirred for homogenization, left at room temperature for 5 min, and then the absorbance was measured at 700 nm using a control sample which was prepared similarly to the tested compound sample, using 0.5 mL of DMSO instead of 0.5 mL of tested compound sample (10,11). For each tested compound sample, the effective concentration (EC_{50}) was calculated by linear regression analysis. Diclofenac (0.045 mg/mL, 0.09 mg/mL, 0.18 mg/mL, 0.36 mg/mL) and ascorbic acid (AA) (0.015 mg/mL, 0.030 mg/mL, 0.045 mg/mL) were used as reference and positive control, respectively. All tests were performed in triplicate.

Phosphomolybdenum Reducing Antioxidant Power (PRAP) Assay

Stock solutions of 7.5 mg/mL were prepared by dissolving the tested compounds (**4a-s**) in DMSO. From stock solution, different volumes were measured and DMSO was added up to 200 µL in order to obtain different concentrations (0.09 mg/mL, 0.18 mg/mL, 0.37 mg/mL, and 0.75 mg/mL). To samples of different concentration, 2 mL of reagent solution (0.6 M sulfuric acid, 28 mM disodium phosphate and 4 mM ammonium molybdate) were added, and the solutions were incubated at 95°C for 90 minutes; after cooling to room temperature the absorbance of each sample was measured at 695 nm using a control sample prepared from 200 µL DMSO and 2 mL reagent solution (12, 13). For each tested compound sample, the effective concentration (EC_{50}) was calculated by linear regression analysis. Diclofenac (0.09 mg/mL, 0.18 mg/mL, 0.37 mg/mL and 0.75 mg/mL) and ascorbic acid (AA) (0.022 mg/mL, 0.045 mg/mL, 0.09 mg/mL) for were used as reference and positive control, respectively. All tests were

performed in triplicate.

RESULTS AND DISCUSSION

Biopharmaceutical characterization

The biopharmaceutical characteristics of diclofenac derivatives with hydrazone structure (**4a-s**) such as OWPC, S+log P, S+log D, oral absorptive capacity by checking Lipinski's rule, MM, M_NO, T_PSA and HBDB were predicted using the MedChemDesigner™ program. All these data are shown in first table.

TABLE I

Biopharmaceutical characteristics of diclofenac derivatives with hydrazone structure (4a-s)

Lipinski's rule is commonly used to predict the degree of digestive absorption of an active substance. This rule, known as "rule of five", imposes substances some limitations in order to be orally administered. In this respect, for a maximum oral absorption and bioavailability, the molecule compound has to meet the following conditions: OWPC value less than 5, molar mass less than 500 g/mol, HBDH less than 5, number M_NO less than 10. The T_PSA is calculated by summing the surfaces corresponding to the polar fragments of a compound. This value highlights the polar nature of a substance and, implicitly, the oral bioavailability. A T_PSA over 140 indicates reduced digestive absorption, while less than 60 shows absorption in the

digestive tract of more than 90% (14-16). The analysis of the obtained results (tab. I) revealed that the substitution of the aromatic ring with the radicals: *methoxy* (**4g**), *cyano* (**4b**), *methyl* (**4i**, **4r**) and *hydroxyl* (**4d**) results in increased cell membrane crossing. For these compounds, the OWPC and OWDC values ranged between 3.913 and 4.529. In case of *halogen* in the aromatic ring, the OWPC and OWDC values were higher than 5, meaning that the absorption rate was negatively influenced.

Antioxidant assays *Ferric Reducing Antioxidant Power (FRAP) Assay*

The results recorded for diclofenac derivatives (**4a-s**), expressed as absorbance values at different concentrations (0.045 mg/mL, 0.09 mg/mL, 0.18 mg/mL, 0.36 mg/mL), are shown in first figure.

Based on the absorbance values recorded at different concentrations, the EC_{50} for each compound was determined (tab. II), a lower EC_{50} value indicating a higher reducing power.

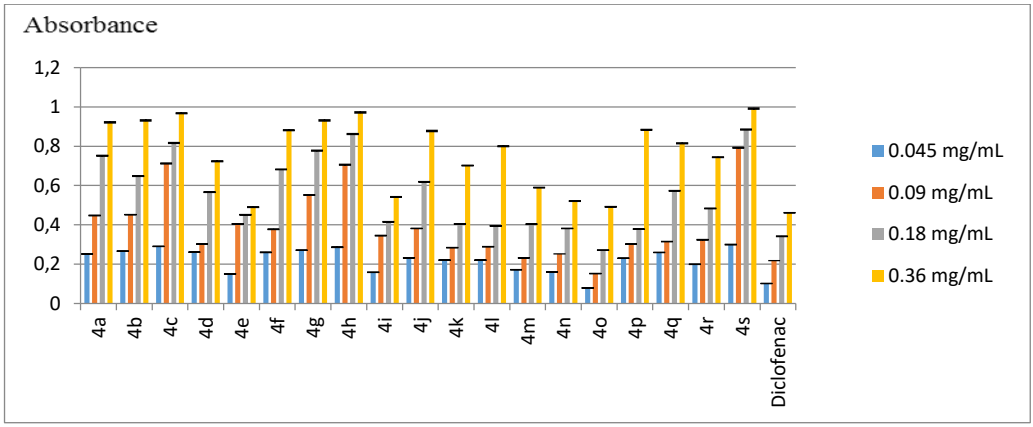

Fig 1. Absorbance values of diclofenac derivatives with hydrazone structure (4a-s) at different concentrations

TABLE II

The ferric reducing antioxidant power (EC_{50}, mg/mL) of diclofenac derivatives with hydrazone structure (4a-s)

Compound	EC_{50} mg/mL	Compound	EC_{50} mg/mL	Compound	EC_{50} mg/mL
Diclofenac	0.4351 ± 0.036	**4g**	0.0831 ± 0.005	**4n**	0.3460 ± 0.027
4a	0.1079 ± 0.008	**4h**	0.0687 ± 0.006	**4o**	0.3702 ± 0.028
4b	0.1157 ± 0.010	**4i**	0.3122 ± 0.027	**4p**	0.2211 ± 0.020
4c	0.0565 ± 0.005	**4j**	0.1378 ± 0.009	**4q**	0.1560 ± 0.011
4d	0.1607 ± 0.007	**4k**	0.1971 ± 0.013	**4r**	0.2082 ± 0.017

4f	0.1284 ± 0.011	**4m**	0.3055 ± 0.027	**AA**	0.0162 ± 0.005

AA = ascorbic acid

It was observed that all tested compounds were more active than diclofenac but less than AA. The most active compounds were **4s**, (R=2-Br-3-OH-4-OCH_3, EC_{50}=0.054±0.008)

and **4c** (R=3-NO_2, EC_{50}=0.0565± 0.005), which were 8 and 7.7 times, respectively more active than diclofenac (EC_{50}=0.4351±0.036). An appreciable activity was also shown by **4h** (R=H, EC_{50}=0.0687±0.006), **4g** (R=4-OCH_3, EC_{50}=0.0831±0.005) and **4a** (R=2-NO_2, EC_{50}=0.1079±0.008) which were 6.30 times, 5.20 times and 4 times, respectively, more active than diclofenac.

Phosphomolybdenum Reducing Antioxidant Power (PRAP) Assay

The results recorded for diclofenac derivatives (**4a-s**), expressed as absorbance values at different concentrations (0.09 mg/mL, 0.18 mg/mL, 0.37 mg/mL and 0.75 mg/mL) are shown in figure 2.

Based on absorbance values recorded at different concentrations, the EC_{50} for each compound was determined (tab. III), a lower of EC_{50} value indicating a higher reducing power.

It was observed that most of the tested compounds were more active than diclofenac but less than AA. The most active compounds were **4h** (R=H, EC_{50}=0.0954 ±0.010), **4j** (R=3-CF_3, EC_{50}=0.0987±0.007), **4g** (R=4-OCH_3, EC_{50}=0.0988±0.009) and **4b** (R=4-CN, EC_{50}=0.1008±0.007), which are approximately 5 times more active than diclofenac (EC_{50}=0.4694±0.018). An appreciable activity was also shown by **4f** (R=2-Cl-5-CF_3, EC_{50}=0.1041±0.004) and **4e** (R=4-Br-2-NO_2, EC_{50}=0.1096±0.007) which were approximately 4.5 times more active than diclofenac.

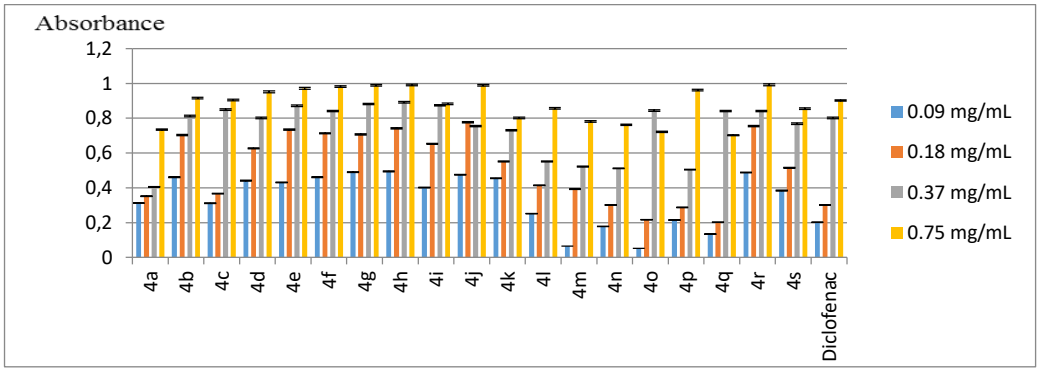

Fig 2. Absorbance values of diclofenac derivatives with hydrazone structure (4a-s) at different concentrations

TABLE III

The phosphomolybdenum reducing antioxidant power (EC_{50}, mg/mL) of diclofenac derivatives with hydrazone structure (4a-s)

Compound	EC_{50} mg/mL	Compound	EC_{50} mg/mL	Compound	EC_{50} mg/mL
Diclofenac	0.4694 ± 0.018	**4g**	0.0988 ± 0.009	**4n**	0.7173 ± 0.014

AA = ascorbic acid

CONCLUSIONS

In this paper we have presented the biopharmaceutical characteristics of some diclofenac derivatives with hydrazone structure (**4a-s**) were predicted using *in silico* computerized methods. Different parameters such as the OWPC, OWDC, the level of digestive tract absorption, and the topological area of the polar surface were determined. Based on the obtained results it can be concluded that the condensation of diclofenac hydrazide with different aromatic aldehydes is associated with increased lipophilic character of the synthesized derivatives, which is beneficial for diffusion through the lipid membranes, and indicates a good pharmacokinetic profile.

The antioxidant power of diclofenac derivatives was assessed using the ferric and phosphomolybdenum reducing antioxidant power assays. The results highlighted that the most active compounds were **4s** (R=2-Br-3-OH-4-OCH_3) and **4h** (R=H), obtained through the condensation of diclofenac hydrazide with 2-bromo-3-hydroxy-4-methoxybenzaldehyde and benzaldehyde, respectively.

AN ATTENUATED TOTAL REFLECTANCE STUDY OF DIFFERENT ALGINATE IMPRESSION MATERIALS USED IN DENTAL MEDICINE (Abstract): The aim of this study is to characterize and compare different alginate impression materials used in dental medicine. For this, we have prepared three different commercially available impression materials which have been characterized through the FTIR-ATR technique, thus highlighting rapidly and easily functionalized groups contained in these materials. This is possible as consequence of the absorption of electromagnetic radiation at certain frequencies that are associated with the vibrations specific to each type of chemical bond existing in the analyzed molecule. The materials used for this study were three impression materials commercially available (Kromopan and Alginor-ortho from Lascod, and Tropicalgin from Zhermack). For the spectral analysis a Bruker Vertex 70 spectrometer (Bruker Optics, Ettlingen, Germany) was used, and the spectra were obtained in the ATR (Attenuated Total Reflectance) mode, at room temperature in the range of 4000-600 cm^{-1} with a resolution of 4 cm^{-1}. Spectral ranges results are shown for each material, as well as the deconvoluted spectra for the most representative ranges. The alginate composition for each of the materials has been calculated and based on the obtained results we can indicate the use of these materials for the impression step in indirect restorations, as study models and casts and for fabrication of primary casts.
Keywords: ALGINATE IMPRESSION MATERIALS, DENTISTRY, FTIR-ATR STUDY.

In dental restoration, impression taking represents the first step of the process by creating a form in which working analogues can be obtained, thus helping the clinician undergo diagnosis and part of the treatment (1).

The field of dental medicine is in a constant improvement mode as technology and characterization methods have progressed over the last years. The performance of a dental material still relies on its properties and qualities, a fact that makes knowing these characteristics a particularly important step in selecting and using such a material (2, 3).

Alginate impression materials are irreversible hydrocolloids commonly used in impression taking which change from a sol to a gel state without being able to reverse back to the sol state and are usually constituted of sodium and potassium salts of alginic acid (4, 5). Alginic acid is an anion-

ic polysaccharide that can be extracted from brown algae of the *Phaeophyceae* family (6). The setting phase can be controlled through temperature and water usage, parameters easy to work with (7). These materials are recommended as impression materials by their easy flow, minimal displacement, and swift setting time (8).

Alginate materials poses the quality of being hydrophilic which makes them able to take impressions even in the presence of saliva or blood (9). Thus, alginate impression materials are used for prosthodontic reasons in the fabrication of primary casts, for indirect restorations as final impression materials and for orthodontic reasons as study models and casts as duplication materials (10).

Specific frequencies of light correspond to the specific molecules' structure, this is the principle that is used in the spectral analysis of the Infrared (IR) studies. Attenuated total reflection (ATR) spectroscopy is the sampling technique that along with the IR property allows the direct examination, without elaborate preparation, of samples in solid or liquid state. ATR-FTIR, or attenuated total reflectance used with the Fourier transform IR spectrometers allows the study of materials that do not have the property of being transparent (11). This represents a very big advantage in the characterization of imprinting dental materials as such materials do not always have the transparency property, alginate materials being an example, and is a very useful tool to determine the functional groups as well as characteristic spectrum of substances contained in such a material that can be recognized and identified. Also, as water solutions (or water itself) are used as compounds for different biomaterials and impression materials are among these materials, the ATR technique is the relevant one and a development from FTIR alone since infrared spectroscopy and water are not compatible (12).

MATERIALS AND METHODS

Lascod's Kromopan and Alginor-ortho products are alginates, elastic impression materials with dimensional stability, promising high accuracy and quick setting time. For the easy use of these materials, the alginates have a chromatic indicator of phase, helping the impression work in convenient environmental conditions of temperature and wettability (13).

Tropicalgin is an alginate impression material, from Zhermack, also having the chromatic phase indicator, promising easy-working procedures and good thixotropy properties. Its main distinctive characteristic recommends it as 'user-friendly' with a fast type of setting (14). This material is used in the dental practice as an impression system in the preliminary impression stage as a universal alginate. In the first table are centralized some of the important characteristics for these materials for efficient comparison, properties that were given by the producers (13, 14).

The three impression materials were prepared accordingly to the producers instructions, mixing the powder with a liquid phase (distilled water), in the indicated proportions, first figure showing the obtained products after hardening.

As method of characterization, Attenuated Total Reflectance (ATR) mode of an Infrared (IR) Bruker Vertex 70 spectrometer (Bruker Optics, Ettlingen, Germany) was used, and the measurements were carried out at room temperature with a 4 cm^{-1} resolution and in the 4000-600 cm^{-1}

range. Figure 2 illustrates the ATR mode of the spectrometer with a probe.

The obtained spectra were shown by the *OPUS 6.5 software* connected to the device.

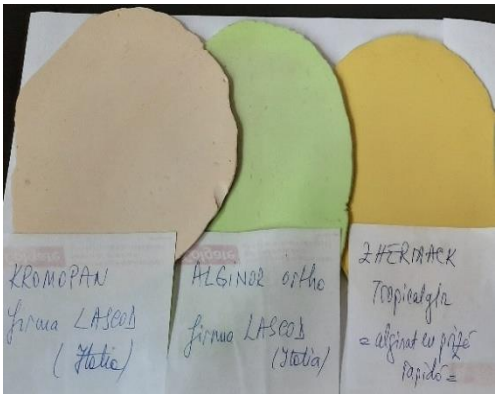

Fig. 1. The three commercially available impression materials used, after hardening

Fig. 2. The ATR mode of an IR spectrometer

TABLE I

Given characteristics of materials (12, 13)

Material	Working time (min: sec)	Biological contact time (min: sec)	Accuracy (μm)	Compressive strength resistance	Elastic recovery
Kromopan	1'45''	at least 30''	20	95.5%	95.5%
Alginor-ortho	1'45''	at least 30''	20	95.5%	95.5%
Tropicalgin	1'35''	1'	high	1.4MPa	99%

RESULTS AND DISCUSSION

ATR-FTIR analysis of the alginate (ALGINOR-ortho, KROMOPAN, TROPICALGIN) samples revealed the characteristic bands in the range 3800-3000 cm^{-1} assigned to –OH intramolecular and intermolecular stretches modes from alginate-based derivatives mixtures.

The most representative bands can be observed in the range 1800-600 cm^{-1}. The number and position of the peaks in this spectral region have been calculated by the second derivative of the spectra.

Based on the obtained maxima, the spectra have been deconvoluted by a curve-fitting method and the areas were calculated with a 50% Lorentzian and 50% Gaussian function by using OPUS 6.5 software. The procedure led to a best fit of the original curve with an error of less than 0.003. The specific peaks and area are presented in the second table.

In the 1800-1460 cm^{-1} spectral range the stretching vibrations assigned to the asymmetric carboxylate bands can be observed at 1636 cm^{-1} (ALGINOR), 1638 cm^{-1} (KROMOPAN) and 1641cm^{-1} (TROPICALGIN), while the symmetric stretching vibrations can be seen at 1416 cm^{-1}.

Based on the ration between area corresponding to the symmetric and asymmetric carboxylate stretches one can say that a lower content in alginate can be found in TROPICALGIN (fig. 3).

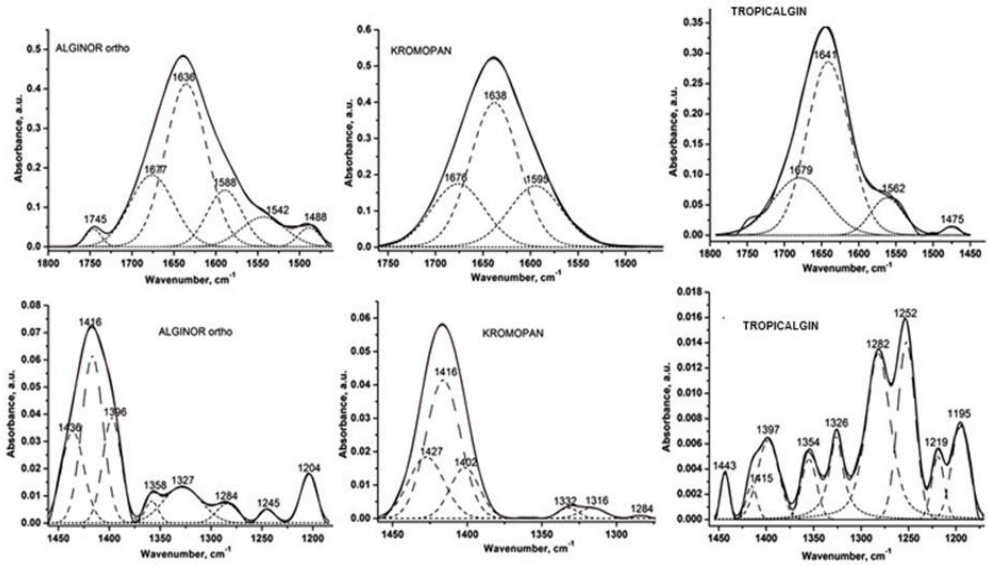

Fig. 3. ATR-FTIR deconvoluted spectra in the 1800-1170 cm^{-1} spectral range

The other bands in this spectral region are assigned to the alginic acid fragments (1677 cm^{-1}) and water (OH deformation vibrations conjugated with the C-O groups from carboxylate) at 1588, 1595 and 1562 cm^{-1}. In the 1470-1170 cm^{-1} spectral range a number of bands assigned to the different vibration modes of the C-H groups can be observed: C-H bending (1443-1427 cm^{-1}), C-H C-H bending (1399-1354 cm^{-1}) and C-H wagging (1326 cm^{-1}) (fig.3).

The bands at 1332-1200 cm^{-1} are characteristic for the asymmetric stretching vibrations of the sulphate groups.

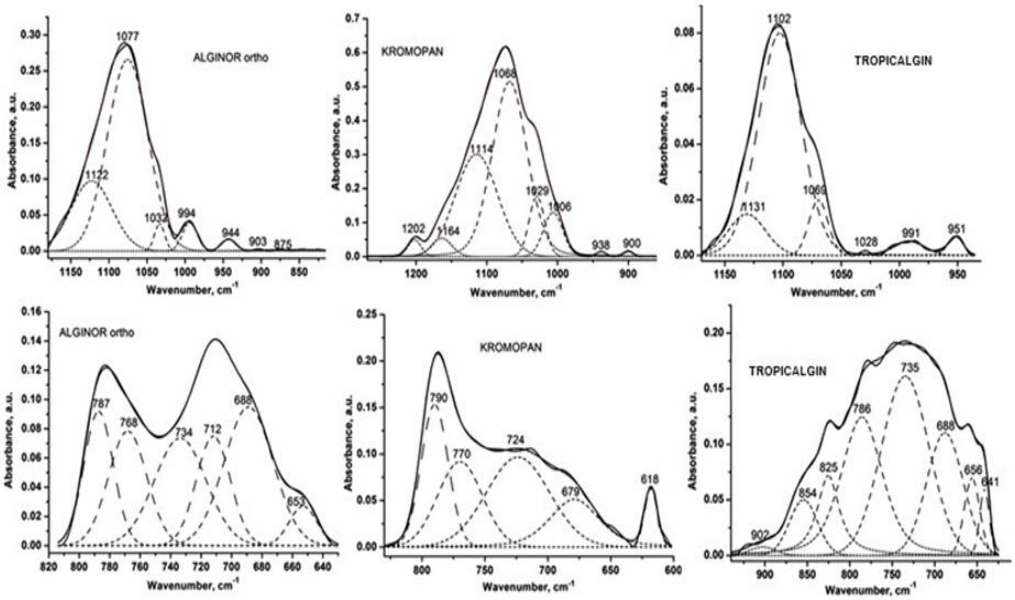

Fig. 4. ATR-FTIR deconvoluted spectra in the 1170-600 cm^{-1} spectral range

The strong bands of the ionic sulphates appeared in the spectral range 1200-1080 cm^{-1} (the symmetric stretching vibrations).

Based on the ratio between the symmetric and asymmetric stretches of the sulphate groups one can conclude that the higher content in sulphates is present in TROPICALGIN sample. The same sample presents the most bands in the 900-600 cm^{-1} spectral range, which are specific for the sulphate ion. The polysaccharide rings can be observed by the bands at 1077-1030 and 790-786 cm^{-1} (fig. 4).

CONCLUSIONS

Even through hydrocolloids were the first elastic materials used in the medical dental field, alginate impression materials are still used nowadays having multiple advantages.

Three alginate commercially available impression materials (Kromopan and Alginor-ortho from Lascod, and Tropicalgin from Zhermack) have been prepared as instructed by the producers and studied through Attenuated Total Reflectance-Fourier Transformed Infrared spectroscopy.

For the three alginate impression materials tested in our study we can say that based on the ratio between the area corresponding to the bands 1077/1030 and the area corresponding to the band at 787 cm^{-1},

one can determine the alginate composition, respectively the glucuronic acid and mannuronic acid contents.

Thus, the calculated glucuronic and mannuronic acids in ALGINOR sample is 92.66% and 7.33%, respectively for KROMOPAN sample is 62.91% and 37.08% and for TROPICALGIN is 75.93 % and 24.07%. In this case, the three alginate materials exhibit the appropriate properties for being used for the impression step in indirect restorations, as study models and casts as duplication materials, and for fabrication of primary casts.

PSYCHO-EMOTIONAL FACTORS AND CRANIOMANDIBULAR DISORDER SEVERITY (Abstract): Craniomandibular disorders (CMD) are a series of clinical dysfunctions on the level of masticatory muscles, temporomandibular joint (TMJ) or both. The symptomatology is represented by: muscle pain in the head and neck region, noise and pain in the temporomandibular joint, limitation of the mandibular mobility. This study aims to analyze the interrelation between psycho-emotional status and the severity of cranio-mandibular disorder (CMD) in patients from NE Romania. **Materials and methods:** We conducted a cross-sectional study in a cohort of 106 consecutive volunteer patients who attended private praxis in Iasi during an eight-month period (October 2023- March 2024). Before the clinical evaluation, patients were required to answer a personalized merged version of the Temporomandibular Disorder-Pain Screener (TMD-Pain Screener) (ver. October 11, 2013) and Fonseca Anamnestic Index questionnaire used for screening of CMD. After this step the patients filled in the Patient Health Questionnaire-9 (PHQ-9) (ver. May 12, 2013), which consists of 9 closed-ended questions and is designed for screening, diagnosing, monitoring, measuring the severity of depression. This questionnaire is completed by the patient and can also be administered repeatedly, to reflect improvement or worsening of depression in response to treatment. **Results:** The analysis of the scores recorded by patients on the PHQ-9 questionnaire, revealed that most of subjects (85.9%) have minimal (43 subjects) or mild levels of depression (48 subjects), in almost equal proportions (p=0.183). Only 11.3% of patients were registered with moderate depression, while 2.8% of patients (3 cases) were classified as having moderately-to-severe depression. We noticed that the severity of depression increases among subjects with a demanding profession (economist, commerce, IT). **Conclusions:** The severity of CMDs is more common in women and at the young age. Stress has been established as one of the most significant risk factor for TMJ disorders apart from parafunctional habits (clenching and grinding) and pathologic occlusion. **Keywords:** CRANIOMANDIBULAR DISORDER, PSYCHOSOCIAL FACTORS, TEMPOROMANDIBULAR JOINT, STRESS.

Craniomandibular disorders (CMD) are a series of clinical dysfunctions on the level of masticatory muscles, temporomandibular joint (TMJ) or both; there is an important influence for other muscle-articular structures of the head and neck and for the postural stance (1, 2).

The symptomatology of CMD is widespread in adult population and an average value of 44% against 30% of the latter (1), but they are not just found in adult life, but also in children and teenagers.

The main symptomatology is muscle pain in the head and neck region, noise and pain in the temporomandibular joint, limitation of the mandibular mobility; and also, symptoms like: headache, facial and posterior neck pain, dental pain, tinnitus dysgeusia are present.

CMD has multifactorial etiology. The pain is determined by a complex interaction between mechanical, biological, cognitive, and psycho-emotional factors, also there are predisposing, instigating and perpetuating factors (3, 4).

The predisposing factors include 3 main categories: morpho-structural alterations (anatomical alterations), psycho-emotional alterations (stress, anxiety) and pathophysiological alterations (parafunctions).

The instigating factors include micro-traumas and macro-traumas. Perpetuating factors are represented by the psycho-emotional dimension of the patient (emotional and social factors) (3-5).

This study aims to analyze the interrelation between psycho-emotional status and the severity of cranio-mandibular disorder (CMD) in patients from NE Romania.

MATERIALS AND METHODS

We conducted a cross-sectional study in a cohort of 106 consecutive volunteer patients who attended private praxis in Iasi during an eight-month period (October 2023- March 2024). Before the clinical evaluation, patients were required to answer a personalized merged version of the Temporomandibular Disorder-Pain Screener (TMD-Pain Screener) (ver. October 11, 2013) and Fonseca Anamnestic Index questionnaire used for screening of CMD. Since the TMD-Pain Screener contains only 4 items, we decided to attach the rest of the items from the Fonseca Anamnestic Index to obtain statistically relevant results. After this step the patients filled in the Patient Health Questionnaire-9 (PHQ-9) (ver. May 12, 2013), which consists of 9 closed-ended questions and is designed for screening, diagnosing, monitoring, measuring the severity of depression. This questionnaire is completed by the patient and can also be administered repeatedly, to reflect improvement or worsening of depression in response to treatment.

Volunteers were fully informed on the research objectives, experimental procedures, potential risks, and benefits, and were instructed to select only one response for each item. They were also told that they could take as much time as needed to complete the questionnaire.

The study was approved by the Ethics Committee Board of “Grigore T. Popa” University of Medicine and Pharmacy of Iasi (Nr. 271/14.02.2023), and all subjects provided written informed consent before enrollment.

Subjects who had been previously diagnosed with CMD or were currently receiving CMD treatment were excluded from the study. The inclusion and exclusion criteria are presented in second table.

TABLE I.

PHQ-9 Questionnaire (6)

Q.I Abrev		N.A	S.D	M.H.D	N.E.D
Q I.1	Little interest or pleasure in doing things				
Q I.2	Feeling down, depressed, or hopeless				
Q I.3	Trouble falling or staying asleep, or sleeping too much				
Q I.4	Feeling tired or having little energy				
Q I.5	Poor appetite or overeating				
Q I.6	Feeling bad about yourself or that you are a failure or have let yourself or your family down				
Q I.7	Trouble concentrating on things, such as reading the newspaper or watching television				
Q I.8	Moving or speaking so slowly that other people could have noticed. Or the opposite being so fidgety or restless that you have been moving around a lot more than usual				
Q I.9	Thoughts that you would be better off dead, or of hurting yourself				

Interpretation of Total Score	Depression Severity
1-4	Minimal depression
5-9	Mild depression
10-14	Moderate depression
15-19	Moderately severe depression
20-27	Severe depression

N.A- Not at all; S.D- Several days; M.H.D- More than half the days; N.E.D- Nearly every day.

TABLE II.

Inclusion and exclusion criteria

Inclusion criteria	Exclusion criteria
• patients who are at least 18 years old • patients who have provided completed informed consent forms • patients who have completed the questionnaire PHQ-9	• patients who refused to participate in the study. • uncooperative patients • patients with systemic joint disorders • patients with neurological diseases • patients with psychiatric diseases • patients with cervical spine alterations • patients with facial paralysis • patients with previously diagnosed temporomandibular joint (TMJ) pathology

Data analysis

The data were centralized in *SPSS 24* databases and processed with suitable statistical function. Both descriptive and analytical methods were used.

The analysis of the results entailed assessing the frequency distribution of responses to the questionnaire. We compared

average percentages between various genders and severity levels using the Pearson Chi-squared test, with a significance level of error set at 95%.

The Mann-Whitney Test is parametric statistical test used to compare two samples or groups with low numbers of individuals in each group which are not normally distributed, and where the data are continuous.

The Kruskal-Wallis test is a nonparametric test in which we compared three or more frequency distributions intergroupally.

RESULTS

We investigated a sample of 106 patients, mainly women (70.8%), generally of young age - with an average age of 39.51 ± 12.324 years; women are about 8 years older than men, with an average of 41.80 ± 11.856 years compared to 33.97 ± 11.834 years - the observed difference being statistically significant. The youngest patients were 18 years old, and the oldest is a 75-year-old man (tab. III).

We also made a division of patients by age groups of approximative 10 years; the majority of patients are of adult age, between 26 – 55 years (72.7%), the percentage of young people between 18-25 years being 18.9%, and that of adults over 55 years being of only 8.5% (tab. IV).

TABLE III.

The age of the investigated patients – descriptive statistics (global sample and comparatively by gender)

Gender	n	Age Average	Std. error of the mean	Std. deviation	Min	Max	Median	Mann-Whitney test
F	75	41.80	1.369	11.856	21	65	43.00	U = 699.500
M	31	33.97	2.125	11.834	18	75	29.00	p = 0.001**
Total	106	39.51	1.197	12.324	18	75	39.00	

TABLE IV.

The structure of the investigated sample by age groups

		n	%
Age group	18-25 yrs.	20	18.9
	26-35 yrs.	23	21.7

	46-55 yrs.	29	27.4
	over 55 yrs.	9	8.5
	Total	106	100.0

The sample's structure by occupations is quite heterogeneous: 40% of the interviewed patients are economists, to which is added a percentage of people working in

commerce (17.0%) or IT (10.4%) and also a percentage of almost 10% students; the other categories of occupations occur in relatively isolated cases (tab. V).

TABLE V.

	Optician	1	0.9
	Retired	2	1.9
	Policeman	1	0.9
	Student	10	9.4
	Total	106	100.0

Patients were given a questionnaire consisting of 9 items, to which they had 4 options of answer, namely "not at all", "several days", "more than half the days" and "nearly every day". The global analysis of patients' responses to the questionnaire reveals that most responses (over 75%) fall into the "not at all" and "several days" categories. It can also be noted that none of the patients reported severe signs of depression, all responding with "not at all" to the item targeting them (Q I.9 – "Thinking that you would be better off dead or of hurting yourself in some way") (tab. VI).

TABLE VI.

Structure of patients' responses to the questionnaire – global characterization

Consequently, based on the analysis of the scores recorded by patients on the questionnaire, it is found that most of them (85.9%) have minimal or mild levels of

depression, in almost equal proportions. Only 11.3% of patients were registered with moderate depression, while 2.8% of patients (3 cases) were classified as having moderately-to-severe depression (tab. VII).

We also analyzed comparatively by genders and age groups the patients' responses to the questionnaire.

The comparative study by genders reveals that generally, no statistically significant differences were found between women and men regarding their responses, with one exception, namely item Q I.4. (tab. VIII).

TABLE VII.

The overall degree of depression assessed by the questionnaire is also different between genders. It can be noted that a percentage almost double of women compared to the similar percentage of men have a minimal degree of depression (45.3% vs. 29.0%); on the other hand, a significantly higher percentage of men compared to women have mild depression (61.3% vs. 38.7%) and again a double percentage of women compared to men have moderate depression (13.3% vs. 6.5%). Of the 3 patients with moderate-to-severe depression, one is male and two are female, corresponding to 3.2% of men and 2.7% of women, respectively (tab. IX).

TABLE IX.

The structure of the investigated sample according to the degrees of depression identified by questionnaire – comparatively by genders

		Gender				Pearson Chi-squared test
		M		F		
		N	%	N	%	
Interpretation	minimal depression	9	29.0%	34	45.3%	$Chi^2 = 4.858$

N.A- Not at all; S.D- Several days; M.H.D- More than half the days; N.E.D- Nearly every day.

There are no statistically significant differences between age groups in which concerns the distribution of patients by degrees of depression (tab. XI). It can be noted, however, that the lowest percentage of cases with minimal depression (15.0%) was reported in the age group 18-25 years (while it tends to 50% in the other age groups), but also the highest percentages of cases with mild (60.0%), moderate (20.0%) and moderate-to-severe (5.0%) depression were reported again here.

TABLE XI.

The structure of the investigated group according to the degrees of depression identified by questionnaire – comparatively by age groups

		Age group										Pearson Chi-squared test
		18-25 yrs.		26-35 yrs.		36-45 yrs.		46-55 yrs.		over 55 yrs.

Total		20	100.0%	23	100.0%	25	100.0%	29	100.0%	9	100.0%	

A numerical depression score was also calculated based on the questionnaire's responses. Men have a slightly higher score than women, with an average of 6.16 ± 3,407 versus 5.53 ± 3,923, and the highest depression score was recorded in patients between 18-25 years, with an average of 7.70 ± 3,827, while the lowest score was observed in the age group 36-45 years, with an average of 4.80 ± 3,149 (tab. XII).

DISCUSSION

Depressive and anxiety disorders are the two most common mental disorders, affecting 280 and 301 million people around the world, respectively (7).

Over the decades, many studies have demonstrated positive correlations between CMD and symptoms of anxiety and depression. In the systematic review of De La Torre Canales *et al*, a high prevalence of moderate–to–severe depression was observed to range from 21.4 to 60.1% in patients diagnosed with CMD (8).

The results of the current study suggest that the developed questionnaire is useful for the initial assessment of the psycho-emotional state of CMD patients and obtained information, can be an invaluable addition to the diagnosis of CMD patients and may constitute a critical element for effective treatment of the disorder. The results are significant and suggest that patients with CMD suffer from psycho-emotional problems and require more frequent consultation than healthy individuals (9). Sleep is paramount for managing depression, in line with medication and professional psychological support. Pop *et al.* claims in a study that sleep-related problems and stress were also considered a problem among medical students. Studies showed that medical students have more sleep-related problems compared to non-medical students (10), and in our opinion this could open a way for specifically applying our questionnaires to this category of subjects.

It can be observed in our study that exists a correlation between static style of life (Economists, IT worker), active style of life (Engineer, Mechanic) and the risk of TMJ diseases. Patients with static occupations are more likely to develop craniomandibular dysfunction. A special category for evaluation is represented by healthcare professionals. Iorga *et al.* affirmed that apart from burnout, depression is one of the most important psychological problems experienced by adults during their working time. Identifying and providing knowledge about depression and burnout among healthcare professionals is an important aspect of medical education (11).

We also analyzed comparatively by genders and age group the patients' responses to the questionnaire (tab. VIII). The only item for which statistically significant differences between genders were found is, as already mentioned, item Q I.4, which refers to the feeling of fatigue and lack of energy. The perceptions differ between genders, even if it is not possible to detect a systematic association between them and the patients' gender. Almost a quarter of women (21.3%) said they did not feel at all tired or having little energy, compared to only 12.9% of men. On the other hand, a higher percentage of women than the corresponding percentage of men report this feeling "several days" (58.7% compared to 45.2%), while a percentage almost 3 times higher of men than the corresponding percentage of women report this feeling "more than half the days" (41.9% compared to 14.3%); none of the men, however, find themselves feeling tired or lacking energy "nearly every day".

A significantly higher amount of men (67.7%) compared to the equivalent amount of women (52.0%) stated that "several days" they have little interest or pleasure in doing things (item I.1); also, the percentage of men claiming to have such feelings "more than half the days" is slightly higher than the similar percentage of women (9.7% vs. 8.0%).

Regarding the feeling of depression and hopelessness (item I.2), the percentages of women and men who report it "several days" are relatively close, although it can be seen in this case that men who have such feelings "more than half the days" are almost double in percentage compared to women (9.7% compared to 5.3%).

A percentage 40.0% of women said they have no sleep disturbances at all (neither insomnia nor tendency to sleep too much – item I.3), compared to only 25.8% of men. Of these, on the other hand, 51.6% complain about the presence of sleep disorders "several days" compared to 42.7% of women and 19.4% say they have such problems "more than half the days" compared to 14.7% of women.

In the case of appetite disorders (item I.5) the differences between genders are even smaller than in other items. A slightly higher percentage of women compared to the corresponding percentage of men report this feeling "several days" (46.7% vs. 41.9%), while a slightly higher percentage of men compared to the corresponding percentage of women report this feeling "more than half the days" (16.1% vs. 12.0%).

The negative feelings towards oneself, the feeling of failure and being disappointed (item I.6), are more acute in women than in men. Thus, although a higher percentage of men compared to the similar percentage of women accuse such feelings "several days" (35.5% compared to 21.3%), yet a percentage almost 4 times higher of women compared to the similar one of men accuse such feelings "more than half the days" (12.0% compared to 3.2%).

A relatively similar situation is observed in the case of difficulties of concentration on things (item I.7): the percentage of men who think that they do not have such a problem is higher than the similar percentage of women (48.4% compared to 41.3%), while the percentages of women who consider that they have this problem "several days", as well as "more than half the days" are higher than the similar percentages of men. There were 1 man and 2 women who said they had such difficulty of concentration "nearly every day".

The behavior disorders as hyperactivity or its opposite, slowness in reactions (item I.8), are reported in their intense forms slightly more frequently in women than in men. Thus, 8.0% of women compared to 6.5% of men said they had such problems "more than half the days", and in addition one woman (and no men) said they had this problem "nearly every day".

The comparative study by age groups reveals, in turn (tab. X), that none of the patients over 35 years of age complained of lack of interest or pleasure in doing things (item Q I.1), except at most "several days", all patients who complained of this feeling "more than half the days" belonging to the young age, between 18-35 years. Among patients under 25 years old, 65.0% complain of this feeling "several days" and 25.0% accuse it "more than half the days", a situation that improves significantly in the next age group. Thus, of patients between 26-35 years, half (52.2%) do not have this problem at all, 30.4% accuse it "several days" and only 17.4% accuse it "more than half the days". With advancing in age, the presence of this feeling is reported less and less – being reported only "several days", by 76.0% of patients between 36-45 years, 58.6% of those between 46-55 years and only 44.4% of those over 55 years.

Negative feelings towards oneself, feel-

ing of failure and being disappointed (item Q I.6), are instead significantly associated with the age of patients. They seem to be characteristic in both young ages and adults over 55 years old. Of the 18-25 age group, only 35.0% do not experience such feelings, with 55.0% reporting them "several days" and 10.0% reporting them "more than half the days". Among patients over 55, 33.3% report such feelings "several days" and another 22.2% report them "more than half the days". In the other age groups, although there are percentages of patients who complain about these feelings "more than half the days" ranging between 3 and 13%, the amount of those who do not experience such feelings increases over 65%.

Hyperactivity or slow reaction disorders (item Q I.8) are also most associated with young patients, with ages between 18-25 years, of whom 65.0% report them "several days" and another 5.0% report them "more than half the days". Their percentage decreases to about 30% in the age groups 26-35 years and 36-45 years, then increases to 41.4% in the age group 46-55 years, after which it decreases to 22.2% of those over 55 years. The level of significance associated with this item is 0.056, very close to the statistical significance threshold.

In their cross-sectional analysis, Fredricson *et al.* demonstrated a strong association between the occurrence of mental and behavioral disorders and CMD. Pain, the most common symptom of CMD, was associated with anxiety and stress-related disorders, which are modified in CMD (12).

Several studies emphasize the importance the assessment of psycho-emotional state performed by dentists and developing tools to refer patients for specialized consultation. Although the etiology of TMD is complex and still not clearly understood, it is generally believed to comprise of biological, psychological, and social factors, it is important to also consider the psychological symptoms during diagnosis of the disease (13).

In Romania many patients have confidence in the pharmacist opinion and ask for advice regarding suitable medication formulations for specific conditions (14). Probably this has to do with a reduced number of visits to dentists and or medical physicians compared to other Western EU countries (15), as a consequence of lower average income. We have to state that dental procedures are partially supported by the National Health Insurance House in Romania, and this can contribute to a lower addressability for the Romanian patient, who has to bear the remainder cost.

According to a Eurostat study conducted in 2019, Romania is the country with the lowest percentage of chronic depression at European level. The average is 1.5%, with an incidence of 1% among men and 2% among women (16). In our study the highest depression score was recorded in patients between 18-25 years, while the lowest score was observed in the age group 36-45 years, the results obtained are in line with the previously mentioned studies.

In other study, Seweryn *et at.* discovered a correlation between the intensity of pain associated with CMD and the quality of life and sleep. These parameters are influential in modifying CMD management (17).

The results of the study suggest that the questionnaire PHQ-9 can be used as a supplement to the examination for CMD diagnosis, so we find ourselves in agreement with similar studies (18, 19). Also, it

can help dentists in identifying potential psycho-emotional issues in patients and recommending therapeutic management (20, 21).

The implication of stress in CMD is apparently not enough researched at the present moment due to a scariness of result in PubMed Database. I am aware it is a difficult task to initiate type of study in EU country with the smallest occurrence of depression.

CONCLUSIONS

Based on the findings of this research, it can be noted, that the lowest percentage of cases with minimal depression was reported in the age group 18-25 years.

According to the results of this study, the severity of CMDs is more common in women and at the young age. Stress has been established as a significant risk factor for TMJ disorders apart from parafunctional habits (grinding, thumb sucking, or tongue thrusting) and pathologic occlusion.

Our study, aligned to the other studies with the same topic, demonstrated again that exist an interrelation between CMDs and psycho-emotional factors.

We can conclude that craniomandibular disorders (CMDs) is a significant concern that should be deemed a matter of significant importance in dental medicine and addressed accordingly.

The study advocates for an increased awareness in the medical community for the relationship between temporomandibular joint (TMJ) screening and the role of psycho-emotional factors.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest. This study received no funding. This study is part of the first author's research program at the Doctoral School.

INSTITUTIONAL REVIEW BOARD STATEMENT

The study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy of Iasi (271/14.02.2023)" for studies involving humans.

INFORMED CONSENT STATEMENT

Informed consent was obtained from all subjects involved in the study.

ODONTOGENIC MAXILLARY SINUSITIS: CLINICAL AND PARACLINICAL STUDY ON ETIOPATHOGENY, DIAGNOSTIC AND THERAPEUTIC MANAGEMENT (Abstract): Chronic sinusitis has an estimated prevalence rate of about 10.4% in Europe. Odontogenic sinusitis is defined by inflammation of the paranasal sinuses caused by dental conditions. Chronic maxillary sinusitis of dental cause is the common clinical form and can occur from the beginning in this form or may be the result of chronic acute maxillary sinusitis, the condition becomes chronic if it lasts for more than 3 months. **Materials and methods:** This study investigated 47 patients admitted to the ENT Clinic of the Iasi Clinical Recovery Hospital between January 2022 - June 2023 diagnosed with maxillary sinusitis. **Results:** The study revealed a maximum incidence of maxillary sinusitis in the decade between the ages of 41 and 50 years more frequently in the male sex, and with relatively low frequency of odontogenic cause (14.8 %), versus rhino genic sinusitis. **Discussion:** Odontogenic S is a pathology at the border of two specialties, ENT and OMF with an interdisciplinary treatment approach. The maxillary status is dependent on the correct and efficient treatment of the underlying cause which sprouts from the dental root and maxillary floor. Endoscopic approach of the rhino logical pathology is a good option after the resolution of the oromaxillary interface osteitis and has successfully replaced other more invasive procedures (like Caldwell-Luc operation). **Conclusions:** odontogenic sinus pathology is a growing but frequently undervalued and underdiagnosed condition whose dimensions and impact on patients' health require a multidisciplinary approach. Odontogenic maxillary sinusitis can be prevented by maintaining a rigorous oral hygiene, regular dental checkups, correct treatment of odontal and periodontal diseases, avoiding smoking. Maxillary sinus FESS is an efficient and comfortable treatment option for resolving rhinological accuses.
Keywords: ODONTOGENIC MAXILLARY SINUSITIS, ETIOPATHOGENY.

INTRODUCTION

Acute and chronic sinusitis is a significant public health problem, both because of its high prevalence and the economic im-

pact it generates.

Chronic sinusitis has an estimated prevalence rate of about 10.4% in Europe and about 14% in the U.S. (1). For acute sinusitis, prevalence estimates are more difficult to make because many patients do not require specialized medical care for this condition. The costs associated with the treatment and management of sinusitis are substantial. In the United States, direct and indirect annual costs are estimated to exceed $6 billion, plus approximately $2 billion for over-the-counter treatments (1). These costs include expenses for medical consultations, imaging investigations, pharmacological treatments and, in some cases, surgery.

Odontogenic sinusitis is a pathology distinct from rhinosinusitis in several features. It is an inflammatory and infectious condition of the maxillary sinus of dental origin or is a complication of dental procedures. Most often it appears unilaterally and is in close association with underlying dental conditions (2). The maxillary sinus is the largest of the four paranasal sinuses (maxillary, frontal, ethmoid, sphenoid) and, because of its close relationship with the underlying dentition, is often susceptible to inflammatory processes. Although odontogenic sinusitis may present symptoms similar to those of rhinosinusitis, such as facial pain, nasal congestion and nasal discharge, its origin and pathological mechanism are distinct (2).

Odontogenic sinusitis is defined as inflammation of the paranasal sinuses caused by dental disease. It always starts with the maxillary sinus, given its size and position in relation to the dental arches, but can evolve to pan-sinusitis (all sinuses affected on the affected side) or even produce complications (orbital, thrombosis, brain abscess, sepsis). As with other forms of sinusitis, the maxillary sinus is prone to inflammation and infection when there is pathological communication between the oral cavity and the sinus in question. This pathology occurs when a dental condition, arising from a lack of proper oral hygiene or from inappropriate dental interventions (extractions or dental implants), comes to affect the maxillary sinus (1).

The incidence of odontogenic sinusitis is about 10-12% of sinusitis cases and this percentage increases with age. Thus, in people over the age of 50 who suffer from sinus infections, there is an approximately 50% probability that they have a dental cause following pulpal, periapical, periodontal disease or as a result of infectious complications of upper wisdom molar or upper canine inclusion (1).

These conditions can also be caused by incorrect dental procedures such as: Overflow root canal fillings in a tooth with sinus involvement, in which the filling material will form a foreign body in the maxillary sinus; incomplete or missing root canal fillings in abutment teeth of old prosthetic work, accidents and complications of tooth extraction, unnoticed or incorrectly treated oro-sinus communication, perforation of the sub antral space by untimely curettage; pushing of a root into the maxillary sinus during dental extraction, pushing of the upper wisdom molar into the maxillary sinus during odontotomy, failures in oral implantology, insertion of improper end osseous implants or errors in surgical technique in sinus lifting (3, 4, 5).

The risk factors for dental maxillary sinusitis are related to pathology of the teeth with sinus relation and the alveolar bone of this level, including following accidents and complications of dental treatments such as chronic inflammation and can be aggravated by several rhinological conditions: allergic

diseases of the rhinosinusal mucosa, obstruction of the ostium in the middle nasal meatus, by inflammatory mechanism - mucosal edema or mechanically - sinus polyps, deviated septum, decreased ciliary motility, simultaneous with increased mucus secretion. Also, some general factors are important: decreased overall resistance of the body to infection, diabetes, liver and kidney pathology, smoking and exposure to a noxious environment (6).

The clinical signs of acute maxillary sinusitis are: unilateral pain, located in the mid-face, radiating to the orbital, frontotemporal or occipital region, exacerbated by head tilt; stuffy nose, purulent nasal discharge, anterior or posterior, most commonly unilateral. Fever, sensation of pressure in the genian region; digital pressure exerted on the anterolateral wall of the sinus is painful, subjective cacosmia, dental pain, sometimes pulsatile in character, swollen and congested genial teguments, painful on pressure; altered general condition, lack of appetite, halitosis, cough and fatigue (4, 7).

Chronic dental maxillary sinusitis is the most commonly encountered clinical form and may be present from the outset in this form or may be the result of chronicization of acute maxillary sinusitis, the condition becoming chronic if it lasts more than 3 months.

Maxillary odontogenic sinusitis can be prevented by maintaining rigorous oral hygiene, regular dental check-ups, correct treatment of dental and periodontal diseases, avoidance of smoking (9, 10).

Given the trend of increasing resistance to conventional treatment of odontogenic sinusitis, the need for an interdisciplinary consensus of odontogenic sinusitis is emphasized. The therapeutic algorithm usually includes two stages: the first stage is non-surgical treatment with antibiotic treatment for infection and resolution of dental lesions, and the second stage is sinus surgical treatment (8, 10).

MATERIALS AND METHODS

This study investigated 47 patients admitted to the ENT Clinic of the Iasi Rehabilitation Hospital between January 2022 and June 2023. Patients required medical care for common symptoms of maxillary sinusitis, which were also associated with signs and symptoms of other systemic or local conditions. The age range of patients included in the study was between 13 and 77 years. After treatment, which included drug, surgical or a combination of drug and surgical options, patients were discharged and follow-ups were planned for a specified period of time.

The study was conducted retrospectively, based on analysis of discharge notes of patients included in the initial selection. This method allowed to evaluate the efficacy of the treatment administered and to analyses their post-treatment evolution. Therefore, the study provides an important insight into the management and treatment outcomes of maxillary sinusitis in this institution.

The study included patients who presented with maxillary sinusitis objectified on computed tomography (CT) imaging and evaluated by nasal endoscopy. Cases were assessed according to several variables, including age, gender, duration of hospitalization, location of maxillary sinusitis (right/left/bilateral), predominant clinical symptoms, treatment modality (medical, medical + surgical; type of surgery), comorbidities, and preoperative and postoperative complications.

Cases with traumatic, tumoral or allergic rhinosinusal pathology, trigeminal neu-

ralgia, dental pathology without sinus involvement, fungal sinusitis, associated with polypoid formations (such as nasal polyposis, sinus-choanal polyp) or in ciliary immobility (e.g. Sjogren's) or allergic syndromes (Vidal syndrome) were excluded from the study.

These inclusion and exclusion criteria were applied to ensure an appropriate selection of cases that would meet the specific objectives of the study and provide relevant data for the evaluation of maxillary sinusitis in the study population.

Patient assessment included: ENT clinical examination, general clinical examination, ATI consultation, internal medicine consultation, infectious diseases consultation, ophthalmology consultation and dental consultation; ENT clinical examination included buco-pharingoscopy (BFS), anterior rhinoscopy, posterior rhinoscopy, indirect laryngoscopy, nasal endoscopy or fibroscopy, palpation of trigeminal points, percussion of anterior sinus wall and upper quadrant teeth (canine, premolar, molar); pituitary congestion and edema, status of the inferior and middle turbinate, appearance of the middle meatus, presence of mucous or purulent secretions in the middle meatus; purulent secretions were collected from the middle meatus when present on admission.

Paraclinical investigations performed are: computer tomography (CT) examination, recommended in all cases; sometimes additional MRI (nuclear magnetic resonance) examination; bacteriological and microbiological examination of secretions with antibiogram and antifungigram; dental X-rays - if a dental cause of sinusitis is suspected; chest X-ray, EKG and cardiological consultation, in case of surgery under general anesthesia.

Pre-operatively the patients underwent tests such as: hemolucogram, coagulogram, liver tests, kidney tests, blood glucose.

RESULTS

It is interesting to note that in this study, the highest incidence of maxillary sinusitis was recorded in the age decade between 41 and 50 years. This finding suggests that this age group may be more prone to the development of maxillary sinusitis compared to other age groups. The biggest prevalence was however between ages 31 and 60 with 33p from the total of 47 (70.21%).

In the following graph, the incidence of maxillary sinusitis has been plotted by gender, and as can be seen, of the 47 patients selected for this study, the highest incidence is identified in males.

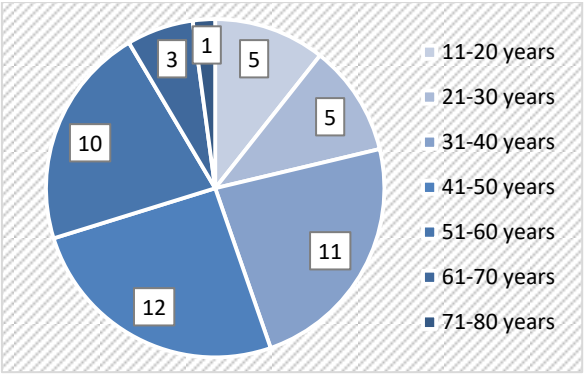

Fig. 1. Age of patients by decades diagnosed with maxillary sinusitis

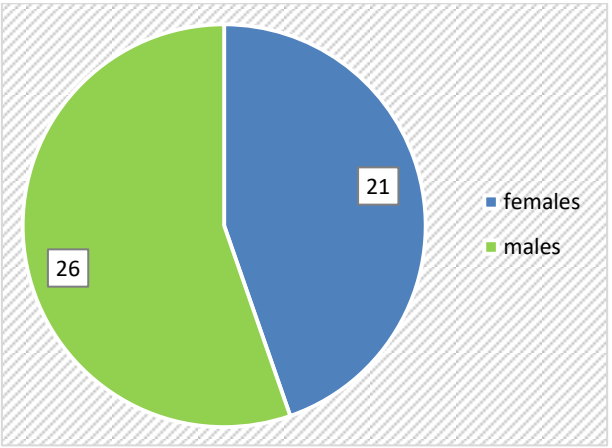

Fig. 2. Incidence of maxillary sinusitis by gender

In the diagram below, the incidence by location of maxillary sinusitis is shown. There is an increased incidence of bilaterally located sinusitis. Thus, we found 10 cases of left-sided maxillary sinusitis, of which 2 were odontogenic sinusitis, 16 cases of right-sided maxillary sinusitis, of which 5 were odontogenic sinusitis, and 21 cases of bilaterally located maxillary sinusitis, with no cases of odontogenic sinusitis.

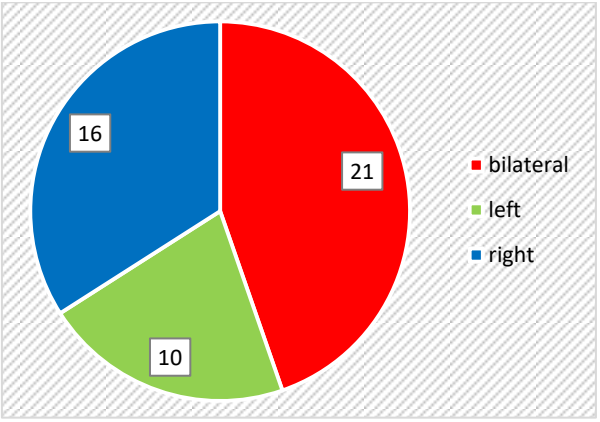

Fig. 3. Location of maxillary sinusitis

No statistically significant differences were found either between the sexes or between the 3 age groups in the localization of maxillary sinusitis (tab. I). However, it can be noted that sinusitis with bilateral localization was observed slightly more frequently in females than in males, with an incidence of 57.1%, and in most cases also in adult patients aged 31-60 years (71.4%). Left-sided sinus sinusitis was observed equally in females and males, and most frequently in adult patients (60.0%), while right-sided sinus sinusitis was observed predominantly in males (75.0% of cases) and also in adult patients (75.0%), being completely absent in elderly patients.

TABLE I.

Distribution of maxillary sinus sinusitis according to localization, by sex and age groups

		Location						
		bilateral		left		right		
		N	%	N	%	N	%	p-value†
Gender	male	9	42.9%	5	50.0%	12	75.0%	0.139

Total		21	100.0%	10	100.0%	16	100.0%	
†Pearson Chi-squared test; p<0.05* statistically significant								

The most pronounced clinical symptoms with which patients presented to the clinic were: nasal obstruction (right/left/ bilateral); anterior and/or posterior purulent rhinorrhea; facial pressure and pain; cacosmia, hyposmia, anosmia; intermittent

headache. Nasal obstruction syndrome is usually the first symptom, accompanied by anterior and/or posterior purulent rhinorrhea.

In the following diagram, we have represented the subjective symptoms of the selected patients. All patients had nasal obstruction and most of them (42) had also purulent rhinorrhea; we also found 13 patients with headaches, 8 patients presenting facial pressure sensation, 5 patients presenting hyposmia, 4 patients with facial pain, 2 patients presenting cacosmia, and 1 patient presenting anosmia (fig. 5).

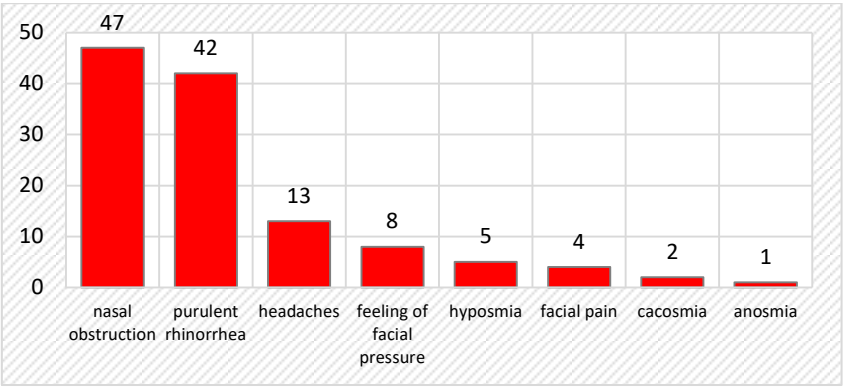

Fig. 5. Incidence of the most important subjective symptoms of patients in the study

We comparatively investigated the presence of symptoms according to the type of sinusitis, its localization, as well as the age group and gender of the patients, the results of which are presented in tables III-VI. There were no statistically significant differences in the incidence of symptoms between the listed categories.

TABLE III.

Incidence of symptoms compared by type of sinusitis

The average incidence of the number of days of hospitalization of selected patients is around 2 or 3 days – 37 patients from 47 (78.72%). The longest hospitalization was of 9 days in case of one patient.

The average number of days of hospitalization was 3.13 ± 1,345, being statistically significantly higher in women than in men (with 3.57 ± 1,660 days compared to 2.77 ± 0.908 days) and in older patients compared to the others (tab. VII). Thus, for patients over 60 years of age the average length of hospitalization is 5.00 ± 2.944 days, while for those under 30 years the average length of hospitalization is practically halved (2.40 ± 0.516 days). Adult patients fall between the two extremes, with an average length of hospitalization of 3.12 ± 1.053 days.

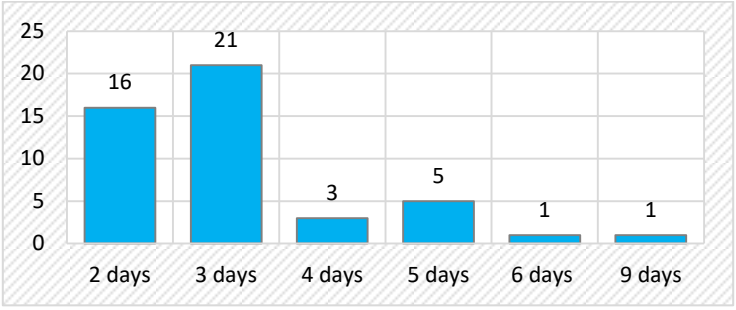

Fig. 6. Incidence by number of hospital days

Also, the mean number of days of hospitalization is statistically significantly higher in patients with bilateral sinusitis (with a mean of 3.90 ± 1,640 days) compared to other patients, for whom the mean hospitalization is two and a half days. The mean number of days of hospitalization is slightly lower in the 7 patients with odontogenic sinusitis compared to the others (with a mean of 2.57 ± 0.535 days versus 3.22 ± 1.423 days), but the difference is not pronounced enough to be statistically significant.

We also comparatively investigated the number of days of hospitalization according to the presence/absence of observed symptoms (tab. VIII). No statistically significant differences were found, although in general the number of days of hospitalization tends to be slightly higher in patients presenting with symptoms compared to others.

DISCUSSION

Treatment of odontogenic sinusitis involves two stages: drug therapy and surgery. In the case of the patients included in the study, some of them first received antibiotic medication (VANCOMICIN combined with MEROPENEM) but the results were ineffective. Pre-operative medical treatment includes: identification of the causative factor of dental nature and its suppression, topical nasal steroids, antibiotic therapy (after antibiogram from nasal swab), nasal irrigation, antiseptics, anti-allergic.

Dental maxillary sinusitis is a well-recognized condition in both the dental and ENT communities. It is estimated that more than 30% of cases of maxillary sinusitis may have underlying dental pathology (11). Failure to identify a dental cause can frequently lead to progression to chronic sinusitis, which is often associated with serious complications (12). The close anatomical proximity of the root apices of teeth, particularly the second molar, to the maxillary sinuses gives dental conditions considerable potential to be a source of dissemination of infection into the maxillary sinuses. Untreated dental infections, such as periapical abscesses or deep dental caries, may allow bacteria to enter the maxillary

sinuses through natural communication channels or pathological perforations of the sinus walls (13).

The incidence of odontogenic sinusitis is low, accounting for 10-12% of all forms of sinusitis. However, despite the significant prevalence of dental infections, in recent years these conditions appear to be experiencing a significant increase in incidence, recent studies indicate that dental conditions associated with odontogenic sinusitis are increasing, with an estimated incidence of approximately 40% (1, 26).

In our study the incidence was almost 15%, possibly due to late presentation to dental treatment (or none), deficitary access to medical facilities in rural isolated areas, etc.

It is often refractory to initial antibiotic therapy due to its polymicrobial, predominantly anaerobic nature.

The condition should always be considered by otolaryngologists and dentists when a patient presents with unilateral nasal symptoms that do not respond to medical treatment, especially recent dental treatment in the past. Thus, the diagnosis of odontogenic sinusitis requires multidisciplinary team, systematic dental imaging examination and computed tomography, including three-dimensional techniques such as cone beam computed tomography (14, 15) in some cases.

A common consensus on the treatment plan for odontogenic sinusitis is not yet established; and the ideal therapeutic management algorithm is not yet standardized. However, there are studies that have reported promising results with different approaches, including endoscopic sinus surgery and dental surgery.

Endoscopic sinus surgery is especially recommended when the osteomeatal complex is blocked and the sinus mucosa is significantly thickened. In this context, elimination of the dental source of infection, such as endodontic treatment of the causative tooth or elimination of periapical or periodontal infection, is essential for prevention of sinusitis recurrence (16). Recent studies have highlighted the benefits of concurrent management of endoscopic sinus surgery and dental surgery, which can ensure complete resolution of infection. In addition, antibiotic treatment is often used as first-line treatment to control infection and reduce inflammation. It is also important to point out that common procedures in dental practice, such as insertion of dental implants or sinus lift procedures, may affect the maxillary sinus (17). Therefore, these procedures should always be preceded by an otolaryngologic examination to assess the status of the osteo meatal complex and to minimize the risk of complications. The success of dental implants can be significantly influenced by the health of the maxillary sinus and the integrity of its mucosa.

There are various opinions on the methods of treatment of dental sinusitis, which may include medical management, dental treatment or surgery (18). Medical management may involve administration of antibiotics to control infection and nasal irrigation with saline to reduce inflammation and remove sinus secretions (19, 20). Dental treatment may include endodontic therapy to treat root infections or tooth extraction in severe or irreparable cases. Endoscopic sinus surgery may be necessary in cases where there are complications or obstructions of the maxillary sinuses (21).

Despite the diversity of therapeutic ap-

proaches, it is important to emphasize that the therapeutic protocol of odontogenic sinusitis is not yet standardized (22, 23). However, it is clear that this complex condition requires a mandatory multidisciplinary approach, involving close collaboration between dentists, ENT and, in some cases, other relevant specialists. Only a comprehensive assessment and a personalized treatment plan, tailored to the specific needs of each patient, can ensure effective and successful management of odontogenic sinusitis.

Although odontogenic sinusitis is a relatively common condition, especially in certain age groups, it is underdiagnosed because of its non-specific symptoms. In addition, it can frequently be confused with rhinogenic sinusitis and thus not treated properly. A multidisciplinary team composed of an ENT specialist, a specialist in dento-alveolar or maxillo-facial surgery and a dentist is required for correct diagnosis and optimal therapeutic management.

Treatment of odontogenic sinusitis can involve a complex approach, usually divided into two distinct stages: non-surgical and surgical. However, it is crucial to emphasize that the therapeutic success of any intervention is often conditional on the resolution of the primary etiological factor, which is dental in nature. In the absence of effective management of this fundamental issue, treatment outcomes may be limited or even suboptimal (24).

Odontogenic sinusitis usually presents unilaterally affecting the maxillary sinus adjacent to the affected tooth or the inflamed dento-alveolar region. However, in the absence of adequate treatment it can be complicated by pan- or polysinusitis, orbital complications, general complications sometimes life-threatening. In its management, tooth extraction and curettage of osteolytic areas are considered crucial steps in the favorable post-operative and remote course. In cases where medical treatment is ineffective or insufficient, surgery is required.

Surgical intervention is in some cases delayed until the patient's hemodynamic balance is achieved. Some patients have severe co-morbidities such as liver disease with altered clotting factors, sepsis or organ failure, diabetes mellitus, cardiovascular disease, which may delay surgery. However, in emergency cases, especially those with orbital abscess consecutive with visual impairment, and those with generalized septic status, immediate surgical intervention is appropriate, requiring careful assessment of surgical treatment and intraoperative vital risk (25, 26). The treatment of choice is usually surgical; performing functional endoscopic rhinosinusional surgery (FESS) with favorable postoperative outcome in most cases.

Apical periodontitis, periodontal disease and iatrogenic foreign body extrusion into the sinus are the main causes of OS. Although the exact prevalence of dental sinus pathology is still controversial, ENT physicians are increasingly aware of its importance. In cases of treatment-resistant or unsatisfactory sinusitis, a dental origin should be considered and properly investigated. This requires close collaboration between dentists and ENT specialists for a comprehensive assessment and appropriate management of the condition.

CONCLUSIONS

Odontogenic sinus pathology is a growing but frequently under-diagnosed and

under-recognized condition, whose dimensions and impact on patients' health require a multidisciplinary approach.

By recognizing and properly managing dental sinus pathology, the quality of life of patients can be significantly improved and severe complications associated with the condition can be prevented.

It is essential that physicians from both specialties are aware of this link and work together effectively to ensure optimal care for affected patients.

FESS is a good option for treating odontogenic sinusitis, with good results if it is conducted correctly and performed after or concomitant with dental cause correction. It has replaced more invasive procedures used commonly for odontogenic sinusitis treatment, such as anterior sinus wall trephination, with advantages like shorter hospitalization, less pain and faster recovery.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

PERCEPTION OF MEDICAL PROFESSIONALS ON RADIOLOGICAL SAFETY PRACTICES IN THE WORKPLACE (Abstract): Radiation protection aims to reduce unnecessary exposure to radiation to minimize the harmful effects of ionizing radiation, this goal is achieved by using different means and methods of radiation protection. The **aim** of this study was to analyze the knowledge, perceptions, and attitudes of medical personnel in the N-E Region of Romania regarding radiation protection and the effects of ionizing radiation. **Materials and methods:** The study was carried out based on the use of a structured questionnaire for data collection, a questionnaire that was distributed to the medical staff (doctors, nurses, radiologists) from hospitals and medical centers in the N-E Region of Romania. **Results:** The results show that most respondents know about the stochastic and deterministic biological effects of ionizing radiation, but a significant group has incomplete, average, or uncertain knowledge about this topic. **Conclusions**: These aspects suggest a need for additional education in the field of radiation protection in the workplace. **Keywords:** RADIATION PROTECTION, IONIZING RADIATION, BIOLOGICAL EFFECTS.

INTRODUCTION

In the medical field, ionizing radiation has become an inevitable tool used for diagnosing and treating a variety of medical conditions. Ionizing radiation is radiation (electromagnetic or corpuscular) that has enough energy to ionize the atoms (molecules) of the substance with which it interacts.

As their use has evolved, so have the cumulative doses of lifetime radiation that both patients and healthcare providers (healthcare professionals) receive. This requires a thorough understanding of the risks of radiation exposure and radiation dose reduction techniques in order to prevent biological effects. It was observed that although there were extraordinary benefits, there were associated dangers, equally great, not only for patients who underwent X-ray investigations, but also for the personnel who operated the facilities using X-rays. In addition to wearing radiation protection equipment (lead aprons, thyroid protection collars, lead salt glasses, gloves with lead insert), there were recommendations on limiting the exposure time (exposures as short as possible), along with X-ray beam filtering and the use of collimation (1-8).

Radiation exposure produces important biological effects, and prolonged exposure can lead to cell death. Biological effects are divided into stochastic effects and deterministic effects. The stochastic effects are due to cellular changes (DNA) and proliferation towards malignant diseases. The severity of the effects is independent of the dose but may increase with increasing dose. There is no threshold dose, the effects can occur even at very low doses, but the probability of the effect increases proportionally with the dose. The deterministic effects are due to cell death and have a threshold dose – a few Grays. They are specific depending on the affected tissue, and the severity of the effect is dose-dependent, the threshold being different from individual to individual (3, 14**).**

In the case of the use of CBCT (Cone Beam Computed Tomography), it has been observed that there are genotoxicity and cytotoxicity effects at the level of exfoliated oral epithelial cells. Cytotoxicity can lead to nuclear changes and usually causes lethal injury or necrosis (15).

Radiation protection is the totality of methods and means of reducing the harmful effects of ionizing radiation. Radiation protection aims to minimize the harmful effects of ionizing radiation by reducing unnecessary exposure to radiation. Ionizing radiation is used in the medical field to diagnose and treat a variety of medical conditions. The more they are used, the higher the cumulative lifetime radiation doses received by both professionally exposed personnel and patients (1).

After the discovery by W. C. Roentgen of X-rays in November 1895 and the increasingly accelerated use in the twenty-first century, the role of radiation protection was highlighted as an important tool for the management of health protection measures against the risks (for people and the environment) arising as a result of the use of ionizing radiation (5, 8).

A particular concern has been observed with long-term irradiation, at low, cumulative doses, which can lead to an increase in malignant diseases and genetic mutations, effects that can propagate to future generations. Thus, it is important to analyze the risk-benefit factor when using irradiation techniques (14). In order to reduce the radiation dose, the aim was to implement strategies to improve dose optimization, to draw up standard protocols, as well as to implement the concept of good practices (7, 12).

The radiation protection system aims to prevent the occurrence of deterministic effects and to reduce the occurrence of stochastic effects. Medical personnel working both in interventional radiology and in specialties that use interventional radiology techniques (cardiology, neurosurgery, orthopedics, urology, pulmonology, vascular surgery) are exposed to ionizing radiation coming from artificial sources (radiological installations), their protection is ensured by the use of lead screens (lead aprons, lead screens) (2, 16).

In the case of interventional radiology, the leaded apron with or without a collar is the standard clothing used against ionizing radiation. It is designed sleeveless, so the armhole can be an unprotected area, and the radiation scattered from the patient can contribute to an increase in doses to different organs of the operator and thus increase the effective dose (6). Since the equipment mentioned above is quite heavy and has a drawback, the absence of sleeves, we tried to introduce a much lighter protective equipment, in order to observe its effectiveness against ionizing radiation. Thus, it was found that the proposed new equip-

ment reduces the dose by approximately 98.1% and 90.1%, respectively. With the addition of radiation protection shields, a dose reduction of 99.0% and 98.2% was observed (17).

Another method of dose reduction is the "As Low as Reasonably Achievable" (ALARA) principle. This principle was first introduced in the nuclear energy sector and was later adopted in the field of radiology and medical imaging, with the aim of warning professionally exposed personnel that medical imaging should be used with justification (13).

Studies conducted so far indicate a low level of knowledge of radiation exposure in medical imaging among both healthcare professionals and patients (4). Studies from Greece and Turkey have highlighted significant deficiencies in radiation protection, influenced by educational level and professional experience, recommending continuous training and review of medical training to correct misperceptions and improve the quality of services (9, 10, 11).

In Romania, radiological safety in medicine is regulated and studied within the norms imposed by CNCAN (National Commission for the Control of Nuclear Activities). Research and regulations focus on diagnostic, interventional, and nuclear medicine radiology, with an emphasis on staff training, risk assessment, and implementation of radiation protection programs. For example, mandatory radiation protection courses for healthcare professionals and occupational exposure monitoring programs to ionizing radiation are required, tailored to the specific risks of each medical practice (18-20). What is important to emphasize is the lack of studies carried out at the national level, studies that assess the level of knowledge and attitudes regarding radiation protection. Thus, the purpose of this study was to analyze the knowledge, perceptions, and attitudes of medical personnel in the North-East Region of Romania regarding radiation protection and the effects of ionizing radiation.

MATERIALS AND METHODS

The observational study carried out in the North-Eastern region of Romania, between May 20 and June 15, 2024, aimed to analyze the knowledge, perceptions, and attitudes of medical personnel (doctors, nurses, radiologists) regarding radiation protection and the effects of ionizing radiation. The data were collected through a structured questionnaire, developed based on the literature and the research objectives, after obtaining the opinion of the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy Iasi.

The sample, consisting of 100 participants selected by a convenience technique, ensured adequate representativeness for statistical analyses.

The questionnaire, applied online between May 20th and June 15th, 2024, through the Google Forms platform, included questions about the biological effects of radiation, known methods of radiation protection, optimal exposure intervals, and workplace safety measures. Before data collection, a pilot phase was carried out to validate the instrument. Only fully completed questionnaires were considered, and the process included coding and statistical analysis of data, providing a detailed insight into the level of training and awareness of medical staff.

Statistical analysis was descriptive, presented in the form of frequencies, percentages, and mean values for the variables of interest, and the correlation analysis where Pearson or Spearman correlation coefficients were used to examine the rela-

tionships between the variables. The threshold of statistical significance was set at p=0.05.

RESULTS

The analysis was conducted on a representative sample of 95 respondents. Of the total participants, 75.8% have bachelor's or post-secondary studies (in the case of nurses), 10.5% have master's degrees, and 13.7% have completed postgraduate studies. 45.3% of respondents have 10 years or less of seniority in the specialty, which suggests that almost half of the respondents are at the beginning or middle of their career (fig. 1).

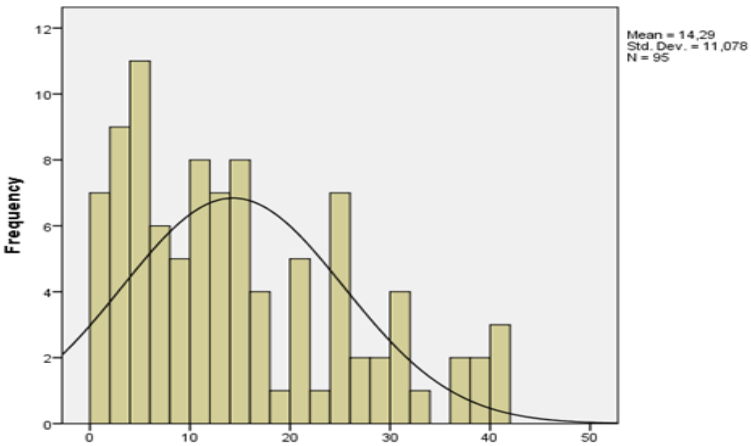

Fig. 1. Distribution of years of seniority of medical professionals

The perception of the safety status was achieved through the analysis of indicators, such as knowledge of the stochastic biological effects of ionizing radiation, fear of radiation effects, known radiation protection methods, optimal exposure range, and safety measures at work. After analyzing the results, it was found that most of the respondents (74.7%) have knowledge about the stochastic and deterministic biological effects of ionizing radiation, which shows a high level of information among the staff. A significant group (22.1%) has incomplete or average knowledge, suggesting a possible need for further education in this area. Very few respondents (2.1%) have no knowledge or are uncertain about this topic, which is positive, but still indicates the need for continuous awareness (tab. I).

TABLE I.

Do you know the stochastic/deterministic biological effects of ionizing radiation?

		Frequency	Percent	Valid Percent	Cumulative Percent
Valid	Yes	71	74.7	74.7	74.7
	Not	1	1.1	1.1	75.8
	Partially	21	22.1	22.1	97.9
	Ns/Nr	2	2.1	2.1	100.0
	Total	95	100.0	100.0	

From the analyses performed, a moderate positive correlation can be observed Pearson = 0.234, (Sig. 2-tailed) = 0.022 between the knowledge of these effects and the level of study. This suggests that as the level of education increases, knowledge of the biological effects of radiation tends to increase as well. Moreover, there is a significant but weak negative correlation between fear of ionizing radiation and level of education, suggesting that people with higher education tend to have less fear of radiation (-0.263, p = 0.010) (tab. II).

TABLE II.
The correlation between the level of education and knowledge/fear in relation to ionizing radiation

		Studies
Studies	Pearson Correlation	1
	Mr. (2-tailed)	
	N	95
Do you know the stochastic /? deterministic biological effects of ionizing radiation?	Pearson Correlation	,234*
	Mr. (2-tailed)	,022
	N	95
Are you afraid of ionizing radiation?	Pearson Correlation	-,263*
	Mr. (2-tailed)	,010
	N	95

The most harmful of all the diseases listed are leukemia and hematological diseases. The damage to the digestive system has an average of 2.83, which indicates a lower perception of harmfulness compared to other effects, and with a moderate perception (mean = 3.64) we have effects on the immune system. All perceptions of harmful effects (cancer, genetic mutations, leukemia, and thyroid disease) are strongly correlated with each other, with correlation coefficients ranging from 0.656 to 0.817. This indicates that those who consider one effect to be harmful tend to attach similar importance to the other effects (tab. III).

We found a negative correlation between the knowledge of these biological effects and the fear of radiation (-0.213). which suggests that there is a relatively weak association between the two investigated variables. which is nevertheless statistically significant (0.038). Thus. as the level of knowledge about the biological effects of ionizing radiation increases. the fear of ionizing radiation tends to decrease. and vice versa (tab. IV).

From the analysis of the data. we find that 62.1% of people say that they do not have a certain fear of ionizing radiation. but there is a considerable percentage that says that there are certain aspects that can lead to fears in the activity they do.

Concerns about ionizing radiation and the assessment of its biological impact highlight significant correlations between fear of radiation and the perception of serious conditions associated with exposure to it. For cancer. the correlation coefficient is 0.390. indicating a moderate and statistically significant positive correlation (p = 0.000) between fear of radiation and the belief that it is a serious effect of radiation exposure. This suggests that people with a

greater fear of radiation tend to consider cancer as one of the most severe consequences of such exposure. For genetic mutations. the correlation coefficient is 0.220. statistically significant at the level of 0.05 (p = 0.032). which reflects a weak positive correlation between fear of radiation and its perception as harmful effects. Respondents with an increased fear of radiation are more likely to perceive genetic mutations as dangerous. although this association is less strong compared to that for cancer (tab. V).

TABLE V.

Correlations between fear of radiation and the perception of serious conditions associated with exposure to it

Correlations		Are you afraid of ionizing radiation?	What biological effects do you consider to be more harmful?			
			Cancer	Genetic mutations	Leukaemia and hematological disorders	Thyroid disorders
Are you afraid of ionizing radiation?	Pearson Correlation	1	.390**	.220*	.323**	.266**
	Mr. (2-tailed)		.000	.032	.001	.009
	N	95	95	95	95	95
**. Correlation is significant at the 0.01 level (2-tailed) / *. Correlation is significant at the 0.05 level (2-tailed).						

In the case of leukemia and hematological disorders. the correlation coefficient is 0.323. significant at the level of 0.01 (p = 0.001). indicating a moderate positive correlation. People who show a greater fear of radiation are more inclined to consider leukemia and hematological disorders as harmful effects of radiation. For thyroid disorders. the correlation coefficient is 0.266. significantly at the level of 0.01 (p = 0.009). which indicates a moderate positive correlation. but relatively weaker than that observed for leukemia or cancer. There is a standard deviation of responses above 1 within the variables "Reproductive system impairment" and "Immune system suppression." which suggests a wide dispersion of opinions. indicating that participants have different perceptions of the severity of these effects (tab. 3).

In the study on the recognition of radiation protection methodologies. several techniques were evaluated to determine the level of familiarity and perception of their effectiveness among participants. Lead barrier screens. with a score of 90.6%. stand out as a widely accepted and considered effective method. Personal dosimetry. which obtained an average score of 60.4%. is not the most recognized method of radiation protection but indicates a high appreciation of its importance in safety measures (fig. 2).

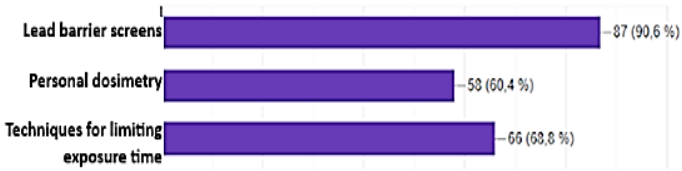

Fig. 2. Known radiation protection methods

Concerning the category of various protective methods (classified under "Other.."). the most frequently mentioned methods of radiation protection are the collimation of the radiation beam and the use of personal protective equipment. such as the protective apron with Pb insert and the collar with Pb insert. to protect the thyroid.

each of which is mentioned several times. Also mentioned were the collimation. the use of filters. the walls plated with lead or barite. the leaded glass. and the performance of radiological investigations as rarely as possible.

When asked about the optimal interval between exposures for optimization (referring to professionally exposed personnel - doctors. nurses. medical bioengineers. physicists). 24.2% of the participants opted for an interval of one hour. 11.6% for a day. 10.5% for a week and 8.4% for a month. while 45.3% gave other varied answers (tab. VI).

TABLE VI.

Best exposure interval for optimization

		Frequency	Percent
Valid	1 hour	23	24.2
	1 day	11	11.6
	1 week	10	10.5
	1 month	8	8.4
	Another answer	43	45.3
	Total	95	100.0

In terms of protection measures. respondents were questioned about the following variables: confidence in safety measures. regular updating of these measures. consultation with experts on radiation safety. and collaboration with radiation protection experts (tab. 7).

Regarding trust in security measures. the media of 7.94 indicates a relatively positive assessment of trust in existing security measures. although it is not perfect. The median of 9.00 suggests that most respondents rate this confidence close to the top of the scale. The standard deviation of 2.633 indicates moderate variability in responses. Positive kurtosis (0.553) suggests a slightly flat distribution. indicating that there are more very high ratings than in the case of a normal distribution (tab. 7).

TABLE VII.

Degree of confidence in radiation safety

How do you rate on a scale from 1 (not at all) to 10 (very much) the following statements?		[I am confident in the safety measures in place in the workplace]	[Security measures are periodically updated according to new technologies and research in the field]	[The occurrence of incidents related to workplace safety is low]	[We are regularly consulted on radiation safety]	[We call on radiation protection experts in case of incidents that occur in the workplace]
N	Valid	95	95	95	95	95
	Missing	0	0	0	0	0
Mean		7.94	7.81	6.75	7.29	8.23
Median		9.00	9.00	9.00	9.00	10.00
Std. Deviation		2.633	2.818	3.501	3.118	2.804
Kurtosis		.553	-.047	-1.445	-.888	.370
Std. Error of Kurtosis		.490	.490	.490	.490	.490

The results highlight that those who say they are confident in the safety measures are fully aware of the biological effects considered more harmful. There is a very strong and statistically significant relationship between the updating of security measures regularly and the level of confidence of employees in the security measures implemented in the workplace. The Pearson coefficient of 0.889 indicates a very strong and positive correlation. This means that as the clarity and availability of emergency procedures are present. employee confidence in radiation safety measures also increases. The meaning of 0.000 confirms that this relationship is extremely robust.

Moreover. in this examination. the associations between knowledge of radiation protection methods and confidence in safety measures were analyzed. The Pearson coefficient of 0.261 indicates a weak positive association between understanding the use of lead screens and confidence in safety protocols. suggesting that a deeper awareness of the protective role of these barriers contributes to increased confidence in workplace safety. although the influence is not particularly pronounced.

In terms of the perception regarding the periodic updating of security measures. the general perception is positive. but the variation in responses indicates that some employees believe that this aspect can be improved (mean: 7.81 - standard deviation: 2.818). Regarding the degree of occurrence of incidents related to safety at work. the average of responses is 6.75. showing a greater concern among employees regarding security incidents. However. the perception is quite varied. with a high dispersion of the answers provided (tab. VIII).

Regarding the periodic consultation of staff in relation to radiation safety. the variation in responses is relatively large. suggesting that some employees feel that they are not consulted often enough on issues related to radiation safety.

TABLE VIII.

DISCUSSION

The present study was carried out starting from the following variables. namely. the knowledge of the stochastic biological effects of ionizing radiation. the fear of the effects of radiation. the known radiation protection methods. the optimal exposure interval. and the safety measures at the workplace.

In terms of knowledge of the stochastic

biological effects of ionizing radiation. the analysis showed that some of the respondents have adequate knowledge about the effects of radiation. but we have an important number of those who show that they have incomplete knowledge. indicating the need for additional education. The moderate positive correlation between knowledge of the effects and level of education suggests that more advanced education is associated with a better understanding of the effects of radiation. These conclusions are also supported by the cross-sectional study carried out in Greece involving 132 members of the medical staff. including nurses. radiographers. and doctors. with a response rate of 97% (10). A study in Nigeria found that 92% of medical personnel demonstrated a solid knowledge of radiation safety. but only 81% complied with protective measures (20). In Sri Lanka. nurses showed satisfactory awareness of radiation protection. but gaps in understanding the effects of radiation persisted. indicating a need for further training (21).

In terms of fears about the effects of radiation. the perception of risks varies significantly. with healthcare professionals and patients often having limited knowledge and fears related to exposure. The fear of radiation decreases with the increase in the level of education. having a significant negative correlation coefficient. The negative correlation between knowledge about the effects of radiation and fear of it suggests that a better understanding of the effects of radiation helps reduce fears. although fear is greater in the case of cancer. leukemia. and genetic mutations. Numerous studies reiterate the need for a high level of knowledge about radiation protection (22). There is a fairly unified perception regarding the harmfulness of biological effects. Analyzing the average of the responses on the knowledge of these effects. the following can be found: for carcinogenic effects. there is an average of 4.25 responses. which indicates that most consider cancer as one of the most harmful effects of ionizing radiation. In terms of genetic mutations. the average of 4.15 suggests that they are considered to be very harmful.

In terms of radiation protection methods. various radiation protection methods have been implemented to reduce the risks associated with radiation exposure. These include the use of protective equipment (lead aprons. collars for thyroid protection). limiting exposure time. filtering the X-ray beam. and collimation. By applying these measures. significant reductions in the effective dose have been achieved (8. 16. 17). Our research supports these conclusions. from applied questionnaires showing that lead barrier screens are the most known and appreciated (90.6%). and personal dosimetry has a moderate recognition (60.4%) (fig. 2). However. awareness of radiation protection methods has a weak correlation with trust in security measures. indicating that a better understanding of protection does not significantly influence confidence in security measures. Correlated with our results. a survey in Karachi revealed that although radiology workers had a basic understanding of radiation protection. their confidence in patient protection measures was insufficient (23).

Other research. however. has shown a significant correlation between understanding radiation and protective practices. but this has not extended to trust in safety measures (“An empirical analysis of the relationship between understanding. attitudes. and practices toward radiation – Focusing on the population eligible for South Korean National Health Insurance Service Examination”) (24).

Regarding the optimal exposure range**.** the ALARA principle ("As Low as Reasonably Achievable") remains an essential benchmark. which aims to minimize radiation exposure by justifying each exposure. This approach focuses on minimizing the radiation dose received. both for patients and occupationally exposed staff (13). From our results. the optimal interval between exposures varies significantly. with most respondents indicating short intervals (for 1 hour). and a considerable proportion giving varied answers. Overall. the implementation of these optimization strategies is essential to protect healthcare professionals while ensuring high-quality imaging (25).

The study also looked at trust in workplace safety measures. This is relatively high. but variable. The very strong correlation between the regular updating of security measures and the level of trust suggests the importance of keeping the measures up to date in order to ensure a high level of confidence in these measures. Especially in interventional radiology and other specialties that use radiological techniques. safety measures are essential. These include wearing protective equipment and using lead screens. Studies have shown that new protective equipment can significantly reduce the dose of radiation. but there are still unprotected areas. such as the arms. that require additional solutions to minimize exposure (6. 17).

The main limitation in the present study was represented by access to medical professionals and the presence of non-probability sampling.

CONCLUSIONS

The analysis shows that the level of education of medical professionals significantly influences the knowledge about the effects of ionizing radiation. Most respondents have a good understanding of these effects. although there is a need for continuous training. An inverse correlation was observed between the level of education and fear of radiation. with those with advanced education being less fearful. The fear of radiation is directly proportional to the perceived severity of these conditions. The variability of perceptions of the optimal exposure range suggests the need for clearer guidelines.

Confidence in radiation safety measures is high. but constant updates and consultations with experts are essential to maintain it. A well-protected and educated work environment reduces perceived radiation-related risks.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

TOXOPLASMOSIS IN NORTHEAST ROMANIA. DESCRIPTIVE STUDY COUNTING CASES BETWEEN 2010 AND 2016 (Abstract): Infection with the parasite protozoa *Toxoplasma gondii* has a worldwide distribution. The mandatory intracellular parasite can infect humans, practically all warm-blooded animals, including mammals and birds. The study aim was to highlight descriptive epidemiology data on toxoplasmosis in patients admitted to a regional infectious disease hospital in North East Romania. **Material and methods**. We conducted a descriptive longitudinal study on a group of 160 patients admitted to the Iasi Clinical Hospital of Infectious Diseases with the diagnosis of toxoplasmosis, during 2010 and 2016. **Results**. Annual distribution of patients with toxoplasmosis had a maximum of frequency in 2010 (34 cases – 21.25%) and a minimum in 2016 (6 cases – 3.75%), with an increasing trend for the whole interval of study. Most of the patients were females (111 cases – 69.37%; M/F ratio = 0.44), from urban area (59.0%; U/R ratio = 1.43). The most affected age group was that of 15-24 years (38 cases – 23.75%), followed by 25-34 years (36 cases – 22.50%). Children aged between 1-4 years were less affected (3 cases – 1.87%). Either infants aged 0-1 year, or elderly persons over 74 did not admitted with toxoplasmosis. **Conclusions**. The frequency and severity of the disease are used to assess its medical relevance, and data on this can be collected in specific studies or surveillance systems. Targets for the future could be the implementation of a surveillance system of toxoplasmosis of any kind (acquired or congenital), a vaccine and, over time, a zero-incidence level of the disease.
Keywords: TOXOPLASMOSIS, EPIDEMIOLOGY, WATERBORNE DISEASE, MARINE, WILD FELID.

The world, whatever it is, the land, the navy or the wings, is full of toxoplasmosis. Infection with the parasite protozoa *Toxoplasma gondii* has a worldwide distribution. The mandatory intracellular parasite can infect humans, practically all warm-blooded animals, including mammals and birds. The first description was made by Nicolle and Manceaux in 1908 in rodent populations in North Africa, but its entire lifecycle was only definitively understood in the late 1960's, with the discovery of the cat's central role as

the definitive host for the sexually parasitic cycle and the spread of oocysts through faeces. His medical significance remained unknown until 1939, when *T. gondii* was identified in the tissues of a congenital infected child, and the veterinary importance became known in 1957 when it was found to have caused abortion in sheep. The discovery of the Sabin-Feldman test in 1948 led to the recognition that *T. gondii* is a common parasite of the warm-blooded host with a worldwide distribution. The real significance of the clinical implications of toxoplasmosis in humans was unknown until the first reports of cases of congenital toxoplasmosis, subsequently the role of *T. gondii* infection in immunocompromised patients was recognized in the mid-1970's and the concept of reactivation of the infection was subsequently investigated. In the last decade, the development of new genotyping tools has led to discoveries in understanding the global evolution of *T. gondii* phylogenetics and the recent advances in studies related to the degree of virulence of the protozoan associated with some genotypes (1, 2, 3, 4, 5).

Approximately 25-30% of the world's human population is infected with *Toxoplasma*. In fact, prevalence varies greatly between countries (from 10 to 80%) and often in a particular country or between different communities in the same region. The decrease in seroprevalence (10-30%) was observed in North America, Southeast Asia, North Europe, and the Sahel region of Africa. Moderate prevalence (30-50%) was found in Central and South European countries, and in Latin America and African tropical countries there were high prevalence rates (1, 2).

Screening of the large diversity of *Toxoplasma* host species has no specific test. The sensitivity and specificity of the techniques depend on animal species and the cutoff values are difficult to establish because the reference sera in experimentally infected animals are missing. Even when these sera are available for a species, they do not reflect natural conditions because experimental animals are often infected with high doses and sometimes by unnatural pathways that can cause excessive antibody titers. The modified agglutination test (MAT) seems to be most appropriate for a large number of species, but specific tests for enzyme immunoabsorption (ELISA) have been developed for certain species of domestic animals (1, 2, 3).

The incidence of toxoplasmosis in the general population in Romania and the incidence of congenital malformations were decreased according to the data reported to the Center for Calculation and Sanitary Statistics during 2000 and 2011. The mean incidence was 1.45‰ with the highest value (1.97‰) in 2003 and the lowest (1.15‰) in 2000. The highest average incidence was in the environment urban (1.96‰) and the age group under 1 year (2.24‰) (7).

In Romania, toxoplasmosis is a disease with mandatory reporting. Cases of *T. gondii* have been reported since 2007 as a "single case report of the communicable disease case" within 5 days of the detection of the suspect or confirmed case (8).

The study aim was to highlight descriptive epidemiology data on toxoplasmosis in patients admitted to a regional infectious disease hospital in North-East Romania.

MATERIAL AND METODS

We conducted a descriptive longitudinal study on a group of 160 patients admitted to the Iasi Clinical Hospital of Infectious Diseases with the diagnosis of toxoplasmosis, during 2010 and 2016. The data were collected from patient records and reported

files, respecting the confidentiality of the information. Inclusion criteria were limited to diagnosis of toxoplasmosis, and exclusion criteria did not refer to gender, residence area, or any age group. Secondary diagnoses and co-morbidities did not take into consideration, also.

The data was processed with the MS Excel 2010 software.

RESULTS

Annual distribution of patients with toxoplasmosis had a maximum of frequency in 2010 (34 cases – 21.25%) and a minimum in 2016 (6 cases – 3.75%), with an increasing trend for the whole interval of study (fig. 1).

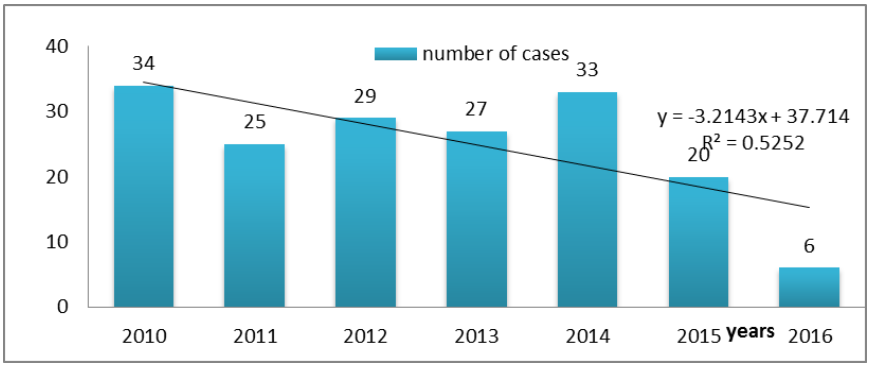

Fig. 1. Distribution of cases with toxoplasmosis by year of study

Most of the patients were females (111 cases - 69.37%; M/F ratio = 0.44), from urban area (59,0% ; U/R ratio = 1.43). The most affected age group was that of 15-24 years (38 cases – 23.75%), followed by 25-34 years (36 cases – 22.50%). Children aged between 1-4 years were less affected (3 cases – 1.87%). Either infants aged 0-1 year, or elderly persons over 74 did not admitted with toxoplasmosis (fig. 2).

	<1	1-4	5-14	15-24	25-34	35-44	45-54	55-64	65-74	>74
age histogram	0	3	9	38	36	32	21	14	7	0

Fig. 2. Age histogram of patients with toxoplasmosis

Most of patients had a diagnosis of toxoplasmosis without any specification of site or organ involvement (149 cases – 93.12%, M/F = 0.43). There are several cases suffered from toxoplasmosis with ocular involvement (2 cases, both males – 1.25%), as well as other organs (9 cases – M/F = 2/7) (fig. 3).

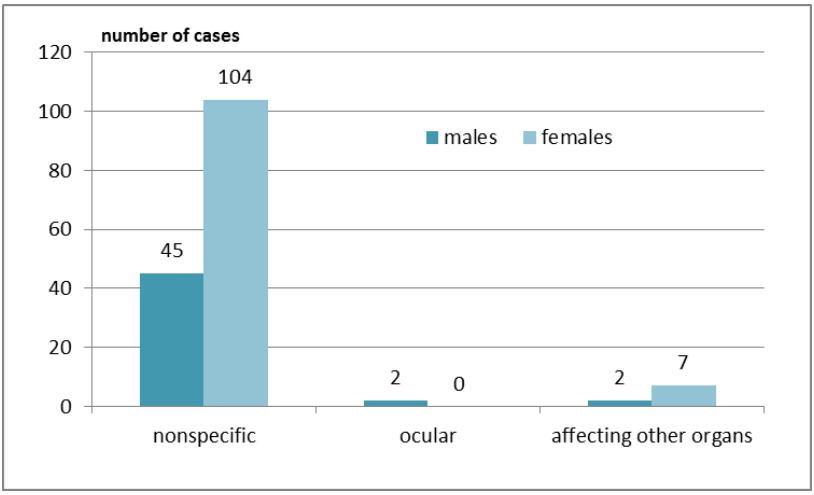

Fig. 3. Toxoplasmosis cases related to gender and specific sites

Distribution by month of admission showed a cluster of cases diagnosed during April - May and another one during September, with a maximum in May (21 cases – 13.12%) and a minimum in December (5 cases – 3.12%) (fig. 4).

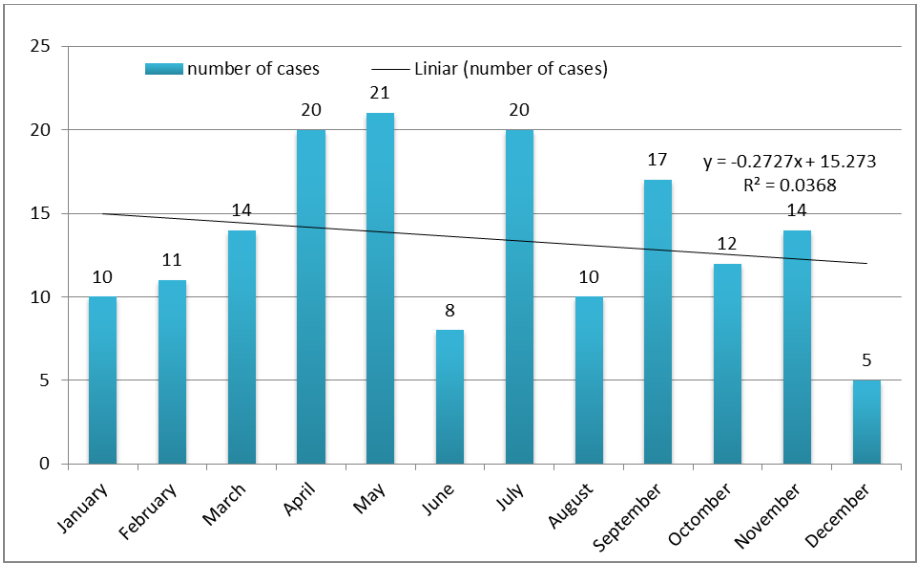

Fig. 4. Distribution of cases by month of admission

Seasonal distribution highlighted a predominance of cases admission during Spring (55 cases – 34.37%), then in Autumn (43 cases – 26.87%), Summer (38 cases – 23.75%), and Winter (26 cases – 15.01%) (fig. 5).

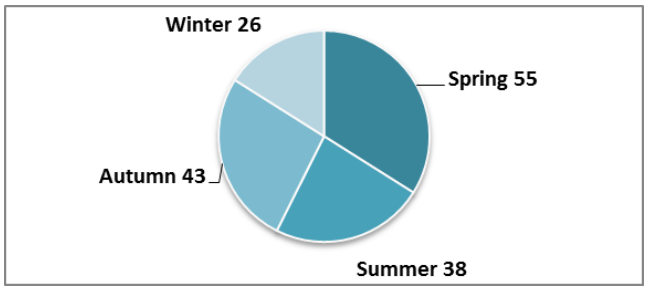

Fig. 5. Seasonal distribution of cases

As compared with hospitalization days due to all diagnoses were of 540,721 for all 72064 cases admitted with infectious diseases, during 2010 and 2016, hospitalization days for 160 patients with toxoplasmosis were 939, from which nonspecific – 895 days, ocular – 8 days, and toxoplasmosis affecting other sites – 36 days (tab. I)..

TABLE I.
Average length of stay

Diagnosis	Number of cases	Hospitalization days
All	72064	540721
Toxoplasmosis - nonspecific	149	895
Toxoplasmosis - ocular	2	8
Toxoplasmosis - other organs	9	36

DISCUSSION

Toxoplasmosis has been identified in mammals and birds which more than 350 host species, mammals and birds, most of them in the wild.

Peridomestic felid species habiting near farms or wild species can contaminate the environment by eliminating oocysts. Intermediate wildlife will subsequently become contaminated when the felids are present in the environment. Of the 39 feline species in the world, serological and parasitologic studies have shown that 31 species have *T. gondii* infection. In wild felids, the seroprevalence is high and can reach 100%. The processes leading to the infestation of wildlife populations are complex, involving physical, biological, ecological, and zoological factors and characteristics. The dry and warm climate is considered to be unfavorable to the survival of the oocysts. Countries with such climate report lower values of the prevalence of toxoplasmosis in wild animals, but countries in wet tropical regions report increased levels of toxoplasmosis prevalence. The susceptibility of the host species to *T. gondii* infection is a condition for the occurrence of diseases. Studies have shown that some species are resistant or heal spontaneously. Other studies have highlighted that the lifespan of animal species (dependent on their size and weight) influences the risk of infestation and explains the low incidence rates (1-5%) of toxoplasmosis in small rodents (9, 10).

Food behavior is another risk factor, the prevalence of infection being often lower

in ruminants than in omnivores and carnivores, due to the cumulative efficacy of the predator cycle of the parasite. Among the wild mammals in the Amazon forest (French Guyana), terrestrial mammals were significantly more exposed to *T. gondii* than arboreal mammals, due to ground-based behavior in carnivores. In the northern hemisphere, a high prevalence was found in carnivores (black bears and red foxes) or in omnivorous species such as wild boars that are exposed to infections by ingestion of both oocysts and tissue cysts. An ecological approach to studying the parasite movement in wildlife includes factors such as bird migration, fragmentation of the landscape (through rivers, roads, cultivated areas, localities, etc.), oocyst dispersion, or predatory behavior of different species of felids in various wild environments. Marine mammals such as sea otters, dolphins, seals and mollusks have recently been studied, with prevalence ranging between 47 and 100%. These marine mammals serve as sentinels for environmental contamination by oocytes through the drainage of freshwater into the marine ecosystem (1, 12, 13).

There are many risk factors which can influence the seroprevalence values of toxoplasmosis in humans. Higher prevalence values were observed for tropical countries with wet and warm climates and the lowest in countries with arid or cooler climate. Anthropogenic factors explain much of the variation in human seroprevalence, including eating habits, hand washing, eating meat and cooking, cleaning vegetables, etc. Other economic, social or cultural factors, water quality and sanitation are worthy of consideration. Seroprevalence increases with age, but age-related infection rates vary by country and socio-economic level. The assessment of maximum seroprevalence can be achieved in childhood in populations living in poor hygienic conditions, probably related to contamination of water, food, or by the ingestion of oocysts (1, 14).

Contaminated water is an important way of transmitting infection to humans in areas where non-filtered surface water is used for consumption and probably also in areas where fresh water is in contact, for example for recreation. For example, in a city located in the northern state of Rio de Janeiro (Brazil), adjusted age-adjusted seroprevalence was 84% for the lower socio-economic group compared to 62% for seroprevalence and 23% for higher socio-economic groups. Most people (up to 84%) of the lower socio-economic population were infected by the age of 15, while the infection was mainly obtained after the age of 20 in the higher socio-economic population (from about 20% for 20-29 age groups to 70% for the 40-49 age groups). In a multivariate analysis of the risk factors, this was attributed to water supply differences, with the poorest populations living in areas with unfiltered water. These different models of *Toxoplasma* infection depending on socio-economic levels may be more relevant in under-developed tropical countries, but in the United States, toxoplasmosis has also been considered a poverty-related infection. Increased socio-economic levels, along with improved hygiene conditions, changes in farm systems, frozen meat consumption, and sterilized food cats have led to a steady decline in seroprevalence in most industrialized countries over the last decades. In the United States, a national study found a decrease in age-adjusted *T. gondii* prevalence in 12-49 age groups, from 14.1% in 1988 - 1994 to

9% in 1999 – 2004. In France, seroprevalence in pregnant women was approximately 80% in the early 1960's, around 66% in the 1980's, 54% in 1995 and 44% in 2003, while the average age of pregnant women increased. This decrease in seroprevalence was observed in all areas where it was studied in Europe. For example, in the Netherlands, seroprevalence decreased from 35.2% in 1995 - 1996 to 18.5% in 2006 - 2007 in women at reproductive age (1, 2, 5, 15, 16, 17).

CONCLUSIONS

Our study highlighted that it is important to correctly report cases of toxoplasmosis in the general population, as well as to pregnant women, fetuses, neonates and children as this contributes to the motivation of the different screening programs currently performed worldwide. The frequency and severity of the disease are used to assess its medical relevance, and data on this can be collected in specific studies or surveillance systems. Targets for the future could be the implementation of a surveillance system of toxoplasmosis of any kind (acquired or congenital), a vaccine and, over time, a zero-incidence level of the disease.

NEWS

TREATMENT OF ERYTHEMATO-TELANGIECTATIC ROSACEA WITH BRIMONIDINE

In a study by Micali et al, the outcome of a group of patients with erythematotelangiectatic rosacea treated with brimonidine alone or combined with a vascular laser was evaluated. The patients were affected by persistent erythema and varying degrees of telangiectasias. The patients were evaluated using erythema-directed digital photography by VISIA-CR™ system and X10 dermoscopy. A single application of brimonidine 0.33% gel was used for patients showing marked background erythema and minimal telangiectasias. A session of Nd: YAG laser was used for patients in the second group showing marked erythema and telangiectasias, followed by a reevaluation 1 month later after a single application of brimonidine. At the end of the therapy, an Investigator Global Assessment of outcome was done. A marked reduction of the background erythema was observed in all patients 6 h following the application of brimonidine. In the second group, there was a marked reduction of the erythema in all cases 6 h after brimonidine application, but not of telangiectasias. Complete clearing of facial erythema was observed following the treatment with brimonidine 1 month after the Nd: YAG laser session. The results of the study showed that the preliminary evaluation of the vascular component by erythema-directed digital photography and dermoscopy is helpful for selection of the appropriate treatment in erythematotelangiectatic rosacea (Micali G, Dall'Oglio F, Verzì AE, Luppino I, Bhatt K, Lacarrubba F. Treatment of erythematotelangiectatic rosacea with brimonidine alone or combined with vascular laser based on preliminary instrumental evaluation of the vascular component. *Lasers Med Sci* 2017 Sep 9. doi: 10.1007/s10103-017-2318-3).

MULTIDRUG RESISTANT URINARY TRACT INFECTION - IS *KLEBSIELLA SPP*. THE FIRST ENEMY TO FIGHT WITH? (Abstract): *Klebsiella spp* is the second causative bacteria of urinary tract infection. **Aim:** To identify the profile of urological patients with *Klebsiella spp.* urinary tract infection. **Material and methods:** Review of the medical records of all patients with multidrug resistant urinary tract infection (MDR-UTI) admitted to the Iasi Urology Clinic between 2013 and 2016. **Results:** A total number of 753 patients with *Klebsiella spp.*-positive urine culture aged 18 to 95 years, mean age of 66.3 years were included in the study. The elderly was the age group most affected by *Klebsiella spp.* UTI. One quarter (25.89%) of patients had a neoplasm history and one third (31.07%) poor hygiene conditions. Almost one quarter of patients (24.70%), had a history of antibiotic use in the last three months and 520 patients had different urinary stents, most frequently bladder catheter (n=385). *Klebsiella spp.* strains resistance to penicillin was 40-99%, to cephalosporins 38-88%, fluoroquinolones 85-94%, gentamicin 80%, carbapenemes 21-33%, colistin 66%, Fosfomycin 21%, TMP-SMX 90% and to Piperacilin 75%. **Conclusions:** MDR-UTI due to *Klebsiella spp.* remains a challenge for clinicians both in terms of treatment and prevention. **Keywords**: KLEBSIELLA, ANTIBIOTIC RESISTANCE, UTI.

Urinary tract infections (UTIs) are one of the most common microbial diseases encountered in medical practice affecting people of all ages are. Worldwide, the prevalence of UTIs was estimated to be around 150 million persons per year (1). It is well known that UTI is the single most common hospital-acquired infection. While traditionally the most commonly encountered bacteria in UTI is *E. coli, Klebsiella spp*. is well-known as a causative agent of both community and hospital acquired pneumonia, bacteremia, and UTIs. In large epidemiological studies *Klebsiella spp* is the second most common causative bacteria of UTI (1, 2). Besides its high incidence we need to better understand this pathogen because of the increase in the number of vulnerable patients and in antibiotic resistance. The aim of our study was to identify the profile of urological patients with *Klebsiella spp.* UTI.

MATERIAL AND METHODS

In this prospective study, the medical records of all patients with multidrug re-

sistant urinary tract infection (MDR-UTI) admitted and treated to the Iasi Urology Clinic between January 1st, 2013 and January 1st, 2016 were reviewed. We considered MDR-UTI those urine cultures with bacteria resistant to more than 3 antibiotics of different classes or all antibiotics of a single class, regardless of the urological and other comorbidities (3). Data on age, sex, prior antibiotic treatment in the last three months, the presence of a urinary catheter, history of recurrent cystitis, menopause, habitual constipation and diabetes mellitus were collected. We have also evaluated the possibility of proper hygiene through the availability of running water and indoor toilet facilities at home.

Statistical analysis was made using Student t-Test for 2 Independent Means and Chi-Square test, calculated online on http://www.socscistatistics.com/tests/Default.aspx , statistical significance was defined as p value ≤ 0.05.

RESULTS

Between 2012-2016, 1742 patients, 1171 (67.22%) men and 571 (32.77%) women aged 18-95 years, mean age 65.05 years (SD=14.69) were diagnosed in our clinic with UTI. Although we expected that *E. coli*, to be most frequently identified bacteria, *Klebsiella spp.* - 43.22% (n=753) was the most commonly isolated bacteria, followed by *E. coli* - 20.78%, *Pseudomonas* - 14.17%, and other bacteria – 21.83%. A total number of 753 patients with *Klebsiella spp.*-positive urine cultures were included in the study, 506 (67.19%) males and 247 (32.80%) females. The age of patients with *Klebsiella spp.* UTI ranged from 18 to 95 years, with a mean age of 66.3 years. The mean age of female patients with UTI was 59.76 years, significantly lower than that of the male patients, 68.59 years (p=0.0001, t= 7.64973). The age-group distribution is shown in the Table I.

TABLE I
Age-group distribution of UTI patients

Age	18-30	31-40	41-50	51-60	61-70	>71
n= 753	18	19	46	108	195	367
%	2.3	2.5	6.1	14.3	25.8	48.7

The elderly was the age group most affected by *Klebsiella spp*. UTI with a frequency of 74.62%. A total of 195 (25.89%) patients had a history of cancer. Bladder cancer (43.07%, n=84) was the most common, followed by prostate cancer (21.02%, n=41) and cervical cancer (19.48%, n=38). The other cancers are shown in the chart below (fig.1).

Almost one quarter of patients (24.70%, n=186) had a history of antibiotic use within the last three months. The most frequently used antibiotic was ciprofloxacin (20.43%, n=38), followed by ceftriaxone (17.74%, n=33). Other antibiotics used were amoxicillin + clavulanic acid (8.06%, n=15), Tazocin (8.60%, n=16), cefixime (6.98%, n=13), Cefoperazone + Sulbactam (6.45%, n=12), gentamicin (4.30%, n=8), carbapenems (5.37%, n=10), ceftazidime (3.76%, n=7), colistin (1.61%, n=3), TMP-SMX (2.68%, n=5) and 26 (13.97%) patients could not specify.

Other identified predisposing factors were recurrent cystitis (18.06%, n=136), menopause (15.40%, n=116), habitual constipation (9.42%, n=71) and diabetes melli-

tus (8.36%, n=63). We were surprised to find that almost one third of patients (31.07% (n=234) had no access to running water and 28.41% (n=214) did not have indoor toilets at home.

The presence of a urinary stent was identified in 520 patients. The most frequently encountered was the bladder catheter (74.03%, n=385). Elderly patients have a significantly higher rate of a catheter dwelling (p=0.00001, χ^2=32.1311), as shown in Table II.

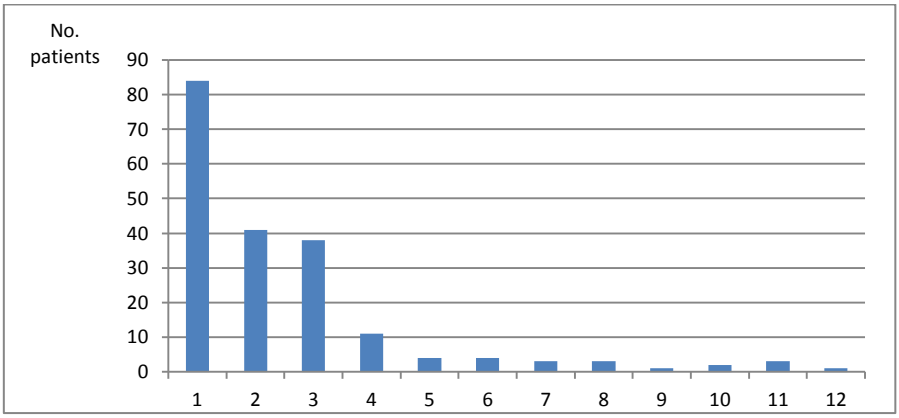

Fig. 1 Cancers in the history of the study patients.

Vancomycin	19/20	95
Teicoplanin	25/71	35.21

DISCUSSION

Usually, *Klebsiella spp.* is a bacterium in humans and other mammals, colonizing the gastrointestinal tract, skin, and nasopharynx. According to Tzouvelekis et al. (4), in the early 1970s both the epidemiology and spectrum of infections caused by *Klebsiella spp.* changed dramatically when this bacterium was established in the hospital environment and became a (still) leading cause of nosocomial infections. Although it produces only moderate amounts of chromosomal penicillinases, *Klebsiella spp*. is known as a notorious "collector" of MDR plasmids. In the first decade of the new millennium, a global crisis of unprecedented dimensions was noticed due to the rapid dissemination of MDR *Klebsiella spp*. strains producing "carbapenems" encoded by transmissible plasmids.

Ramanathan et al. (5) noticed that UTIs account for up to 40% of all healthcare-acquired infections and nearly 80% of all UTI occur in patients with short-term urinary catheters and are considered as catheter-associated UTI (CAUTI). In surgical patients, rates of UTI range from 1.8% to 4.1% based on surgery type, and development of UTI is correlated with increased duration of hospital stay and mortality.

Traditionally it is considered that women are significantly more likely to experience UTI than men. One third of women will have had at least 1 episode of UTI requiring antimicrobial therapy by the age of 24 years. Almost half of all women will experience one UTI during their lifetime (6). In our study, the men/female ratio was 2:1. This situation can be explained by the fact that our patients did not have community-acquired UTIs, being hospitalized for various urological diseases. This sex ratio is like that reported by Milan et al. (7) in a group of 589 patients, of which only 72 were diagnosed with infection on admission and were classified as CAUTI.

Although in our study patient age ranged from 18 to 95 years, we had significantly more old males (54.58%). This finding is not unusual because the incidence of UTI in men without indwelling catheters increases substantially after 60 years of age. According to Schaeffer (9), the incidence of all UTIs among older men is approximately half that among older women, but infection rates among men in the community who are older than 80 years of age approach those among women in the same age range. Older men often have structural and functional abnormalities of the urinary tract such as benign prostatic hyperplasia, which can cause UTI owing to obstruction and impaired urine flow. Moreover, these patients can have comorbidities associated with an increased susceptibility to infection, such as diabetes mellitus. However, in

our study group only 8.36% of the total number of patients had diabetes mellitus.

In our study, a quarter (25.89%) of patients had a cancer history. Most of them (83.58%, n=163) had a pelvic cancer. According to Rolston (9), the factors that increase the risk of infection in neoplastic patients include neutropenia, disruption of anatomic barriers, obstruction due to primary or metastatic tumor, diagnostic/therapeutic surgery, prosthetic devices or advanced age. Obstructive uropathy and complicated UTIs go hand in hand and are often recurrent and difficult to eradicate. In patients with retroperitoneal or pelvic cancers acute or chronic ureteral obstruction is a complication of the malignancy. Prompt decompression of the obstruction is required. For this procedure ureteral stents or, more frequently, percutaneous nephrostomy tubes are used. According to Bahu et al. (10) the use of stents and nephrostomy tubes is associated with a significant rate of pyelonephritis and eradication of such infections is difficult to accomplish.

Urinary catheter, especially bladder catheters are only used in neoplastic patients. Older men, as most patients in our study group, often need bladder catheters for urinary retention due to benign prostatic hyperplasia. In our study, of the 385 patients with bladder catheter indwelling, 88.57% were over 60 years of age. According to Ramanathan (5) the presence and duration of catheterization are the strongest risk factors for bacteriuria development. Approximately 10% to 25% patients with bacteriuria progress to symptomatic UTI and 1% to 4% develop urosepsis. In patients with indwelling urinary catheters or in patients with a recent history of indwelling urinary catheterization, the catheter serves as the most common route of access for microorganisms into the bladder. Bladder catheters facilitate bacteriuria by two ways: either through direct inoculation of the bladder during catheter insertion or through biofilm ascension along the catheter.

MDR-UTI has a very vague definition. According to Magiorakos et al (11) a bacterial isolate was considered non-susceptible to an antimicrobial agent when it tested resistant, intermediate or non-susceptible when using clinical breakpoints as interpretive criteria, and not epidemiological cut-offs provided by the European Committee on Antimicrobial Susceptibility Testing (EUCAST), the Clinical and Laboratory Standards Institute (CLSI). In literal terms, MDR means ‘resistant to more than one antimicrobial agent', but no standardized definitions for MDR have been agreed upon yet by the medical community. Many definitions are being used to characterize patterns of multidrug resistance in Gram-positive and Gram-negative organisms. For these germs, the definition most frequently used is ‘resistant to three or more antimicrobial classes'. Another method used to characterize bacteria as MDR, is when they are ‘resistant to one key antimicrobial agent’, carbapenems for *Klebsiella spp.*

Prior antibiotic use can be associated with a high prevalence of resistance in patients with UTI. After analyzing more than 5,000 urine culture, Bidell et al (2) noticed that more than two prior antibiotic exposures were associated with slightly higher incidences of fluoroquinolone non-susceptibility, multidrug resistance, and extended-spectrum β-lactamase phenotype compared with no or one exposure. The authors suggest an increased risk for resistant Gram-negative pathogens among hospital patients with UTI occurring ≥3 days after admission. Micek et al (12) re-

vealed that exposure to antimicrobial agents in the previous 90 days is associated with significantly higher hospital mortality, longer hospital stays and higher hospital costs. The authors concluded that clinicians and hospital administrators should consider the potential impact of recent antibiotic exposure when formulating empiric treatment decisions for patients with severe infections attributed to Gram-negative bacteria. In our study, almost one quarter of patients (24.70%) had a history of antibiotic use within the last three months. Fluoroquinolones, especially ciprofloxacin were the antibiotics most frequently used prior to admission. This has leaded to a high incidence of fluoroquinolone nonsusceptibility in patients with *Klebsiella spp* UTI, ranging from 94.11% (levofloxacin) to almost 86% (ciprofloxacin and norfloxacin).

The European Association of Urology (13) recommends routine daily personal hygiene to maintain meatal hygiene, meaning soap and water is sufficient to achieve this goal. Special attention must be given to educating non-circumcised patients to clean underneath their foreskin daily to remove smegma, as this may increase their risk of developing a UTI. Surprisingly, almost one third of patients had no access to running water and had no indoor toilets. This situation makes them have a poor hand and genitalia hygiene. It becomes difficult for many of our patient which have urinary catheter, to follow Septimus et al. (14) recommendations for a good hand hygiene before and after catheter insertion or bag manipulation to prevent device-related healthcare-associated infections.

The rise in antibiotic resistance of *Klebsiella spp.* represents a growing threat to patients worldwide, especially when we should treat infections with carbapenem-resistant *Klebsiella spp.* (CRKP). The treatment of these infections is problematic, as few therapeutic options are available. In a review by Tansarli et al. (15) the antimicrobial susceptibility of *Klebsiella spp* isolates in CAUTI varied at the following rates: amoxicillin-clavulanic acid, 0 to 69%; cefotaxime, 43 to 100%; ceftazidime, 40 to 100%; imipenem, 100%; ciprofloxacin, 53 to 100%; nalidixic acid, 51 to 94%; gentamicin, 60 to 100%; amikacin, 100%; trimethoprim-sulfamethoxazole, 0 to 56%; nitrofurantoin, 40 to 78%; tetracycline, 43 to 69%; and fosfomycin, 100%(15). In one of the few *Klebsiella spp.* UTI in hospitalized patients by Ben Haj et. al. 16) the susceptibility of all *Klebsiella spp.* isolates to the tested antibiotics was the following: amoxicillin-clavulanic acid, 60%; cefotaxime, 66%; nalidixic acid, 48%; ofloxacin, 73%; ciprofloxacin, 74%; gentamicin, 69%; tobramycin, 70%; amikacin, 97%; trimethoprim-sulfamethoxazole, 57%; nitrofurantoin, 68%; and fosfomycin, 77%. In our patients *Klebsiella spp.* had a high rate of resistance to ampicillin +/- clavulanic acid (>90%), cephalosporins (88-98%) excepting cefixime (35%) or vancomycin (95%). We also encountered high rates of resistance to trimethoprim-sulfamethoxazole (90%) and fluoroquinolones (85-94%), often used as first line of treatment for uncomplicated UTI and gentamicin (80%). For these antibiotics, our results are very like those obtained by El Bouamria et al. (17) in a three-year study of 321 *Klebsiella spp.* positive urine cultures.

The trend of *Klebsiella spp.* incidence in our geographical area seems to be constant. In a report by Pricop et al. (18) between January 2013 and July 2014 the incidence of *Klebsiella spp.* UTI was of 46.15%. It had the same spectrum of re-

sistance throughout the study period: resistant to ampicillin, amoxicillin + clavulanic acid, cephalosporins (cefuroxime, cefotaxime, ceftazidime, cefepime), gentamicin, fluoroquinolones (norfloxacin, ciprofloxacin). *Klebsiella spp* MDR-UTI was associated with the insertion and replacement of "JJ" stents (33.33%), endourological interventions (transurethral resection of prostate - TUR-P 14.10%, transurethral resection of a bladder tumor - TUR-BT 23.08%), diabetes mellitus (19.23%), bladder tumors (17.95%) or prostatic neoplasm (14.10%), status of urethrovesical catheter carrier (46.15%) and with the insertion of probes for percutaneous nephrostomy (15.38%)(18).

The inappropriate antibiotic use in Romania is a major problem. Medicine consumption in Romania, especially antibiotics, is one of the highest across the European Union. In a survey conducted by the European Commission in 2015 Romanians consumes 70% more antibiotics than the average Europeans (19,20). Every day 3.3% of Romania's population takes antibiotics. Moreover, 70% of Romanians believe antibiotics kill viruses, as compared to 49% of the Europeans in a similar case; also, 55% of Romanians believe antibiotics are efficient in flu and cold, as compared to 41% of Europeans. A similar problem is encountered in Romanians hospitals. Tarcea et al. (21) evaluated the use of restricted antibiotics in an academic hospital in Romania. The authors found that the most commonly prescribed antibiotics were vancomycin, imipenem and meropenem, but they were used inappropriately in 49.71, 46.55 and 44.06 % of the cases.

CONCLUSIONS

Our study revealed that in our geographical area the hospitalized patient with *Klebsiella spp.* MDR-UTI is often an elderly man with a history of pelvic cancer or urinary retention due to BPH which required the use of a urinary stent, frequently a bladder catheter, sometimes with poor hygiene condition for which the usually used antibiotics are not effective. Our study stresses the need for frequent re-evaluation of the prevalence of pathogens and antibiotic resistance and the adjustment of the empirical first-line treatment.

HEPATOCELLULAR CARCINOMA WITH CENTRAL SEVERE ARTERIOPORTAL SHUNT-ENDOVASCULAR APPROACH (Abstract): The prognosis of hepatocellular carcinoma is related to the extension of the lesion, as well as to the liver function at the time of diagnosis and associated arterioportal shunts. **Case report**: We report a 70-year-old woman with C virus - related cirrhosis, hepatocellular carcinoma and central severe arterioportal shunt, presenting with upper digestive tract hemorrhage and refractory ascites, treated by embolization of the shunt and trans catheter arterial embolization of the tumor. **Results:** After treatment, both ascites and esophageal varices improved, with good general status for three months. Afterwards, a massive esophageal bleeding uncontrolled by emergent endoscopic hemostatic techniques caused rapid deterioration and death. **Conclusions:** Hepatocellular carcinoma with central severe arterioportal shunt is a challenging clinical situation, whose prognosis is influenced mainly by portal hypertension. Embolization of the shunt is the first option to reduce the pressure in the portal system and to ensure the endovascular treatment of the tumor. **Keywords:** HEPATOCELLULAR CARCINOMA, ARTERIOPORTAL SHUNT, EMBOLIZATION

Liver cancer is the ninth most common cancer in women, the second most common cause of death from cancer worldwide, and accounts for 7% of all cancers (1). Hepatocellular carcinoma (HCC) represents more than 90% of primary liver cancers and its prognosis is related to the extension of the lesion, as well as to the liver function at the time of diagnosis (1). Furthermore, HCC frequently involves portal vein (PV) and creates arterioportal shunts (APS), worsening portal hypertension (PHT) and increasing the risk of gastrointestinal bleeding and hepatic encephalopathy (2).

The present report describes a patient with HCC and central severe APS treated by embolization of the shunt followed by trans catheter arterial embolization of the tumor.

CASE REPORT

A 70-year-old woman, who has been diagnosed with C virus - related cirrhosis for 8

years, was referred to our hospital for rapid deterioration of liver function with refractory ascites and upper digestive tract bleeding. The patient's laboratory data at admission are presented in table I. Child's classification status was B (Child-Pugh score 8).

TABLE I

Laboratory data at the admission, after initial embolization and at 1 month follow-up

Laboratory data	Admission	2 days after TAE1	9 days after TAE 1	3 days after TAE. 2
Total bilirubin level mg/dL (N: 0.2-1.2)	1.50	1.08	1.02	0.96
AST IU/L (N: 5-31)	73	43	35	27
ALT IU/L (N: 5-32)	112	72	52	46
GGTP IU/L (N: 8～59)		119	203	
WBC count /μL,	4010	5910		
RBC count × $10^{4/}$ μL	362	346	377	325
HGB level g/dL	11.3	10.7	11.7	11
hematocrit %	33.1	31.3	33.4	33
platelet count × 0^3/μL	90	82	132	85

AST - aspartate aminotransferase level; ALT - alanine aminotransferase level; GGTP - γ-glutamyl trans peptidase; WBC - white blood cell; HGB - hemoglobin; RBC - red blood cell;

Upper gastrointestinal endoscopy revealed severe esophageal varices and emergent sclerotherapy was performed to control bleeding. Abdominal ultrasound (US) identified a hyper vascular lesion in the 4th segment of the liver, and hepatofugal high velocity flow in PV trunk and branches (up to 190 cm/s) with arterial waveform (fig.1). No thrombus was found in PV. Massive ascites was noticed in all peritoneal spaces. Computed tomography (CT) of the abdomen, with tri-phase acquisition after injection of contrast medium, identified a low-density lesion in the 4th segment only on non-enhanced and late scan. An APS located in *porta hepatis* with early and strong enhancement of enlarged PV trunk at early hepatic arterial phase was seen. An arterial variant was also disclosed, with replaced common hepatic artery (HA) originating from superior mesenteric artery (SMA).

The final diagnosis was HCC with central severe APS and refractory PHT. The patient was then referred to the interventional radiology unit. A common HA arteriography showed a major APS centrally located (between right HA and PV trunk with multiple feeders), but a tumor stain was not visible because of the shunt (fig. 2a). A super selective catheterization of the right HA was performed with microcatheter (3F, Renegade) followed by angiography. Due to the numerous feeders and enlarged right HA and PV, we decided to perform coils trans catheter arterial embolization (TAE) for the major APS. Three coils (Azur Pure, 4 mm in diameter, length 4 and 6 mm) were introduced into the right HA with partial occlusion of the APS (approximately 80%) (fig. 2b).

The follow-up Doppler US performed 1 week after revealed lower velocity in PV but with persistent APS. Clinical status slowly improved with diminishing rate of ascites recurrence.

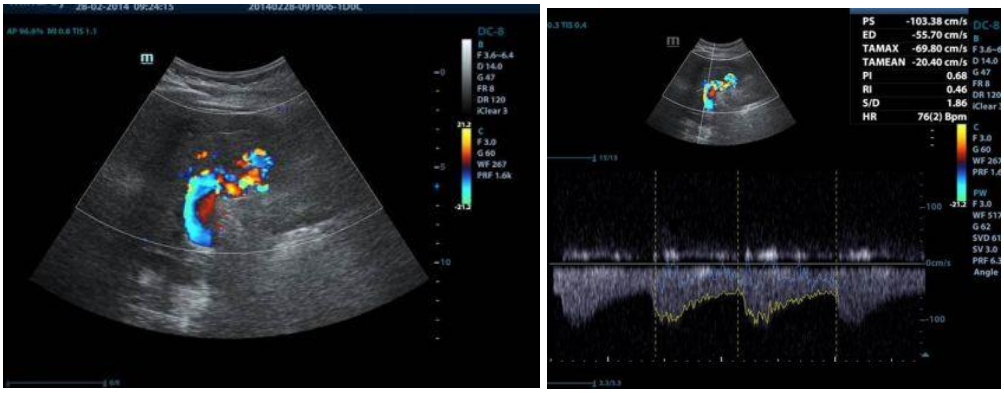

Fig. 1. Liver Doppler ultrasound: a) mixed arterial and venous flow in PV; b) hepatofugal PV flow with high velocity arterial waveform in the portal trunk and branches.

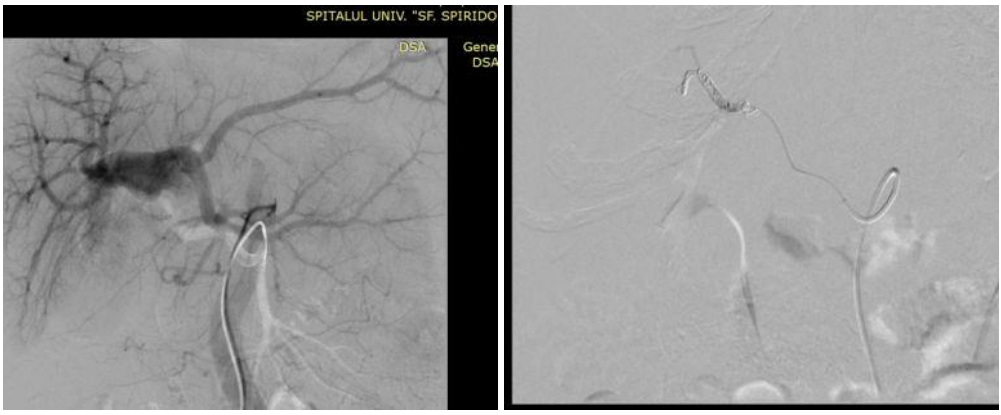

Fig. 2. a) Digital subtraction hepatic arteriography: major APS centrally located (between right HA and PV trunk with multiple feeders); b) TAE: coils into the right HA.

Consequently, we have performed a second TAE within 3 weeks, completing the embolization with Gelfoam and occluding the shunt (fig. 3). The left HA arteriography showed HCC feeders, which were super selective embolized with Embosphere microspheres 300-500 µm. The celiac trunk (splenic, left gastric and left phrenic arteries) was catheterized, but no tumor feeders were depicted.

After treatment, ascites and esophageal varices, as well as laboratory findings improved (tab. I). Doppler US revealed reduced sized PV (14 mm), without thrombosis (fig. 4). The patient was discharged one week after with a small amount of ascites.

Three months later the patient presented a massive esophageal varices bleeding. Emergent CT showed revascularization of the HCC, with arterial supply from left HA, right internal mammary and right gastroepiploic arteries, and an APS in the lower part of the lesion. The right HA was still embolized. Unfortunately, the massive esophageal bleeding was uncontrolled by emergent endoscopic hemostatic techniques, with rapid deterioration and death.

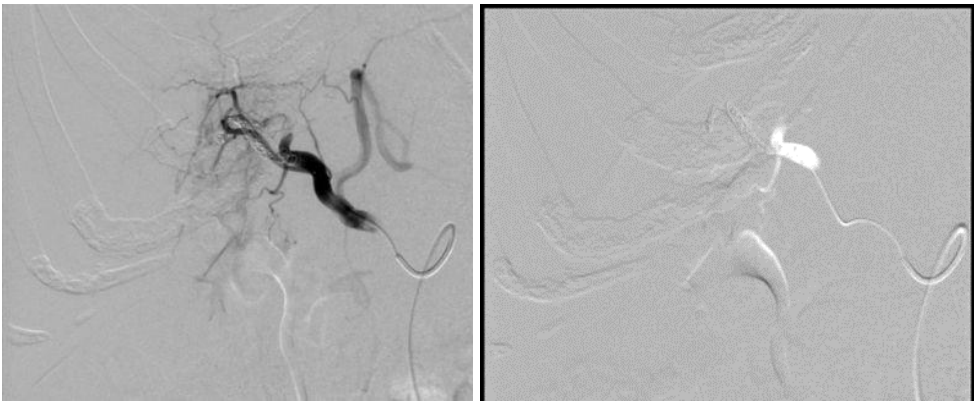

Fig. 3. a) Hepatic arteriography after 3 weeks: persistence of APS;
b) completion of the embolization with occlusion of the shunt.

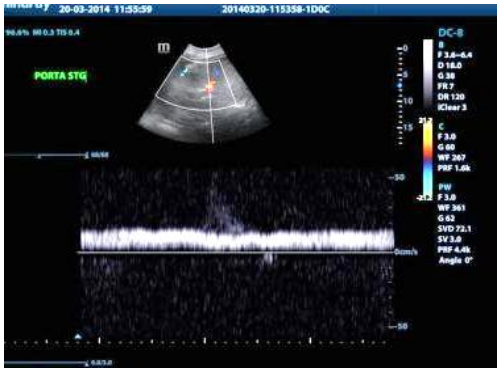

Fig. 4. Liver Doppler US - follow-up after embolization: reduced sized PV (14 mm), without thrombosis and normal hepatopetal flow in the left portal branch

DISCUSSION

Several clinical and imaging classifications of APS are available (3). A central APS is in *porta hepatis* and a severe APS consists in opacification of PV trunk and/or the first-order branches with enhancement at the early hepatic arterial phase, without or with early enhancement of HCC foci (3).

APS occurs in 60% of patients with HCC, marked APS of the main, right or left PV accounting for half of these patients (2, 4). Lesions associated with severe APS shows no enhancement at the arterial phase in dynamic CT due to reduced arterial flow to the tumor, as presented in our case (3).

TAE is the standard treatment for intermediate stage HCC, but there is no consensus about optimal treatment of HCC associated with central severe APS (1). EASL-EORTC Clinical Practice Guidelines have no reference related to the treatment of this complication of HCC, even if microscopic vascular invasion involves 20% of tumors of 2 cm in diameter and APS occurs in more than half of patients with HCC (1).

Moreover, HCC associated with central severe APS is a challenge for interventional radiologist since embolic material can pass through the shunt reducing the effectiveness of the treatment and producing damage of PV branches with higher risk of liver ischemia. Therefore, temporary or permanent occlusion of the supplying arteries of the APS is required before endovascular treatment of the lesion. For severe APS, the procedure is also mandatory to ameliorate PHT (5-11).

TAE of severe APS can be achieved by several embolic materials used alone or combined: gelatin sponge, ethanol, PVA

particles, N-butyl cyanoacrylate, coils (5-11). The choice of embolic agent is based on shunt size, velocity, location, angio-architecture and specific actions of each embolic agent. Coils are generally recommended only for simple APS owing to the difficulty to reach each feeder in complex shunts, but we choose them because of severity of the APS and multitude of feeders which render the selective embolization impossible.

The prognosis of HCC patients with severe APS is related to severe PHT and subsequently, to variceal bleeding, refractory ascites and portal encephalopathy (1). Surgical treatment is reported only for some severe resistant or recanalized APS with recurrent uncontrolled esophageal variceal hemorrhage (12). For centrally located APS the procedure of choice should be a major hepatectomy, unsafe in patients with poor liver function.

CONCLUSIONS

Our case outlines the challenging situation of HCC with central severe APS. Embolization of the shunt is the first option to reduce the pressure in the portal system, as well to render the endovascular treatment of the tumor more efficient and to favor patient survival.

PREVALENCE OF MYOPIA AMONG MEDICAL STUDENTS FROM "GRIGORE T. POPA" UNIVERSITY OF MEDICINE AND PHARMACY (Abstract): **Introduction**: There are scientific evidences that the etiology of juvenile-onset myopia involves both genetic and environmental factors. Excessive near work represents the most frequently cited environmental factor associated with the development of this disease. **Objectives:** The aim of our study was to assess some epidemiological aspects of myopia in today`s medical students from "Grigore T. Popa" University of Medicine and Pharmacy, including the prevalence of this disorder, and the differences between generations. **Materials and methods:** A questionnaire was shared via the internet on the social groups of the University`s Medical Students. Five hundred and seventy-six (576) students filled the survey online: from the 1st year - 105 students; 2nd year - 86; 3rd year - 121; 4th year - 80; 5th year – 86, and from the 6th year - 98 students. **Results:** 73.8% of the students included in the study suffer from myopia. At a first glance, the analysis of myopic students' distribution by the university year showed no significant difference: 1st year – 73.3%; 2nd year – 74.4%; 3rd year – 71.9%; 4th year - 77.5%; 5th year - 68.6%, and 6th year – 77.6% ($p<0.005$). The percentage of the 6th year students that entered the university with myopia was 43.8%. Furthermore, we observed that the number of students that already had myopia before entering the university has progressively increased. To emphasize how important the difference is, this year 64% of the 1st year students already were diagnosed with myopia. **Conclusions:** These results open a debate regarding the causes of the increasing number of students suffering from myopia, including the difficult academic requirements, the behavioral changes, the genetic factors or the poor quality of nutrition. **Keywords**: PREVALENCE, MYOPIA, STUDENTS, UNIVERSITY OF MEDICINE AND PHARMACY.

Myopia, also known as near-sightedness, is a common refractive error developed when a distant object`s image is formed anterior to the retina instead of on the retina. This occurs when the eyeball becomes too long and prevents incoming light from focusing directly on the retina (1). The consequence is blurred vision and requires refractive correction at any diopter for clear focus. It may also be caused by an abnormal shape of the cornea or lens.

For more than 100 years the etiology of

myopia has been discussed and searched, raising a debatable question, whether it is an environmental or a genetic disorder. The studies conducted state that an interaction is involved. However, the exact nature and contribution remains elusive (2). In 2010, myopia was found to be the second most common cause for blindness globally, affecting 108 million persons. Myopia can further cause cataract, glaucoma, retinal detachment and myopic macular degeneration, consequently leading to irreversible vision loss. The American Academy of Ophthalmology's latest meta-analysis predicts that by 2050 there will be one billion people worldwide with high myopia, 7.5 more times than in 2000, bringing both serious economic implications and better eye care facilities throughout the Globe (3).

The aim of our study was to assess some epidemiological aspects of myopia in today`s medical students from "Grigore T. Popa" University of Medicine and Pharmacy, including the prevalence of this disorder, the differences between generations, and the factors that can influence the occurrence of the disease, to analyze if the results found are enclosed in those of other studies regarding the relationship between the development of myopia and the high academic requirements. Most of the factors are modifiable, so the contribution of primary prevention is very important for these subjects.

MATERIAL AND METHODS

A cross-sectional study was carried out among students from "Grigore T. Popa" University of Medicine and Pharmacy from Iasi, Romania. This study was based on a questionnaire shared via the internet on the social groups of the University`s Medical Students to obtain data regarding age, sex, year of study, urban or rural background, eye-sight problems and characteristics, family history, behavioral aspects such as the time spent studying, the type of lighting used and eating habits and the frequency of eye check-ups. The questionnaire was filled in online, anonymously, in two weeks (during May 2016) by five hundred and seventy-six (576) students from each university year (I - VI).

RESULTS

The 576 students' distribution was, as it follows: 1st year - 105 students; 2nd year - 86; 3rd year - 121; 4th year - 80; 5th year – 86, and from the 6th year - 98 students (tab. I). From the 576 participants, there were 487 (84.5%) females and 89 (15. 5%) males. From these, 74.5% (363 out of 487) were women with myopia and 25.5% (62 out of 89) were men with myopic impairment (tab. II).

TABLE I

The distribution of students by year of study

Year of study	Number	Percentage (%)
I	105	18.2
II	86	14.9
III	121	21.0
IV	80	13.9
V	86	14.9
VI	98	17.1
Total	**576**	**100**

73.8% of the students included in the study had myopia (425 students) (tab. II). Analyzing based on the question of diopters, we classified the student`s myopia into four categories: less than -1D, between -1D and -3D, between -4D and -7D and lastly, more than -7D. Most students range from less than -1D (37%) and -1D to -3D (49%), indicating a mild myopia that is not predisposed to further complications (fig. 1).

TABLE II

The distribution of students by gender and health status

Gender	Myopia students			Healthy students			Other categories			Total	
	No.	%		No.	%		No.	%		No.	%
		from total students	from total women		from total students	from total women		from total students	from total women		
Female	363	85.4	74.5	92	80	19	32	88.9	6.5	**487**	**84.5 (from total students)**
Male	62	14.6	69.7	23	20	25.8	4	11.1	4.5	**89**	**15.5 (from total students)**
Total	**425**	**73.8 (from total students)**		**115**	**20 (from total students)**		**36**	**6.2 (from total students)**		**576**	**100**

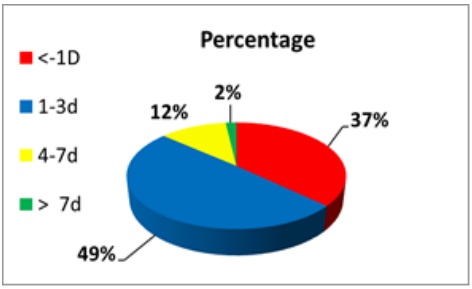

Fig. 1. The distribution of students with different degree of myopia

At a first glance, the analysis of myopic student's distribution by the university year showed no significant difference (p>0.05): 1st year – 73.3%; 2nd year – 74.4%; 3rd year – 71.9%; 4th year – 77.5%; 5th year - 68.6%, and 6th year – 77.5% (tab. III).

TABLE III

The distribution of students by health status and by study year

Health status	Study year												Total	
	I		II		III		IV		V		VI			
	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%
Presently with myopia	77	73.3	64	74.4	87	71.9	62	77.5	59	68.6	76	77.6	**425**	**73.8**
Healthy	22	21	20	23.2	26	21.5	12	15	20	23.2	15	15.3	**115**	**20**
Students with other sight problems	6	5.7	2	2.4	8	6.6	6	7.5	7	8.2	7	7.1	**36**	**6.2**
Total	**105**	18.2	**86**	14.9	**121**	21.0	**80**	13.9	**86**	14.9	**98**	17.1	**576**	**100**

The number of students that already had myopia before entering the university has progressively increased, especially in 1st, 3rd (57.4%), and 4th year (61.3%), as opposed to those who entered the university several years before (5th – 50.8% and 6th years – 53.9%) (tab. IV). To emphasize how important the difference is, we observed that 67.5% of the 1st year students already were diagnosed with myopia.

TABLE IV

The distribution of students already diagnosed with myopia by study year

Health status	Study year												Total	
	I		II		III		IV		V		VI			
	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%
Already diagnosed with myopia	52	67.5	33	51.6	50	57.4	38	61.3	30	50.8	41	53.9	**244**	**42.4**

More students from urban areas developed myopia – 77.4% as opposed to those from the rural areas 63% (tab. V). Furthermore, the students coming from cities have a higher frequency of developing high myopia, almost twice as the students from rural areas, due to food quality, time spent indoors versus outdoors and economic factors (tab. V).

TABLE V

The distribution of students by health status, degree of myopia and origin

Characteristics	Rural area		Urban area	
	No	%	No	%
Health status	**146**	**100**	**430**	**100**
Myopia	92	63	333	77.4

1-3D	49	53.3	160	48
4-7D	7	7.6	43	12.9
> 7D	1	1.1	7	2.1

Our study showed that there are differences between food diet used before admission in the University and during the University years (fig. 2, 3). Before admission, for students with myopia, there was a predominance of food diet bought from supermarket (54.5%) compared with food bought from the producer (45.5%). Also, there are differences between the percentage of food bought from the producer among students with myopia and healthy students (45.4% *versus* 50.4%) (fig. 2).

After entering the University, the students with myopia, had the same diet behavior as before, but with more important differences between the percentages of students which bought the food from supermarket *versus* producer (84% *versus* 16%). The healthy students changed their diet behavior, with a predominance of food

bought from the supermarket (70.4%) compared with that bought from the producer (29.6%) (fig. 3).

Regarding the genetic factors involved in the development of myopia, there are no significant differences between those who have a positive family history and those who show no family history ($p > 0.05$) (tab. VI). The 12 students who developed high myopia of more than -7D have 100% family history.

45% of the medical students questioned had yearly eye exam and 49% had eye exam once every two years or less. Just a small number of students had the eye examination twice per year (6% = 22 students) (fig. 4).

We observed that more than half of students with myopia spent over 4h per day studying during the university year (51.5%). Also, more than 50% of healthy students spent less than 4h per day studying during the university year (52.2%) (fig. 5).

There were no significant differences ($p > 0.05$) between students with myopia (> 6h = 83.1%) compared with healthy students (> 6h = 82.6%) regarding the number of hours spent studying during the exam sessions (tab. VII).

DISCUSSION

In our study the frequency of myopia among medical students was higher than the value found by Chaudhry for Pakistan (73.8% versus 57.6%) (4), and was superior to the values for Norway and Denmark (50%), India (45%), Turkey (33%), and Poland (32%) (5). The prevalence of myopia among medical students from "Grigore T. Popa" University of Medicine and Pharmacy – Iasi was close to that found in China (71%) and lower than the values from Singapore (82%) or Taiwan (93%) (5). However, there are differences between the methodology of these studies and the comparison could have some limitations.

The number of students that already had myopia before entering the university has progressively increased, especially in 1st and 2nd year, as opposed to those who entered the university several years before. To emphasize how important the difference is, this year 64% of the 1st year students already were diagnosed with myopia. This aspect was found in similar studies, throughout Europe, Asia and the United States which were conducted in regions with both large populations and high rate of myopia, raising awareness about the con-

stantly increasing educational standards (4, 5, 6, 7).

Our findings regarding the presence of myopia before the admission in medical University were like those founded by other researchers: most students developed myopia before admission (4).

Studies conducted in the early 20th century on isolated communities with no or little schooling revealed a 0.4% incidence of myopia. The reason is simple: these communities lived a hunter-gatherer subsistence, eating what they produced. 200 years ago, a dietary shift happened, refined goods being slowly introduced, with high a high glycemic load, as opposed to the minimally processed food our ancestors consumed (8). Nowadays, the western dietary patters lead to hyperglycemia, hyperinsulinemia, and type 2 diabetes. These metabolic conditions can induce and affect myopia (9).

Before the Revolution in December 1989, Communist Romania had little access to processed western goods, filled with carbohydrates and sugar. After this event, the democratic regime meant free economic changes. The changes first arrived in the cities and slowly entered the villages, therefore affecting all generations of medical students. Our results that illustrate the nutrition differences before entering the university showed that most students bought their goods directly from the producer, with no preservatives and additives, as opposed to the situation they find themselves in now, agreeing with other studies (9).

As shown in other studies those people with high myopia (-7D) have genetic mutations located on chromosome 7q36 which is inherited autosomal dominant (9). Our results were in accordance with studies from the scientific literature which showed an important family history among subjects with high myopia (4, 9).

Both excessive near work and high educational demands over several years are risk factors for the development and progression of myopia among medical students, especially if they have an initial high prevalence (12). Our study`s findings agreed with other studies, since an average student spends more than 6 hours a day studying during exam sessions, and more than 4 hours a day in a normal university year, which can consequently affect his vision, especially if already diagnosed with myopia (4, 5, 12).

Regardless of their myopia problems, since they undergo a high amount of stress, perform a high amount of near work and are prone to high academic demands it is advisable that they have an eye examination every year, especially if they are already diagnosed with myopia.

Our study has the following limitations: it was not conducted in collaboration with the Ophthalmology department in order to verify the student`s myopia compared to the diopters claimed; more females responded to the questionnaire than males; it is possible to have response bias, with more subjects with myopia choosing to participate than students without myopia impairment; it is prone to subjectivity since the questionnaire was online submitted and the responses may or not be accurate; it is difficult to distinguish the limit between youth-onset myopia (15-20 years) and adult-onset myopia (>20 years) since studies shown a different origin (12).

CONCLUSIONS

In our study, the prevalence of myopia was high among students from “Grigore T. Popa” University of Medicine and Pharmacy – Iasi, Romania and was the most important

among younger students (study years I-III). These results open a debate regarding the causes of the increasing number of students suffering from myopia, including the difficult academic requirements, the behavioral changes, the genetic factors or the poor quality of nutrition. Also, our findings raise the awareness regarding myopia among medical students and the need for primary and secondary prevention.

WHAT CAN WE FIND BEHIND A PARIETAL ABSCESS: CASE REPORT (Abstract): We report a rare case of a 71-year-old female who presented to the First Clinic of Surgery from "Sf. Spiridon" Hospital Iasi, Romania with a mass in the left iliac fossa that started to discharge a feculent secretion five days prior to presentation. The patient had a history of constipation, several episodes of hematochezia associated with significant weight loss over the past 6 months. Following evaluation, a diagnosis of enter cutaneous fistula secondary to a locally advanced sigmoid cancer was made. The patient underwent semi-elective resection of the sigmoid tumor (measuring 20 cm) with 10 cm safe margins, and of the involved lymph nodes and abdominal wall. A termino-terminal colo-rectal anastomosis was performed. The patient was discharged the 10th postoperative day after an uneventful evolution for oncological evaluation. The authors presented this case in order to illustrate the challenges associated with diagnostic and therapeutic management of advanced colorectal cancer that has been discovered through a parietal abscess. **Keywords**: LOCALLY ADVANCED COLON CANCER, ENTERO-CUTANEOUS FISTULA, ABDOMINAL WALL ABSCESS, FECULENT SECRETION.

Colorectal cancer is currently the third most common cancer in the world according to the World Cancer Research Fund International, with 1.4 million cases diagnosed in 2012, and the second malignity as cause of death (1). *Enter cutaneous fistulas* (ECF) in colorectal cancer are rare as they usually occur in case of inflammatory bowel disease, diverticulitis, pancreatitis, radiotherapy, and trauma (external or iatrogenic) (2-4). The authors currently describe the case of a 71-year-old woman who presented with a parietal abscess in the left iliac fossa due to a locally advanced sigmoid colon cancer.

CASE REPORT

A 71-year-old female patient originating from a rural area presented to the Emergency Room, with lower abdominal pain for almost a week, a parietal mass in the left iliac fossa that appeared five days prior to the current presentation and discharge of a feculent secretion that started the previous day.

The patient reported severe weight loss

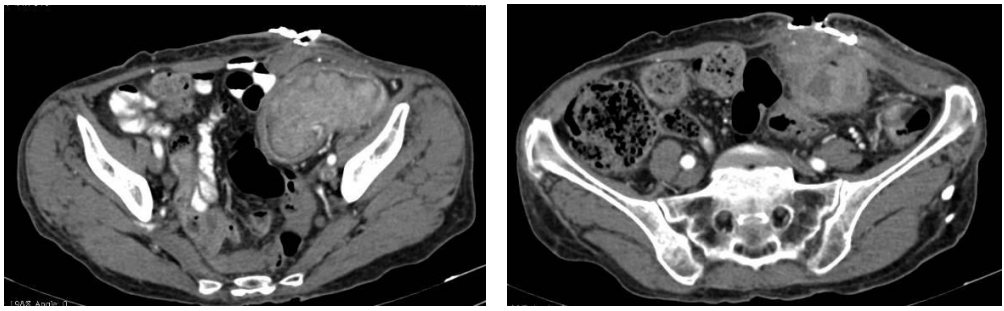
(15 kg) in the past 6 months, a long history of constipation (more than 10 years) and several episodes of hematochezia in the past 3 months. Concerning the surgical history, the patient presented hysterectomy for uterine fibroma 24 years prior to the current presentation complicated by incisional hernia during the same year.

Physical examination revealed stable vital signs, no fever, pale teguments, and a body mass index of 17 kg/m^2, no palpable hepatomegaly, no evidence of ascites, no cardiovascular, respiratory or urinary tract abnormalities. The clinical examination revealed a lump in the left iliac fossa a lump of approximately 15 cm was covered by teguments, with inflammatory signs (pain, red and warm teguments), and a feculent smelling secretion discharged during the manipulation. A diagnosis of parietal abscess probably secondary to an ECF was suspected in the actual clinical context.

Laboratory test results revealed mild leukocytosis (10.16 x 10^3 cells/μL), mild anemia (hemoglobin 11.6 g/dL with a normal hematocrit), thrombocytosis (621 x 10^3 cells/μL), and an increased C-reactive protein (15.03 mg/dL).

An ultrasound examination was also performed and revealed a mass of approximately 17 cm centered on the sigmoid colon, adjacent fat with inflammatory signs and a superficial collection that could not be separated from the sigmoid mass. An ECF secondary to a locally advanced sigmoid cancer was suspected based on these findings, and a computed tomography examination was indicated for preoperative staging.

The Computerized tomography examination revealed a soft tissue mass of 17 cm occupying the entire lumen of the sigmoid colon, with a significant enhancement after contrast administration (40 Hounsfield Units), in contact with a parietal breach in the left iliac fossa, compressing the adjacent small bowel loops without evident signs of invasion, and surrounded by fat, characterized by an inflammatory aspect. Lymph nodes of 12 and 14 mm were noticed in the mezosigmoid. The liver enhanced homogenously and presented no suspect lesions. There was no evidence of intraperitoneal free fluid (fig.1 a, b).

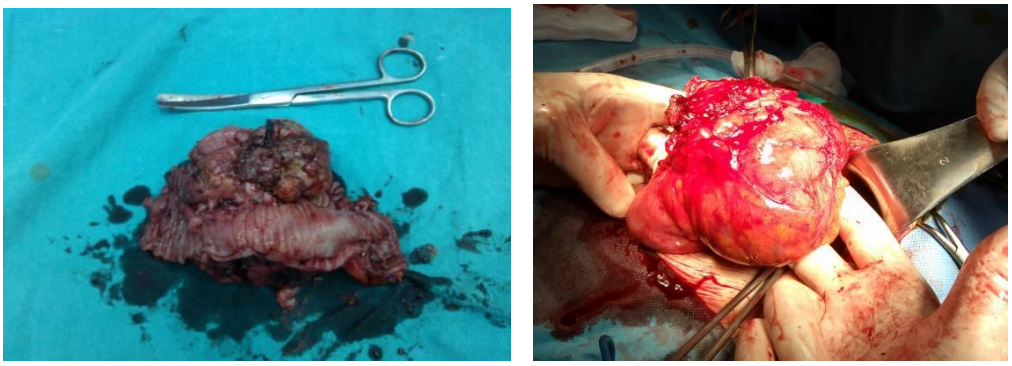


a. **b.**

Fig. 1. a, b. CT aspects of the sigmoid mass after contrast administration:
a. enhancing tumor occupying the entire sigmoid lumen;
b. intimate contact of the tumor with the parietal breach.

After the computerized tomography examination, the patient was prepared for surgery and she was operated. *A navel-to-pubis laparotomy* was performed while the

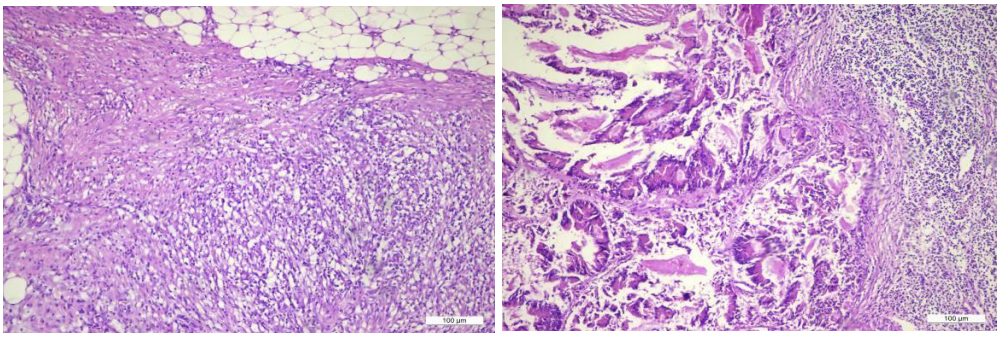
inspection of the peritoneal cavity showed a tumor of approximately 20 x 20 cm with a malignant aspect that invaded the abdominal wall by traversing the rectus sheath, 2/3 of the tumor being located outside the abdominal cavity. No peritoneal or liver metastases were noted during surgical inspection. The tumor was resected together with 10 cm of sigmoid colon on each side (fig. 2 a, b). Adjacent lymph nodes were removed with the tumor section of the sigmoid colon. A colo-rectal termino-terminal anastomosis was performed and the parietal breach was excised as well.



a. **b.**

Fig. 2. a, b. Tumor aspect: a. intraluminal tumor aspect; b. exterior tumor aspect.

Histopathological examination concluded moderately differentiated adenocarcinoma of colic origin, ulcerated, with infiltration and serosal effraction, and extensive areas of hemorrhage and necrosis. The parietal fragment consisted in muscular, adipose and conjunctive tissue with adenocarcinoma infiltration, and extensive areas of necrosis and hemorrhage (fig.3 a, b).



a. **b.**

Fig. 3. a, b. Histopathological aspects of the excised tumor and lymph nodes:
a. Sub serosa necrosis and desmoplastic reaction;
b. Lymph node metastasis of adenocarcinoma (hematoxylin and eosin stain)

The post-operative diagnosis established a loco regional advanced sigmoid cancer (T4bN1aMx (G2)).

The patient was discharged the 10th post-

operative day after an uneventful evolution and was referred for oncological evaluation and treatment to the Oncological Clinic. In addition to surgeons, specialists in nutrition, intensive-care medicine, nursing, wound care, made part of the treatment team.

After six months from the surgical intervention the patient came to a postoperative check after chemotherapy treatment and according to the clinical examination and computed tomography evaluation there were not found secondary neoplasia lesions.

DISCUSSION

Colorectal cancer is among the rarest causes of ECF and exceptionally manifests in this way. ECF usually occurs at any time after surgical interventions, spontaneous fistulas being uncommon (15-25%), usually occurring in patients that received radiotherapy (weeks or years after as mucosal ulcerations persist), have an inflammatory process (bowel disease, pancreatitis), bowel obstruction, or suffered an abdominal trauma (5). Bowel surgery and anastomosis after previous irradiation increases the risk of fistulation (6). According to the Food and Drug Administration website, out of 13.554 patients with colon cancer, only 8 (0.06%) presented with ECF. White et al. performed a study in 1973 concerning abdominal wall abscess as the presenting sign in colon cancer, analyzed 16.000 patients treated at the Massachusetts General Hospital and concluded that only 9 patients (0.05%) with colon cancer presented with abdominal wall abscess secondary to a colocutaneous fistula (3).

A throughout examination is the key point of a rapid and accurate clinical diagnosis.

In case of ECF due to malignant diseases, the only options are surgical resection (*en bloc* if possible) completed by enteric bypass or diversion (7). The presence of a malignant disease is a total contraindication to surgical closure of an ECF. In our particular case, the patient ignored a long period of time lasting constipation and hematochezia. The presentation in our emergency room occurred only when she was alarmed by the discharge of a feculent secretion from a cutaneous lesion.

In the present case, ECF has been already suspected in the emergency room at the moment of the first physical examination. Computed tomography examination is the preferred method of investigation as, compared to barium enema, provides information on the part of the bowel involved, type and extension of bowel disease, fistulous tract, presence of an abscess, other organs involved in the process (8, 9, 10).

Chapman et al. described in an article published in 1964 the key principles of ECF care, principles that apply no matter the etiology: correction of intravascular volume deficit, drainage of abdominal abscess, control of fistula effluent, and skin protection (11). Additional surgical management is required in patients with ECF due to cancer, and the surgical intervention can be performed in an elective or semi-elective manner, like was the case of our patient that underwent preoperative imaging studies for cancer staging. Depending on the size of the cutaneous breach and degree of involvement of adjacent tissues the closure of the abdomen may be performed primary or with a biological mesh that acts like a fascial bridge (12).

Untreated, ECF are associated to a high morbidity and mortality due to sepsis, malnutrition, electrolyte imbalance, and possible massive bleeding in case of vascular erosion.

ECF that complicate an advanced cancer are often associated with a poor overall survival and quality of life as they delay or restrain the administration of an adjuvant therapy.

CONCLUSIONS

Our case is a particular example of an unusual presentation of colorectal cancer as an ECF with abscess formation. The authors presented this case in order to illustrate the challenges associated with diagnostic and therapeutic management of advanced colorectal cancer that has to undergo semi-elective surgery with limited adjuvant therapy.

THE RELEVANCE OF CYTOLOGICAL DIAGNOSTIC IN THE MAMMARY GLAND CANCER (Abstract): Breast cancer is the second leading cause of cancer death in women, while in Eastern Europe the most common form of diagnosed cancer. Out of the multiple possibilities of early detection of mammary neoplasia that have been elaborated, only mammography has proved to be a simple, efficient method and of a high sensitivity, almost 90% However, the cytological confirmation of diagnosis allows us to perform the preoperative radiotherapy treatment or poly chemotherapy. **Material and methods**: we analyzed the informative value of these diagnosis methods in stage I mammary gland cancer (MGC). In this way, in the present paper we demonstrated that collecting samples through fine-needle aspiration biopsy allows the cytological confirmation of the diagnosis of stage I MGC in 30.7% cases. **Results and discussion**: In stage I MGC young patients, under 35 years, the cytological confirmation rate is 22.2% and is lower as compared to the cytological confirmation rate in patients older than 35 years which is 37.9% Also, for a tumor diameter < 0.5 cm, the prevalence of cytological confirmation was only 10.3%, while for the diameter of 0.6 – 1.0 cm the cytological confirmation was around 40.0%. Therefore, in order to improve the cytological diagnosis confirmation rate the tumor biopsy through the USG of the mammary glands is required. Moreover, the cytological investigation of the smear obtained by the first and second puncture was instrumental in confirming the diagnosis in 41.3% and 17.4% cases; the subsequent repetition of the punctures was not useful as it helped to confirmation of the diagnosis only in 9.3% cases. The frequency of diagnosis cytological confirmation depends on the tumor histopathological form and type of growth. **Conclusions:** Thus, the lowest prevalence was in the mixed forms - 12.5% cases, lobular cancer - 24.4% cases, while regarding the type of growth, for the rare forms the cytological confirmation rate was 7.7% and 31.5% cases for the schiros growth type. **Keywords**: MAMMARY GLAND CANCER, CYTOLOGY.

Breast cancer is the most common oncologic disease in women and is one of the major public health issues. Worldwide, breast cancer is the second leading cause of cancer death in women, while in Eastern Europe the most common form of diagnosed cancer. Among the most frequent involved factors in the outset of breast

cancer are included: the hereditary factor - genetically breast cancer develops in 3-5 cases; the genetic factors BRCA 1 and BRCA 2, should be more carefully studied, which up to now have been confirmed as having the greatest impact in breast cancer development risk, age over 35 years, hormonal contraception, incorrect nutrition, therapy with hormonal preparations, ionizing radiation, psychosocial factors and mental stress (1).

The questionable risk factors that are presented in various studies are very different and numerous, in some authors being citing over 300 in number, but none established with certainty. Immune factors along neuroendocrine factors are regarded as responsible for the clinical development of breast cancer (2).

Cancer research is a priority in all the laboratories of the world, in terms of uncovering the appearance causes of the malignant process, understanding the mechanisms of development, but most of all, the discovery of early diagnostic methods and effective treatment. Ignorance, fear of diagnosis, lack of health education and of efficient programs for prevention and screening, from our country cause diagnosis of the disease to be detected in the majority of cases in advanced stages, when treatment remains only palliative and very costly, in this cases the patient's suffering being immense (3).

Out of the multiple possibilities of early detection of mammary neoplasia that have been elaborated, only mammography has proved to be a simple and efficient method of a high sensitivity (almost 90%). In the same time, if the clinical examination is performed by an experienced physician, mammography can play an important role in screening. Moreover, the clinical diagnosis of palpable tumors usually does not present any difficulties because the clinical symptoms that indicate suspicion or clinical diagnosis of MGC are well-known (4).

Morphological factors of prognosis include the following: presence of tumoral emboli of the lymphatic and blood vessels of both tumor and adjacent mammary glandular tissue. The presence of tumoral emboli in the blood and lymph vessels was noticed in 14-29.5% MGC patients, who progressed after surgical treatment (5).

According to MoHceenico B. M., the most important criteria to assess the prognosis of MGC are: 1. The diameter of the tumor. 2. The degree of differentiation of the tumor after Bloom-Richardson. 3. The status of the regional lymph nodes. 4. The degree of expression of the steroid hormones receptors (RE, RP). 5. RNM synthesis activity markers: marking indices, the S-phase fraction, thymidine kinase activity, - Ki-67. 6. Growth factors receptors, including the oncogenes: epidermal growth factor receptor (EGF-R), HER2/neu, insulin-like growth factor receptors (IGF-R), somatostatin receptors. 7. Tumor suppressor genes - p53, -Nm 23 (6).

Also, due to the successes of molecular biology in the arsenal of researchers and clinicians there is a number of accurate indices which contributing to the assessment of predicting the efficacy of the MGC treatment and prognosis and selecting adjuvant and neoadjuvant therapy tactics in combined and complex MGC treatment. The problem concerning the researches in this field is to determine the set of informative indices, which would complement one another, which would enable at a minimum possible examination price to ensure the selection of the most efficient method in the treatment of each patient. The research spectrum in each particular case can depend on the progress stage, the age and

concomitant pathology of the patient, planned therapy and material technical basis of the institution.

In this way, it is generally accepted that the actual methods of MGC treatment which include the surgical component, radiotherapy, chemotherapy (CT) and hormone therapy (HT) could ensure a 90 - 95% rate of over 5 years' survival in stage I of MGC (7).

Still, the cytological confirmation of diagnosis allows us to perform the preoperative radiotherapy treatment or poly chemotherapy; which is why we analyzed the informative value of these diagnosis methods in stage I MGC.

Therefore, even with the mammographic or ultrasonographic clinical conclusion or assessment on the malignant character of the pathological process in the mammary gland, the neoadjuvant treatment becomes feasible only when the diagnosis is confirmed by one of the morpho-pathological methods, such as the cytological or histopathological method. According to the data in the international literature the cytological confirmation in the tumors with dimensions of less than 2.0 cm is problematic and does not exceed 20-25% cases as opposed to the extended malignant processes (8).

MATERIALS AND METHODS

The material of this study includes clinical and laboratory data analysis, the informational value of various investigation and treatment methods on 680 patients, selected between 1996 and 2004.

The patients included in the study were divided into three groups: the retrospective group, the prospective group and the control group.

In this way, the retrospective group included 496 stages I MGC patients, diagnosed and treated during 1996-2004. The retrospective group was divided into 2 groups according to the type of clinical development of tumoral process after treatment: the 1st group including 419 patients without progress for 5 years after the treatment, and the 2nd group including 77 patients with the progressing tumoral process after treatment.

On the other side, the prospective group included 66 stages I MGC patients, diagnosed and treated between 2007 and 2008. For the patients in the prospective group there were assessed the molecular expressions of the HER2/neu molecular markers, CEA tumoral markers, CA-15.3, hormonal receptors RE and RP, hormonal homeostasis and immunological indices.

Finally, the control group comprised of 118 patients, from which 56 patients with Ha, Ilb, or lila stage MGC, and 62 patients with benign diseases.

In the control group the immunological and homeostasis hormonal parameters were studied for comparison with the stage I MGC.

A special inquiry was developed for this study, which included 150 parameters regarding special body or tumor features, the informational of various methods of investigation and the results of different treatment variants applied.

Data analysis

The decisive prognostic factors determination was performed by discriminate analysis. By applying discriminate analysis - within the groups of the retrospective lot the decisive prognostic factors of the clinical evolution variance were determined in the stage I MGC patients.

RESULTS

In this way, the cytological investigation conducted on 475 patients confirmed the diagnosis of cancer of the mammary gland

only in 146 patients, which represented 30.7% cases. The cytological confirmation correlates with the age of the stage I mammary gland cancer patients (tab. I). As a matter a fact, as shown in the table, the diagnosis of MGC was cytological confirmed in 22.2% cases for the patients up to 35 years; in 24.1% cases for the 35-49 years' patients - and in 37.9% cases for the 50-year-old and older patients (tab. I).

TABLE I

The accuracy of cytological confirmation of the malignant process in stage I breast cancer patients by age.

No	Patients Age	No. of recorded patients	Cytological confirmed diagnosis	
			No. abs.	%
1	< 35 years	27	6	22.2
2	35-49 years	216	52	24.1
3	> 50 years	232	88	37.9
4	Total:	475	146	30.7

$X^2 = 11.06$, $p < 0.05$

Also, the cytological conclusion variants were: cancer - 30.7%, the cancer suspicion conclusion -18.9% cases, proliferative process with atypical - in 19.4% cases.

For the other cases other variants of cytological diagnosis, without suspicion of cancer, have been established.

Of these the cytological conclusion for 1 in each 3 patients, which represents 17.5% - consisted in normal glandular epithelial cells without proliferation or atypical signs (tab. II).

TABLE II

Cytological conclusion variants in stage I MGC versions by the number of conducted aspiration biopsies

No.	Cytological analyses conclusion	Quantity of conducted aspiration biopsies							
		1		2		3-4		Total:	
		283 patients		138 patients		54 patients		475 patients	
		No.	%	No.	%	No.	%	No.	%
1	Cancer	117	41.3	24	17.4	5	9.3	146	30.7
2	Suspicion of cancer	34	12.0	35	25.4	21	38.9	90	18.9
3	Proliferation with	22	7.8	50	36.2	20	37.0	92	19.4
4	Glandular epithelial cells	46	16.3	29	21.0	8	14.8	83	17.5
5	Lipids, erythrocytes,	64	22.6	0	0	0	0	64	13.5

$\chi^2 = 38.37$, $p < 0.01$

In addition, as it can be seen in table II, the results for the cytological confirmations by number of conducted aspiration biopsies were: the first biopsy was cytological confirmed in 41.3% cases, for the second biopsy the cytological investigation of the smear from the samples allowed the diagnosis cytological confirmation in 17.4% cases, while the aspiration biopsies repeated 3-4 times cytological confirmed the diagnosis only in 9.3% cases.

Also, we have to mention that the correct cytological conclusion prevalence analysis depending on the tumor diameter revealed that for a tumor diameter < 0.5 cm the correct conclusion of MGC was at-

tained only in 10.3% cases, for 0.6 – l.0 cm in 40% and for l.l – 2.0 cm – in 34.3% cases (tab. III).

Moreover, the diagnosis cytological confirmation frequency depends on the histopathological form and type of tumor growth. 31.6% cases were cytological confirmed for the ductal form, for the lobular form 24.4% cases were cytological confirmed, for the mixed forms (ductal and lobular) 12.5% cases, and for the rare forms that unite a string of highly differentiated forms of MGC (tubular, papillary, medullar, mucinous and other.) - in 41.7% cases (tab. IV).

In addition, the prevalence of the cytological confirmation is depending on the morphological type of the tumor: for the solid growth MGC type, 66.1% of the cases were cytological confirmed; for the schiros growth type 37.5% were cytological confirmed, while the lowest frequency rate of cytological confirmation was in the mixed forms - 7.7% cases (tab. V).

TABLE III

The frequency of the cytological confirmation for the malignant process in patients with stage I MGC by size of the tumor

No.	Size of tumor	No. of marked patients	Cytological confirmed diagnosis	
			No. abs.	%
1	< 0.5cm	39	4	10.3
2	0.6-l.0cm	160	64	40.0
3	l.l-2.0cm	213	73	34.3
4	Total:	412	141	34.2

$\chi^2 = 35.0, p > 0.05$

TABLE IV

Frequency of cytological confirmation in patients with stage I MGC by tumor morphological variant

No.	Morph pathological variants	No of patients	Cytological confirmation	
			No. abs.	%
1	**Ductal**	345	109	31.6
2	**Lobular**	86	21	24.4
3	**Ductal and lobular**	8	1	12.5
4	**Rare forms**	36	15	41.7
5	**Total**	475	146	30.7

$\chi^2 = 65.0, p > 0.05$

TABLE V

Frequency of cytological confirmation in patients with stage I MGC by tumor morphological type.

No.	Morphological type	No. of Patients	Cytological confirmation	
			No abs.	%
1	**Solid**	59	39	66.1
2	**Schiros**	56	21	37.5
4	**Rare forms**	260	20	7.7
5	**Unknown**	100	-	-
6	**Total**	475	146	30.7

$\chi^2 = 5.0\ p > 0.05$

It must be also mentioned that although the cytological diagnosis was confirmed only in 146 patients who represented 30.7% of cases, for the other 329 patients, 69.3%, the morph pathological diagnosis was determined by intraoperative extemporaneous histological investigations.

DISCUSSION

In this way, as previously mentioned, it is generally accepted that the actual methods of MGC treatment which include the surgical component, radiotherapy, chemotherapy (CT) and hormone therapy (HT) could ensure a 90 - 95% rate of over 5 years' survival in stage I of MGC (7). Still, the cytological confirmation of diagnosis is allowing us to perform the preoperative radiotherapy treatment or poly chemotherapy; which is why we analyzed the informative value of these diagnosis methods in stage I MGC.

Therefore, although with the mammographic or ultrasonographic clinical assessment on the malignant character of the pathological process in the mammary gland being available, the neoadjuvant treatment becomes feasible only when the diagnosis is confirmed by one of the morphopathological methods, such as the cytological or histopathological method. According to the data in the international literature, the cytological confirmation in the tumors with dimensions of less than 2.0 cm is problematic and does not exceed a rate of 20-25% cases as opposed to the extended malignant processes (8).

Moreover, serum tumoral markers are used to assess mammary neoplasia evolution: the carcinoembryonic antigen (CEA) and the CA 15.3 (cancer antigen 15.3) (9). In this way, the CA 15.3 concentration occurs in women with the diagnosis of breast cancer, and its usefulness lies in evaluating the evolution of the illness, response to treatment and relapse assessment. The CA 15.3 tumor marker is a mucin-like antigen, with high molecular weight, issued primarily by cells of mammary glandular carcinoma. CA 15.3 is defined by its reactions with two monoclonal antibodies: one of them (115D8) binds to an antigen from human milk; the other (DF3) bounds to a membrane fraction of the carcinomatous cells.

The CA 15.3 blood titer increased in patients with advanced process, drops after chemotherapy treatment and rises again in the case of relapses or metastasis (in particular bone metastasis). Although the sensitivity of this marker in detecting early stages is reduced, lately there is a increasing tendency towards the idea of introducing it as a method of screening in the female population in the age group 45-54 years old (pre-and postmenopausal), considered to be the age group most prone to breast cancer. Also, determining molecular markers is an important tool for the diagnosis, treatment, assessment of therapy response. A slight physiological increase of the CA 15.3 antigen is registered in 4-7% of the nursing women and in about 8% of the pregnant women (9).

Moreover, carcinoembryonic antigen (CEA) is a specific marker for the digestive tract cancers (colorectal, stomach, pancreas, liver, biliary vesicle); subsequently, clinical studies have shown an increase in other malignant diseases (lung, mammary gland, ovary, cervix, prostate).

Historically speaking, the carcinoembryonic antigen was first described in 1965 by Gold and Freedman in a patient

with colorectal carcinoma. The carcino-embryonic antigen is a glycoprotein with the molecular weight of 220 kDa containing approximately 40% proteins and 60% carbohydrates. In this way, it is one of the onco fetal products during embryonic life and fetal development. Its production is suppressed after birth, reaching very low levels into adulthood, less than 3 ng/ml in non-smokers, less than 5 ng/ml in smokers. Immunohistological, the carcino embryonic antigen can be determined in elevated concentrations in the fetal gastrointestinal tract and pancreas, as well as in colorectal adenocarcinoma, and in lower concentrations in the normal intestinal tissue, intestinal mucosa, exocrine pancreas, and in the liver. The function of antigen carcino embrionar is not fully known; it is assumed that the CEA bound to the cellular membrane serves as mechanism for intracellular recognition functioning as a receptor. In addition, CEA is also assigned an immunosuppressive effect through the induction of macrophages and suppressor T lymphocytes (10).

Also historically speaking, we could also mention the unique research carried out in 1962 by H. Bloom, W. Richardson, E. Harries. The authors were able to trace the fate of 250 untreated patients mainly in stage III-IV MGC between the years 1805 and 1933: the median survival was 2.7 years, and the last patient died in the 19th year of surveillance without any treatment (2).

Of particular relevance in this context is also the fact that the prediction factors mirror the relations of reciprocity between tumor biology and treatment (for example, RE, RP and hormonotherapy; HER2/neu and herceptin therapy) (11). In fact, the prediction factors may also have prognosis significance. In this way, MGC is considered to be a heterogeneous pathology, with clinical evolution ranging in various patients from severe aggressiveness to the relatively benign.

CONCLUSIONS

MGC represents a polymorphic and pathogenic disease and it cannot be admitted that all subgroups of patients will obtain identical results from one tactic of treatment determined for all the patients with MGC. Thus, the concept of MGC both clinical and patho morfological, combines different cell clones depending on its microstructure and biology. As a result, the evolution of the disease, the prognosis and the effectiveness of the treatment may vary in different patients at the same stage, depending on the degree of malignancy of the tumor, its histopathological structure, the degree of expression of molecular markers identification and also immunoresistance.

Also, some numbers-related conclusions could be represented by the fact that: collecting samples through fine-needle aspiration biopsy allows the cytological confirmation of the diagnosis of stage I MGC in 30.7% cases. In stage I MGC young patients, under 35 years, the cytological confirmation rate is 22.2% and is lower as compared to the cytological confirmation rate in patients older than 35 years which is 37.9.%. For a tumor diameter < 0.5 cm, the prevalence of cytological confirmation was only 10.3%, while for the diameter of 0.6 – 1.0 cm the cytological confirmation was around 40.0%.

Therefore, in order to improve the cytological diagnosis confirmation, rate the tumor biopsy through the USG of the mammary glands is required.

The cytological investigation of the smear obtained by the first and second

puncture was instrumental in confirming the diagnosis in 41.3% and 17.4% cases; the subsequent repetition of the punctures was not useful as it helped to confirmation of the diagnosis only in 9.3% cases. Moreover, the frequency of diagnosis cytological confirmation depends on the tumor histopathological form and type of growth. Thus, the lowest prevalence was in the mixed forms - 12.5% cases, lobular cancer - 24.4% cases, while regarding the type of growth, for the rare forms the cytological confirmation rate was 7.7% and 31.5% cases for the schiros growth type.

GIANT INTRALIGAMENTARY UTERINE LEIOMYOMA AND ITS COMPLICATIONS

A. Cărăuleanu, R. Socolov, Ivona Anghelache Lupaş cu, V. Rugină, Demetra Socolov
University of Medicine and Pharmacy "Gr. T. Popa" - Iasi
Department of Obstetrics – Gynecology

GIANT INTRALIGAMENTARY UTERINE LEIOMYOMA AND ITS COMPLICATIONS (Abstract): Uterine leiomyomas are benign tumors arising from uterine smooth muscle. Although their pathogenesis remains unclear, they are the most common tumor of the female reproductive tract, occurring in as many as half of women older than 35 years. Uterine leiomyomas represent the most common benign tumors of the female reproductive tract. Giant uterine leiomyomas are very rare and represents a great diagnosis and therapeutic challenge. Uterine leiomyoma is one of the most frequent types of tumours and it is diagnosed in 20-40% of the women of reproductive age. Until the age of 50, approximately 70% of the white women and less than 80% of the black women will have had at least one leiomyoma. The frequency of the emergence of uterine leiomyoma in black women is significantly higher than in white women.
Keywords: UTERINE GIANT FIBROID, SURGERY, HYSTERECTOMY.

Around 200,000 hysterectomies, 30,000 myomectomies and thousands of selective uterine artery embolizations are performed annually in the United States to reduce the size of uterine leiomyomas (4, 5).

These lesions disturb the uterus functions and generate excessive bleeding, anemia, defective implantation of embryos, recurrent miscarriages, premature labour, pelvic discomfort and urinary incontinence; they can also imitate or mask malignant tumours.

The size of the leiomyoma and its location generate characteristic manifestations. Thus, in the case of submucuous leiomyomas, there are excessive or irregular bleedings, infertility, as well as recurrent miscarriage. Subserous leiomyomas developing in the peritoneal cavity can exercise pressure, which is perceived by the patient as pelvic discomfort, and intramural leiomyomas located in the myometrial wall are an intermediary grouping (7, 12).

CASE REPORT

Patient M.B., 44 years old, coming from the rural environment, working as a salesperson, is admitted in 2nd Obstetrics and Gynecology Clinic, at "Cuza Voda" Maternity Hospital of Iaşi for: moderate pain in the hypogastrium and left iliac fossa, pelvic load sensation, repeated metrorrhagias (excessive genital bleeding at irregular intervals, of prolonged duration of the flow > 6 days), enlarged abdomen, pollakiuria, slow bowel movement, pain in the left lower limb.

The personal pathologic history reveals that, 14 years before, the patient underwent surgery for left adnexectomy due to left

ovarian cyst, and her family history is insignificant. At the time of her admission, the patient's general state was good, and the examination of her apparatuses and systems reveals chronic constipation (slow bowel movement), and pollakiuria.

Upon bimanual abdominal palpation, in the left iliac fossa and hypogastrium an abdominal-pelvic tumour is found, which is hard, irregular, of firm consistency, painful upon palpation, of reduced mobility, and with the transversal diameter over 8 cm. The digital vaginal examination reveals a cartilaginous cervix with the internal orifice closed, the uterine body enlarged on the whole, deviated to the left, of polycyclic outline, impalpable annexes.

The abdominal ultrasonography reveals a tumour formation that is hyperechogenic, non-homogeneous, well limited, of 24.4/31 cm, non-visualized annexes, no free fluids in the peritoneal cavity; in the left kidney, there is a 1st degree left hydronephrosis, due to the compression of the tumour. Laboratory tests reveal a mild anemia upon admission (fig. 1).

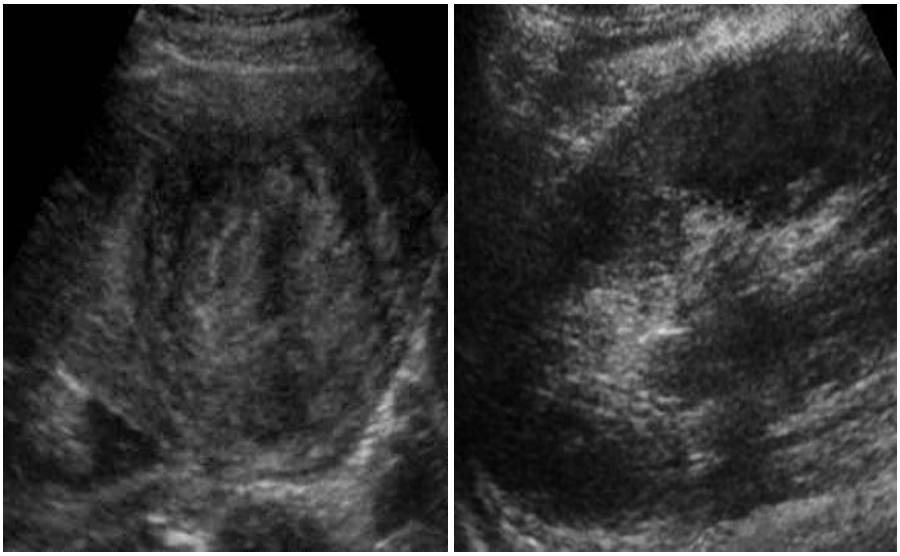

Fig. 1. Transabdominal ultrasound aspects of the uterine leiomyoma

Based on the clinical and paraclinical data, the set diagnosis is uterine polyfibromatosis with an intraligamentary nodule of 25/30 cm, for which surgical therapy is chosen. Surgery is performed and the following is found during surgery: enlarged uterus of approximately 11/9/5 cm, with multiple subserous fibromatous nodules with diameters between 3 and 5 cm, an adherent intraligamentary fibromatous nodule of approximately 25/30 cm, and a posterior isthmic subserous nodule of approximately 7 cm, left annex absent by previous surgical intervention, right annex of normal aspect. Total hysterectomy and right adnexectomy are performed. Difficult hemostasis due to exuberant vascularization of the leiomyoma, but eventually efficient. Two intraabdominal meshes with hemostatic role are left inside as well as a drain in the Douglas space. Postoperative pieces were submitted to an anatomopathologic examination (fig. 2, 3, 4).

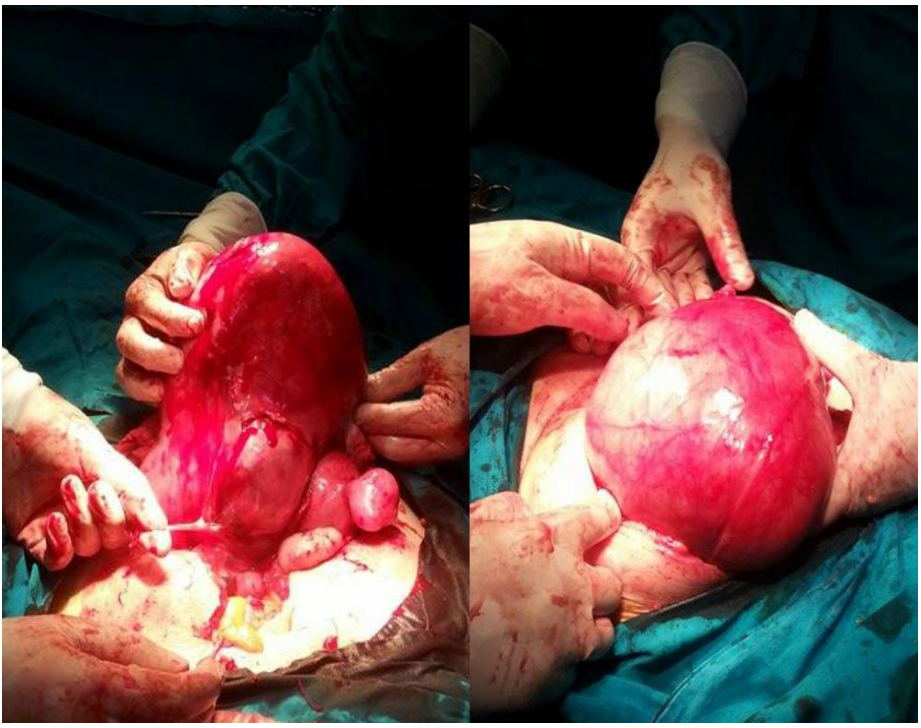

Fig. 2. Intraoperative image (uterine leiomyoma)

Fig. 3. Intraoperative aspects of the pelvic tumour

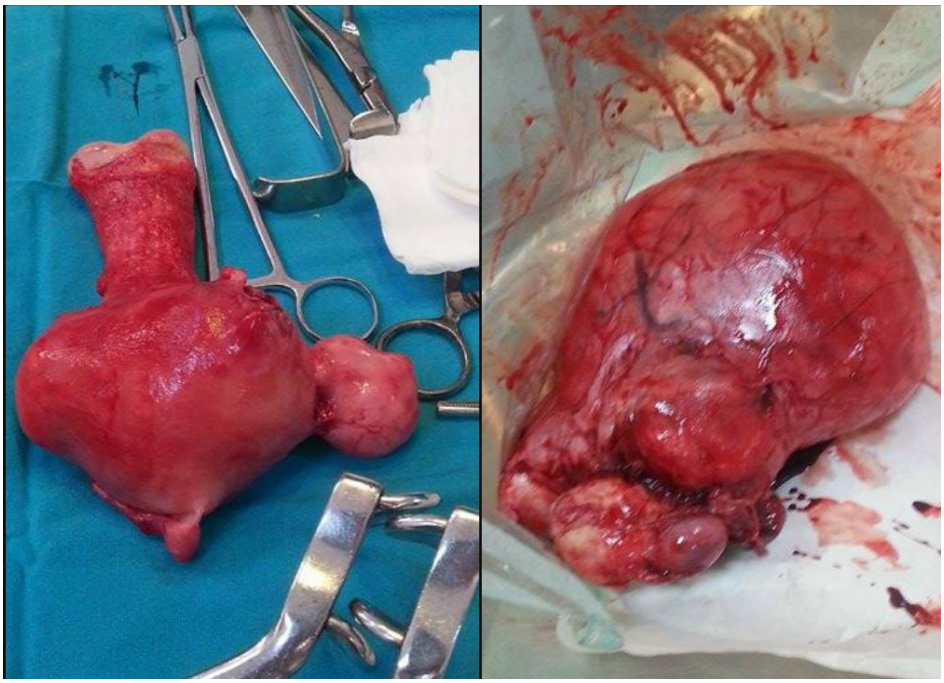

Fig. 4. Operative pieces (uterine body + cervix; intraligamentary uterine leiomyoma of 25/30 cm)

After surgery, following laboratory tests, the patient was transfused with two units of iso-group iso-Rh blood. Her evolution is favourable, she resumed feeding and bowel movement, the abdominal meshes and drain are supressed the second day after surgery. A sample was collected from the wound, which was positive for Staphylococcus OR, sensitive to Ciprofloxacin.

In the anatomopathologic examination, the following is found in the examined sections: subserous nodular leiomyoma (max diameter 33 cm) with densely vascularized areas and hyaline degeneration with no mitotic activity, necrosis or haemorrhage, intramural nodular leiomyoma (diameter = 3cm), endometrium with simple hyperplasia and exacerbated chronic inflammation, non-specific chronic cervicitis, right ovary: follicular cysts, simple serous cyst (2cm), right exacerbated chronic salpingitis.

DISCUSSIONS

Depending on the size and location, the uterine leiomyoma can put pressure on the uterine organs, generating a series of "borrowed" symptoms, of variable intensity, some forms being well tolerated, but others generating important complications.

Generally, leiomyoma is not painful, but in case pain emerges, then we can speak of a trophic complication of the tumour, compressive phenomena exercised on other organs and sometimes even an association to another pathology. Large tumours generate a load sensation in the pelvis, the submucous polypoid ones – spasmodic or colical pain, and in the case of enclosure of a leiomyoma in the true

pelvis, most frequently with isthmic location, there is pelvic pain radiating in the lower limbs due to the compression on the roots of the sciatic nerve. The latter phenomena appears in less than 1% of the cases and is favoured by pregnancy.

The leiomyoma location is important also in detecting other functional disorders, therefore in case of compression on the urinary ducts, there are urination disorders such as pollakiuria, which is generated due to the hindrance of the bladder distension by the leiomyoma. But the most important is the renal-urethral impact, which affects silently the upper urinary ducts, and in the case under discussion the leiomyoma – being intraligamentary – generates hydronephrosis, which comes to compromise the renal function. The posterior development of the leiomyoma can be accompanied by strangury or chronic constipation.

In the case of a leiomyoma with pelvi-abdominal development, the surgical intervention is more laborious, of high difficulty. Most times, the median incision is extended to the left paraumbilical area for increased visibility. The surgical option is determined most often by the tumour size, the organs need to be accurately recognized, avoiding the opening of the urinary bladder in the lower angle of the abdominal approach path. In order to avoid haemorrhage, the contact with the tumour surface should be as tight as possible.

In 1952, Forgue spoke about the precise notions of the detachable areas of the pelvic peritoneum, about the virtual subserous spaces where these tumours develop, and about the lesion risks involved by visceral displacements, which the surgeon should consider.

The surgical difficulty as regards a pelvic tumour of large size is not related to the total size of the uterus, but rather to the presence of included leiomyomas, those tumours developed inside the areas of detachment of the visceral peritoneum.

The intraoperative problems are represented by the probable existence of adhesions between the uterus and neighbouring organs, the presence of intense vascularization feeding growing tumours with haemorrhagic rick. Several planes must be crossed in order to reach the true cleavage surface, these planes can include the ureters; the vessels feeding the tumour can be numerous and large, in some cases as big as the inferior vena cava. Thus, they need to be ligatured before acting in this area (1, 9).

Due to its location, the leiomyoma can displace the uterus, can elongate the vagina or even elevate the urinary bladder. This way, the relations to the organs around are changed, the main risk of the surgical intervention being injuries cause to the uterus. The advantage that the gynaecological surgeon has in case the tumour is benign is the fact that the uterus is displaced laterally by the tumour and not enclosed in it, as is the case of endometrial adenocarcinoma or cervical cancer, which invade one or both parameters from the very first stages. Therefore, we consider that procedures such as catheterizing the uterus before surgery or other imaging methods of evaluation of the exact location of the ureteral route are not absolutely necessary if the paraclinical evaluations prior to surgery support the diagnosis of benign uterine tumour. We consider that the attentive opening of the parameter with the evaluation "at sight" of the parameter elements and avoiding injuring them are the optimum procedure in such cases. The entire pelvic anatomy can be completely changed.

Hence, the surgical technique is not the

standardized one. The surgical intervention begins from the best exposed uterine side. At first, either adnexectomy is performed on that side, or the interadnexal hysterectomy technique is applied ,followed by adnexectomy. Hysterectomy is performed concomitantly on both uterine sides, with the purpose of mobilizing the uterine body and exteriorizing it as much as possible. Another technique that can be performed consists in the initial sectioning of the uterosacral ligaments, which increases the uterus mobility. Total hysterectomy is also possible, but it involves higher blood loss and surgery takes longer. It would be optimum for the hysterectomy duration to be as short as possible and the blood loss to be as low as possible. This way, the surgical technique can be simplified by practicing first subtotal hysterectomy or polymyomectomy followed by the totalization of the intervention and potentially adnexectomy. The totalization of the intervention by extracting the cervix immediately after the subtotal hysterectomy is not subject to the same technical difficulties as totalization of a hysterectomy performed years before. In such cases, the visceral peritonization of the cervical stump determines the elevation of the urinary bladder, which is injured during surgery, while uncovering the cervix. There is no such risk in our intervention (11, 12).

CONCLUSIONS

In our opinion, the therapy for the uterine leiomyoma must start from the particularities of this tumour: it is a benign tumour with negligible risk of turning into a malignant one, and the symptoms that the patient describes are given by afferent complications and not the leiomyoma itself, and it is when the uterine bleeding becomes abundant leading to anemia that it overcomes the stage of sign and it becomes a complication.

The entire pelvic anatomy can be completely changed. Hence, the surgical technique is not the standardized one. It would be optimum for the hysterectomy duration to be as short as possible and the blood loss to be as low as possible. This way, the surgical technique can be simplified by practicing first subtotal hysterectomy or polymyomectomy followed by the totalization of the intervention and potentially adnexectomy.

Also, the section of utero-sacral ligaments at the beginning of the histerectomy is an efficient technique of making the uterus mobile.

NEWS

THE IMPORTANCE OF MOLECULAR BIOLOGY TESTS IN THE DIAGNOSIS OF *CLOSTRIDIUM DIFFICILE* INFECTION

C. difficile is an anaerobic bacterium that causes pseudomembranous colitis after antibiotic therapy. Between 3% and 7% of healthy people are colonized with *C. difficile*, but the percentage increases among people hospitalized. *C. difficile* infection diagnosis is based on clinical manifestation and is confirmed by the immunoassay test for *C. difficile* toxins and PCR for bacterial DNA. A recent study showed that the exclusive use of PCR in the diagnosis of *C. difficile* infection without immunological tests for toxins may conduct to over diagnosis and overtreatment. The duration of diarrhea during treatment, rate of complications and mortality rate for patients Tox−/PCR+ were comparable to patients without *C. difficile* (Tox−/PCR−) and lower than Tox+/PCR+ patients. These findings suggest that the treatment is not necessary for patients who were positive by PCR testing but negative by toxin immunoassay (Polage CR, Gyorke CE, Kennedy MA, Leslie JL, Chin DL, Wang S, Nguyen HH, Huang B, Tang YW, Lee LW, Kim K, Taylor S, Romano PS, Panacek EA, Goodell PB, Solnick JV, Cohen SH. Overdiagnosis of *Clostridium difficile* infection in the molecular test era. *JAMA Intern Med*. 2015. doi:10.1001/jamainternmed.2015.4114).

BURNOUT OUT SYNDROM AMONG PUBLIC AMBULANCE STAFF (Abstract): Healthcare professionals are frequently confronted with urgent situations and a high-risk human intervention. They are usually exposed to what is called burnout syndrome. **Aim:** To identify the effects of burnout syndrome on the professional conduct and attitudes of doctors and nurses who work in the Romanian public ambulance service. Secondary, the causal relationships between burnout and various socio-demographic variables were analyzed. **Material and methods:** The 20-item Toronto Alexithymia Scale (TAS- 20), Maslach Burnout Inventory and Job Satisfaction Questionnaire were administered to 122 ambulance doctors, nurses and drivers (62 females and 60 males). **Results**: The degree of job satisfaction is the most important indicator of burnout syndrome. Significant differences were found between low and high alexithymic subjects. Women are more susceptible to experience higher levels of burnout than men. The level of burnout is influenced by the combined effect of job satisfaction and alexithymia. **Conclusions**: Burnout syndrome is a common problem among people working in the emergency medical system. The causes of job-related burnout have to be identified in order to apply an appropriate level of burnout intervention program and to increase the efficiency of coping strategies. **Keywords**: ALEXITHYMIA, BURNOUT SYNDROME, MEDICAL STUFF, AMBULANCE SERVICE

The term "burnout" was first used in the USA in the '70s among employees of social care services. Typical symptoms of burnout are classified as: physical - fatigue, frequent headaches, gastrointestinal disorders, insomnia, changes in eating habits, lowered immunity and frequent infectious conditions, cardiovascular disorders, muscle disorders; psychological - feelings of guilt, negativism, low motivation, mood swings, irritability, low empathy and self-confidence, mnemonic disorders, and behavioral - frequently absent from or late for work, refusal of dialogue, a tendency to avoid telephone contacts and postpone meetings, low performance, conflicting relationships with family and friends (1, 2, 3). Studies in the field showed that work satisfaction and alexithymia correlate with the burnout syndrome obtaining important results for the understanding, as well as prevention of this phenomenon (4).

Despite the fact that initially burnout was not looked upon as a serious scientific topic, research on it started to flourish from the beginning of the 1980s. From 1975 to

1980, the number of articles published on burnout increased from 5 per year to over 200. Since the beginning of this century, over 6000 articles on burnout have been published (1). Significant aspects of burnout have been studied at length in countries with a tradition in business development, especially from the perspective of preventing and treating such symptoms. Three quarters of employees believe that occupational stress is more significant nowadays than it used to be for the previous generation. Workplace problems are more strongly associated with health complaints than with any other problem, for example, financial or even family problems (5, 6).

Researches were focused on specific groups, the representative ones targeting workers in healthcare (doctors and nurses), social care services, education and students (7,8,9,10).

Comparative studies between risk groups in the same professional field were conducted in various countries, such as Canada and the Netherlands, and the results indicated that the levels of exhaustion and depersonalization of Canadian teachers were higher than those of their Dutch colleagues (11).

In Switzerland, for instance, there are specialized clinics for the recovery of individuals affected by burnout. People take action in order to address this issue without being or feeling stigmatized. In countries like USA, the Netherlands or Spain, burnout is acknowledged as a temporarily disabling condition and people receive specialized help in order to overcome this situation and regain socio-professional functioning (2). Burnout is a transient state, but one that cannot be overcome without taking certain measures.

In Romania, a study conducted in 2007 by Competent Consulting, European Commission agency, on a sample of 2000 subjects showed that 40% of them were affected by occupational stress and 39% by burnout at emotional level (12). In our country the key issue at stake is correct identification of burnout, as it is commonly mistaken for depression or chronic stress, seeing as there is no "tradition" of treating this problem. The burnout syndrome has no immediate manifestations, but appears as a gradual reaction to emotional exhaustion and prolonged exposure to stressors, which, in their turn, lead to a higher degree of dehumanization and professional dissatisfaction (13).

The rising incidence of the burnout phenomenon in Romania caused an increase in specialist interest in this field. Most research work is focused on healthcare professionals: one third of anesthesiologists (mostly women) included in a study conducted in 2012 showed that high levels of exhaustion, daily concerns and workload were the major predictors of depersonalization (14,15).

MATERIAL AND METHODS

The aim of this research was to determine the relationship between work satisfaction, alexithymia, length of service, gender and the occurrence of the burnout syndrome among public ambulance staff.

The research hypotheses were: 1. burnout syndrome in public ambulance staff varies in relation with the level of professional satisfaction and alexithymia, length of service and gender; 2. There are interaction effects between the independent variables level of professional satisfaction, level of alexithymia, length of service and gender and the dependent variable burnout.

The research variables of the study

were: the burnout syndrome as dependent variable and independent variables:

1. Job satisfaction, with two levels: low and high;

2. Alexithymia, with two levels: low and high;

3. Length of service, with two levels: 1-15 years and 16-35 years;

4. Gender: male and female;

5. Professional categories - auxiliary medical staff (nurses) and ambulance drivers.

A number of 122 ambulance doctors, nurses and drivers (62 females and 60 males) from two public ambulance services on North-Eastern Romania voluntarily accepted to participate in this study.

To measure alexithymia we used the 20-item Toronto Alexithymia Scale (TAS 20), which assesses alexithymia as a multifaceted construct, consisting of (1) difficulties in identifying emotions (DIF), (2) difficulties in describing emotions (DDF) and (3) externally oriented thinking style (EOT). TAS 20 consists of 20 self-descriptive statements, and has a good internal consistency (Cronbach alpha coefficient 0.85).

To measure the burnout phenomenon we used the MBI with 3 subscales: emotional exhaustion (the feeling of being emotionally exhausted and depleted by one's work); depersonalization (emotional coldness and impersonal reactions towards the recipients one's service), personal accomplishment (feelings of competence and accomplishment in working with other people).

To assess professional satisfaction we used the Work Satisfaction survey. This includes four factors: Remuneration and promotion (Cronbach alpha =0.820); Leadership and interpersonal relationships (Cronbach alpha =0.760); Organization and communication (Cronbach alpha =0.738). The Cronbach alpha coefficient for the entire survey was 0.872.

RESULTS

Important interaction effects were found between the level of professional satisfaction, level of alexithymia, length of service and gender and the results of the dependent variable burnout:

a. there is a combined interaction effect between the level of professional satisfaction and the level of alexithymia on the burnout variable ($F(3.118)=7.25$; $p= 0.008$), subjects with low levels of professional satisfaction and high alexithymia having the highest burnout values;

b. there is a combined effect of gender and alexithymia on burnout level ($F(3.118)=4.34$, $p=0.03$), female subjects with high alexithymia having the highest burnout values;

c. there is a combined effect of professional satisfaction and length of service on burnout level ($F(3.118)=11.79$, $p=0.001$), subjects with lengths of employment of over 16 years and low professional satisfaction having the highest burnout values;

The second hypothesis emphasizes the relationship between the burnout syndrome in healthcare professionals working in emergency care services and the level of professional satisfaction, level of alexithymia, length of service and gender.

a. relationship between burnout and the level of professional satisfaction. Results obtained after using t tests on independent samples emphasize the fact that there are significant differences between subjects with high levels of job satisfaction ($M=22.13$) and subjects with low levels of job satisfaction, in what concerns the perceived degree of burnout ($t (120) = 6.56$,

p=0.000), in that subjects with high levels of job satisfaction have lower levels of burnout syndrome (M=22.13), compared to subjects with low levels of job satisfaction (M=42.81);

b. relationship between burnout and the level of alexithymia. The *t test* for independent samples reveals significant differences (t (120) = -2.65, p=0.000) in the level of burnout depending on the level of alexithymia, in that those with high levels of alexithymia have higher burnout levels (M=38.23) than those with low levels of alexithymia (M=28.79);

c. As to the influence of the variable length of service on the perceived level of burnout, the research hypothesis was not confirmed;

d. The last hypothesis of the study, which claims that there is a significant female-male difference in burnout, was confirmed. The *t test* for independent samples (t (120) = -6.37, p=0.000) shows that female subjects (M=43.39) have higher levels of burnout than male subjects (M=23.25);

e. there are no significant differences between the perceived burnout and subjects' professional categories (nurses and ambulance drivers).

CONCLUSIONS

Our study emphasizes the fact that the level of professional satisfaction is an important indicator of the emergence of burnout syndrome; the higher the level of job satisfaction, the lower the possibility of becoming the victim of an "internal combustion" (burnout). We may talk about a causal relationship between professional satisfaction and burnout. Much like professional satisfaction, alexithymia also plays a major role; a high level of alexithymia is associated with a high level of burnout, because the inability to identify and express emotions often leads to estrangement from others and from oneself. Alexithymia causes many problems which hinder man's normal functioning in society. Women are more likely to exhibit higher levels of burnout than men. This fact may be explained in terms of gender differences, which make women a lot more susceptible; they tend to be more emotionally involved in their work, to show more soft spots for their patients, and to be more subjective.

ATRIAL FIBRILLATION FROM THE PATHOLOGIST'S PERSPECTIVE

Atrial fibrillation (AF) is the most common sustained arrhythmia encountered in clinical practice. Electrophysiologically, it is characterized by a high rate of asynchronous atrial cell depolarization causing a loss of atrial contractile function and irregular ventricular rates. For a long time, AF was considered as a pure functional disorder without any structural background. Only in recent years, new mapping and imaging techniques have identified atrial sites which are predominantly involved in AF initiation and maintenance, i.e., the pulmonary veins (PVs) and the surrounding left atrial posterior wall of the myocardium. Morphological analysis of these myocardial sites has demonstrated significant structural remodeling. This architectural myocardial disarrangement is induced by the arrhythmia itself and the associated cardiovascular disorders. At the same time, the structural remodeling is also capable of sustaining AF, thereby creating a sort of pathogenetic vicious circle. This review focuses on current understanding about the structural and genetic bases of AF with reference to their classification, pathogenesis, clinical implications and cure. Ablation procedures performed in these specific left atrial sites has very often proved efficient in restoring sinus rhythm in patients suffering from AF. In conclusion, AF itself and the associated cardiovascular disorders are capable of inducing in the atrial myocardium various degrees of remodeling at the histologic and ultrastructural level. The extent of structural remodeling goes hand in hand with the clinical history of AF. As the disease evolves from paroxysmal to chronic, this remodeling spreads to larger portions of the atrial wall often making both classic antiarrhythmic drugs and ablation of the sole PV outlets ineffective. On this basis, the most urgent strategy is preventing the structural remodeling—with special regard to interstitial fibrosis, by early treatment of the arrhythmia as well as its underlying cardiovascular diseases (Corradi D. Atrial fibrillation from the pathologist's perspective. Cardiovascular Pathology 2014, 23: 71–84).

ASSESSMENT OF THROMBOPHILIC STATUS IN TYPE 2 DIABETIC PATIENTS: THE LINK BETWEEN PAI-1 POLYMORPHISM AND THE ONSET OF COMPLICATIONS

ASSESSMENT OFTHROMBOPHILIC STATUS IN TYPE 2 DIABETIC PATIENTS: THE LINK BETWEEN PAI-1 POLYMORPHISM AND THE ONSET OF COMPLICATIONS (Abstract): Diabetes is a very common disease characterized by a prothrombotic status involving both the chronic activation of the clotting system and a decrease in the endogenous fibrinolytic capacity. The existing data regarding the hemostatic alterations in diabetic patients are insufficient and contradictory due to the heterogeneity of the studied population, the presence of cardiovascular complications, glycemic status, other associated risk factors, and the type of treatment. The metabolic changes found in diabetic patients cause disturbances in platelet activity, hemostasis, endogenous fibrinolysis and rheology favoring a prothrombotic status. These systemic changes may lead to an extensive atherosclerotic process derived from the thrombophilic status, thus partially explaining the frequent coronary atherosclerosis in type 2 diabetic patients. Moreover, the hemostatic alterations seen in diabetic patients seem to be responsible for the microvascular localization of coronary atherosclerosis. Recent studies indicate that increased PAI-1 levels are correlated with an increase in the incidence of diabetes mellitus and its complications, such as diabetic neuropathy, diabetic retinopathy and ischemic cardiomyopathy. PAI-1 is synthesized both by endothelial cells and hepatocytes. Endothelial cell activation causes an increase in tissue thromboplastin secretion, a decrease in thrombomodulin expression, a diminished tissue plasminogen activator synthesis and an increase in PAI-1 production. Despite all this, the data regarding the association between PAI-1 levels and the incidence of diabetes mellitus remain unclear. **Keywords:** TYPE 2 DIABETES MELLITUS, THROMBOPHILIC STATUS, PAI-1 POLYMORPHISM.

Diabetes is a very common disease that is characterized by a prothrombotic status involving both the chronic activation of the coagulation system and a decrease in endogenous fibrinolytic capacity. The studies comparing the prevalence of coronary diseases in diabetic and nondiabetic patients showed a threefold higher incidence of atherosclerosis, with an earlier clinical onset and a twofold higher cardiovascular risk in diabetic patients.

Hyperlipoproteinemia, platelet activation and changes in fibrinogen levels seem to play an important role in the onset and progression of diabetic complications. The existing data regarding the hemostatic

changes in diabetic patients are insufficient and inconclusive due to the heterogeneity of the studied population, presence or absence of cardiovascular complications, glycemic status, other associated risk factors, and the type of administered treatment received (1).

It is well known that the vascular diseases in diabetic patients have a multifactorial etiology, being influenced by the changes in thrombosis and thrombolysis balance, consisting mostly in the activation of the thrombotic process, thus leading to ischemic complications.

The association of increased LDL-cholesterol levels, abnormal trigliceride levels, small and dense LDL-cholesterol particles and diminished HDL-cholesterol levels leads to the atherogen lipoproteic phenotype, which is correlated with an early onset of coronary disease and extensive atherosclerosis process in type 2 diabetic patients. Moreover, small and dense LDL particles seem to be a marker for a series of anomalies including the decrease of HDL-cholesterol levels, the increase in apoB concentrations, diminished insulin sensitivity and procoagulant anomalies (increased PAI-1 levels) (2). The association between the atherogenic lipoproteic phenotype and other proatherogenic anomalies is suggestive of a genetic predisposition. Therefore, in 1990 it was proven that the genetic locus responsible for small and dense LDL particles is also associated with increased trigliceryde levels, apoB, VLDL and IDL levels and decreased HDL-cholesterol and apoA1 levels. Even more, genetic linkage studies showed that LDL particle size and HDL and LDL cholesterol levels are correlated with an allele of hepatic lipase gene. The genetic mutations affecting the *Cholesteryl Ester Transfer Protein* (CETP) locus situated on the 16 th chromosome can influence, through its role in the reverse transport of cholesterol, the LDL size and trigliceryde levels (3).Furthermore, there is a constant relation between the atherogenic lipoproteins (oxidized LDL and LP(a)) and the vascular endothelium, thus leading to a diminished fibrinolytic process. The effect is an imbalance between coagulation and fibrinolysis that favors thrombosis which eventually causes the occurrence of thrombotic complications (4,5).Hypercoagulability in type 2 diabetes mellitus seems to result especially from the synthesis of factors that activate the coagulation system and factors that inhibit fibrinolysis (such as factor VII or PAI-1). The hemostatic anomalies in type 2 diabetic patients may also reside from the synthesis in the adipose tissue of inflamatory citokines that can also mediate insulin resistance, such as IL-6 and TNF-alpha (6).

ASSESSING THE PROTHROMBOTIC STATUS IN TYPE 2 DIABETES MELLITUS PATIENTS

Recent studies showed that both endogenous fibrinolytic parametres and platelet activity are changed in type 2 diabetic patients at increased cardiovascular risk. The metabolic alterations that cause a change in rheology, platelet activity, hemostasis and endogenous fibrinolysisfound in diabetic patients favor the occurrence of a thrombophilic status. These changes can cause an extensive atherosclerotic process derived from the thrombophilic status, thus partially explaining the frequent coronary atherosclerosis in type 2 diabetic patients. Even more, the hemostatic alterations seen in diabetic patients seem to be responsible for the microvascular localization of coronary atherosclerosis (7, 8).

The plasminogen activator inhibitor-1 (PAI-1) belongs to the serine protease inhibitor superfamily, and plays a key role in the regulation of extracellular matrix degradation. Studies have indicated that the increase in PAI-1 level was related to the incidence of diabetes mellitus (DM) and its complications, such as an increased risk of diabetic nephropathy (DN), diabetic retinopathy (DR) and diabetic coronary artery disease (CAD). PAI-1 is synthesized by the endothelial cells and hepatocytes. Endothelial cell activation determines an increase in tissue thromboplastinsecretion, a decrease in thrombomodulin expression and an increase in PAI-1 synthesis. Some studies indicated the presence of elevated PAI-1 serum levels in diabetic patients (9).Structurally modified lipoproteins such as VLDL or LDL have the capacity of releasing PAI-1, thus causing a decrease in the fibrinolytic plasmatic capacity, determined by a diminished conversion of plasminogen to plasmin. There are 5 identified polymorphisms of PAI-1 gene: -675 4G/5G, -844 A>G, Ala15Thr, Val17Ile and Asn195Ile; the presence of these polymorphisms may increase the cardiovascular risk in diabetic patients (10). The PAI-1 gene is situated on the 7 th chromosome and contains 8 introns and 9 exons. The 4G/5G polymorphism (the deletion/insertion of guanosine in the 675 position of the PAI-1 gene promoter) is a major genetic determinant of PAI-1 levels. Some authors suggested that the association of the 4G allele with other thrombophillic defects (such as factor V Leiden, prothrombin gene mutation, hyperhomocysteinemia, diminished protein C and protein S activity) increases the risk of thrombosis. In diabetic patients with coronary ischemic disease the presence of 4G/4G genotype was associated with an increased risk of sudden death.

LESSONS FROM CLINICAL TRIALS

Some of the oldest studies that evaluated the association between PAI-1 polymorphism and the risk of type 2 diabetes mellitus showed a positive correlation between the 4G allele of type 1 plasminogen activator and the risk of diabetes mellitus in Pima Indians, in this population the incidence of noninsulin-dependent diabetes being very high. On the contrary, some subsequent studies analyzing the Caucasian population did not manage to show an association between PAI-1 polymorphism and diabetes mellitus. A case-control study on 856 Tunisian patients with type 2 diabetes mellitus showed an increased incidence of 4G/4G genotype, thus suggesting that this polymorphism may be a prothrombotic risk factor associated with type 2 diabetes mellitus. Many studies analyzed the incidence of PAI-1 polymorphism in diabetic Asian patients, but did not succeed to prove a significant statistic correlation between 4G/5G allele and the risk of diabetes (6).

A meta-analysis published in 2013 analyzed the results of 9 studies including 1219 patients, from which 5 studies referred to Caucasian population, 3 studies included Asian patients and 1 study was conducted on Pima Indians. This meta-analysis demonstrated a slight significant statistic correlation between 4G/4G polymorphism and the risk of diabetes complicated with neuropathy. In the subgroup analysis by ethnicity, significantly increased risks were observed among the Caucasian population (for 4G/4G versus 5G/5G, for 4G/4G versus 5G/5G + 4G/5G). In the stratified analysis by average diabetes duration, PAI-1 variation was found associated with a high risk of diabetes retinopathy in patients with duration of diabe-

tes longer than 10 years (for 4G/4G versus 5G/5G).

Another meta-analysis conducted in 2013, consisting of 20 studies, tried to assess the relationship between PAI-1 polymorphism and the risk of developing diabetes mellitus and its complications. Therefore, 6 studies including 1333 patients analyzed the association between PAI-1-675 4G/5G polymorphism and the risk of diabetes, 7 studies including 1060 patients assessed the correlation between this polymorphism and diabetic nephropathy, 10 studies with 1327 patients evaluated the correlation with diabetic retinopathy and 4 studies with 610 patients measured the risk of coronary artery disease in type 2 diabetic patients. The results of this meta-analysis suggested that there is no conclusive association between PAI-1 4G allele and the risk of diabetes mellitus or of developing complications, no matter the type of the evaluated population or diabetes duration.

CONCLUSIONS

The existing data are rather contradictory, some studies suggesting that high PAI-1 levels are constantly present in patients with type 2 diabetes mellitus or with insulin resistance, other studies denying this hypothesis. PAI-1 675 4G/5G polymorphism determines the deletion/insertion of a single guanosine, thus causing the expression of an additional linkage DNA *situs* for a protein with a repressing role in the transcription process, which will have an increased role in PAI-1 plasma levels. Therefore, this polymorphism may become a genetic risk factor for diabetes mellitus. The elevated PAI-1 levels may be correlated with a high incidence of such diabetic complications as diabetic nephropathy, diabetic retinopathy and coronary artery disease, but the results of the existing trials remain unclear and inconclusive. In these conditions unrevealing new genes that contribute to the thrombophillic status present in diabetic patients remains an important fundamental research theme.

THE PROGNOSTIC SIGNIFICANCE OF P53, BCL2 AND MIB1 EXPRESSIONS RELATED WITH OTHER CLINICOPATHOLOGICAL VARIABLES IN SEROUS OVARIAN CARCINOMAS. A CLINICOPATHOLOGICAL STUDY IN PERITONEAL FLUIDS (Abstract): **Objective:** The first cytological study examining the expression of P53, BCL2 and MIB 1 expressions in correlation with other clinicopathological parameters in ascitic fluids of patients with serous ovarian carcinomas. **Materials and Methods**: Fifty women 35-75 years old were diagnosed cytologically and confirmed histologically after operation in the University Hospital of Crete. All carcinomas were serous type and eight(8) of grade I, eighteen(18) of grade II and twenty two (22) of grade III. All carcinomas were staged according to the Figo criteria. Fifteen (15) were of Figo stage III and thirty five (35) were of Figo stage IV. For p53 and bcl-2, staining was evaluated on a semiquantitative scale depending on the number of cells showing positivity. For MIB1, the percentage of positive nuclei was calculated. Main outcome measure(s): The expression of P53, BCL2 and MIB 1 (Ki 67) correlated with tumor grade and Figo stages were estimated by chi-square (x^2). **Results:** The expression of P53 and MIB1 were found to be statistically significant ($p<0,005$) correlated with Figo stage and tumor grade. A statistical significant correlation was also found between BCL2 expression and tumor Grade ($p<0,005$) but not between BCL2 expression and Figo Stage. The study found a high expression of P53 (64%) and MIB1 (72%) and an expression of BCL2 (48%) in ascitic fluid of patients with ovarian carcinoma. A statistically significant correlation between P53 and MIB1 expression correlated with tumor grade and Figo stage ($p<0,005$) and a statistically significant correlation between BCL2 expression and tumor grade but no with the Figo stage was found ($p<0.005$).There was a positive correlation between P53 and MIB1 .No significant association was found between P53 and BCL2 expression or MIB1 labeling index. **Conclusion(s)**: Our data show significant differences in the expression of these markers in ovarian tumors and suggest a possible role for these tumor-associated genes as supplemental tools in prognosis and further definition of the biologic potential of these tumors. **Keywords**: OVARIAN CANCER, P53, BCL2, MIB1, APOPTOSIS.

Cancer of the ovary is one of the most common causes of cancer deaths in women and continues to present a challenge despite advances in our knowledge of the disease

during the past 20 years. The etiologic factors involved in the pathogenesis of ovarian cancer are poorly understood (1).

Recent studies have emphasized the importance of programmed cell death or apoptosis in the maintenance of tissue homeostasis and pathogenesis of tumors (2).Tissue homeostasis is maintained by the balance between cell proliferation and cell loss. There is evidence that much of the cell loss observed is due to programmed cell death or apoptosis (3). Apoptosis is a distinct form of cell death that can result from the activation of a genetically regulated cell suicide program or from cell injury induced by various stimuli. Types of cell damage that initiate apoptosis include: 1) exposure of cells to ionizing radiation 2) hyperthermia 3) toxic exposures 4) viral infections 5) cytokines 6) chemotherapeutic agents.

Numerous genetic factors have been identified as important contributors to the regulation of both cell proliferation and apoptosis. Aberrant regulation of both these processes, which stems from the malfunctioning of such genes and their products, plays an important role in tumor growth and development. The P53 protein produced in response to DNA damage restrains cellular proliferation by binding to specific regions of DNA and regulates the expression of other genes responsible for the cell cycle arrest, DNA repair, and initiation of apoptosis. The P53 gene also regulates expression of the anti-apoptotic BCL2 gene (4). Mutations of the P53 gene constitute the most common molecular genetic change associated with many cancers, including ovarian cancers (5, 6). The BCL2 gene is located on chromosome 18, and encodes the BCL2 protein (7). BCL2 is unique among the proto-oncogenes, as it is located on the mitochondrial membranes and interferes with programmed cell death independently of its ability to promote cell division(8). BCL2 belongs to a still growing family, the members of which are able to form homo- or heterodimers with one another. The most important regulators of apoptosis are found among these dimmers (9, 10)

Proliferating cell nuclear antigen (PCNA) or Ki-67(MIB 1) is an axillary protein of DNA polymerase,an enzyme involved in the catalysis of DNA synthesis and repair. It has been shown that the total proliferative compartment of the tumor can be determined by the expression of this protein (11).

The present study examined the extent of apoptosis, apoptosis regulatory proteins P53 and BCL2 as well as the extent of tumor cell proliferation reflected by MIB1 expression in serous ovarian tumors.

MATERIAL AND METHODS

We studied, retrospectively, 50 women 35-75 years old (mean age 55 years) with serous ovarian carcinoma. All patients were referred and treated surgically at the University hospital of Crete in the Department of Gynecology and Obstetrics, diagnosed cytologically and confirmed histologically in the Department of Pathology-Cytology.

The cytological; histological determination was done by cytologist and pathologist and histological type and grade assigned according to the World Health Organisation Classification (12).All carcinomas were serous type and eight(8) of grade I, eighteen(18) of grade II and twenty two (22) of grade III, as determined by histopathology. All carcinomas were staged according to the Figo criteria. Fifteen (15) were of Figo stage III and thirty five (35) were of Figo stage IV.

For the immunocytochemical staining the following primary monoclonal antibodies were used. Monoclonal mouse anti – human P53 protein (DAKO) that labels wild type and mutant type P53 protein, monoclonal mouse anti-human BCL2 oncoprotein, clone 124 (DAKO) and Ki-67(MIB1), rabbit monoclonal expressed in G1-S-, M-, and G-2 phases of the cell-cycle(Thermo Scientific), at a dilution of 1/50, 1/50 and 1/200, respectively. A standard alkaline -phosphatase method (APAAP) was used with 1-h incubation in a microwave oven at 750 watts, 3 times. A very light hematoxylin counterstaining was performed before cell counting. Tissues from the respective primary serous tumors were used as positive controls. Peritoneal fluids with endometriosis from Yale series (University-based endometriosis referral center) were used as negative controls too. In each specimen (at least 500 cells) in ten high power fields (x 400) were examined (light microscopy).For the statistical analysis chi-square (x^2) test was used.

RESULTS

P53 accumulation was documented in 32 (62%) of the 50 cases showed a nuclear accumulation in more than 10% of neoplastic cells. Cytoplasm immunoreactivity was never encountered. P53 accumulation was positively correlated with grade (grade I 2/8, grade II 10/18, and grade III 20/24) ($p<0,005$) and Figo stage (stage III 6/15 and stage IV 26/35) ($p<0,005$) (tab. I).

BCL2 immunoreactivity

BCL2 immunoreactivity was observed in 24 (48%) of the 50 cases: it was restricted to the cell cytoplasm in more than 10 % of neoplastic cells.An inverse correlation, with grade was found (grade I 8/8 , grade II 9/18 and grade III 7/24) $p<0,005$ but no any correlation with Figo stage (stage III 7/15 and stage IV 17/35) (tab. II).

TABLE I

P53 expression and relationship with other clinical and pathological variables in ovarian carcinomas

Tumor Grade		
I	2/8(25%)	p<0.005

BCL2	<10%	1	0,676
MIB 1	<30%	2,499	0,004

DISCUSSION

The prognosis of advanced-stage ovarian cancer patients has remained largely unchanged over the past 20 years (13).The available clinical and pathological prognostic factors have thus far proven insufficient to clearly define prognostic subgroups of patients.

Several studies have been devoted to identifying novel prognostic indicators for ovarian carcinomas , but the actual prognostic and /or predictive implications of a variety of biological parameters (P53 gene aberration and protein accumulation, BCL2, tumor growth fraction and ploidy) in these malignancies are still highly controversial (14). It s exceedingly difficult to ascertain from the currently available data whether and/or the extent to which evaluation of the above parameters contributes to a better definition of the biology and clinical behavior of ovarian carcinomas, in addition to the information already provided by the conventional clinical (age, performance status) and pathological (histological type, grade and stage of the neoplasms, presence of ascites) prognostic indicators. The aim of this study was to access the prognostic and predictive implications of P53 accumulation, BCL2 expression as regulator of apoptosis and tumor proliferative fraction evaluated by the MIB 1 monoclonal antibody against the Ki-67 antigen in a series of 50 ovarian

carcinoma patients correlated with the grade and stage (15).

Our results in accord with previous reports (14,16,17,18,19,20,21) nuclear P53 accumulation was ascertained in more than 50 % of ovarian carcinomas and was found to be statistical correlated with the tumor grade and Figo stage. The possible prognostic value of P53 aberrations in ovarian carcinomas has been addressed in several studies, many of which documented an adverse prognostic effect of P53 protein accumulation and that nuclear accumulation of P53 protein in more than 10 % of neoplastic cells was significantly correlated with worse disease-free and overall survival (16).

In our study BCL 2 expression was found in 48% of our cases and in more than 10% of neoplastic cells was significantly correlated with the grade of the tumors but not with the Figo stage. In other studies BCL 2 immunoreactivity was not correlated with grade or stage of ovarian tumors (14, 1) but was related to histopathologic subtype, and positive staining was seen most frequently in serous (77%) and endometrioid (56%) carcinomas, but was less common in mucinous carcinomas (20%) (1).

This study clearly showed that MIB 1 was positively correlated with grade and stage of the tumors expressed in 72% of our cases and in more than 30% of the neoplastic cells. A positive correlation between MIB 1 labeling index and P53 accumulation was ascertained, whereas no significant association was found between BCL2 immunoreactivity and P53 accumulation or MIB 1 labeling index in accord with another previous study. (14)

Both P53 accumulation and MIB 1 immunoreactivity correlated significantly with a worse prognosis and a reduced overall survival but BCL2 expression has no independent effect on the survival of patients.

The molecular characterization of ovarian cancer in different subtypes is the cornerstone to build a personalized approach in the era of personalized medicine (22, 23, 24, 25, 26, 27, 28, 29, 30, 31).

CONCLUSIONS

Our results indicate that the simultaneous evaluation of p53 accumulation and MIB 1 labeling index (L. I.) has independent prognostic indications in serous ovarian carcinomas. Our data show significant differences in the expression of P53, BCL 2, and MIB1 in ovarian tumors and suggest a possible role for these tumor-associated genes as supplemental tools in prognosis and further definition of the biologic potential of these tumors.

MECKEL'S DIVERTICULUM - A RARE CAUSE OF INTESTINAL OBSTRUCTION IN ADULTS (Abstract): Although many people have Meckel's diverticulum, only some experience any symptoms, most under the age of 10. In adults it is usually asymptomatic but approximately 4% develop complications. Meckel's diverticulum is usually diagnosed in the first years of life and after that the risk of the complications decreases with increasing age, with no predictive factors for the development of complications. We describe the case of a 34-year-old man admitted in the emergency department with diffuse abdominal pain, nausea, flatulence and lack of transit for feces and gas. The patient had been previously operated for peritonitis due to a perforated ulcer. Clinical examination and paraclinical investigations (abdominal radiography and ultrasound) suggested the diagnosis of intestinal obstruction, probably produced by adhesions due to previous abdominal intervention. The diverticulum was resected using a linear stapler and the patient recovered without any complications. Small bowel obstruction due to Meckel's diverticulitis may be caused by entangled loop of small bowel around a fibrous cord, intussusception, volvulus, or incarceration within a hernia sac. The discovery of a Meckel's diverticulum complication in a mid thirties patient represented an intra-operatory surprise and is the peculiarity of the case. **Keywords:** MECKEL'S DIVERTICULUM, INTESTINAL OBSTRUCTION, COMPLICATION.

Meckel's diverticulum (MD) is an outpouching of the distal ileum, due to persistence of the congenital vitello-intestinal duct, located at the anti-mesenteric border, usually within 45-60 cm of the ileocecal valve (1).

Considered the most common congenital malformation of the gastrointestinal tract (present in 2-4% of population), it was first described in a paper published in 1809 by the German anatomist, Johann Friedrich Meckel (1781-1833), who characterized it as a remnant of the omphalo-mesenteric duct. In the fetal life, it connects the yolk sac to the intestinal tract and usually it obliterates in the 5th to 7th week of life. If this process fails, the congenital anomalies develop, leading to the residual fibrous cords, umbilical sinus, omphalo-mesenteric fistula, entero-cyst and most commonly, Meckel's diverticulum (2).

Meckel's diverticulum is lined mainly by the typical ileal mucosa as in the adjacent small bowel. However, other ectopic

tissue (most common gastric, duodenal, colonic, pancreatic, endometrial mucosa) may be found, usually near the tip (3, 4).

Although many people have Meckel's diverticulum, only some experience any symptoms, most under the age of 10. In adults it is usually asymptomatic but approximately 4% develop complications such as obstruction, due to the intussusception or adhesive band (14-53%); ulceration (less than 4%); diverticulitis; and perforation (2, 5, 6).

Tumoral transformation (carcinoid tumor, stromal tumor, carcinoma, adenocarcinoma), intra-ductal papillary mucinous adenoma of pancreatic tissue and vesico-diverticular fistulae are rare complications.

CASE PRESENTATION

We describe the case of a 34-year-old man admitted in the emergency department with diffuse abdominal pain, nausea, flatulence and lack of transit for feces and gas. The patient had been previously operated for peritonitis due to a perforated ulcer. Clinical examination and paraclinical investigations (abdominal radiography and ultrasound) suggested the diagnosis of intestinal obstruction, probably produced by adhesions due to previous abdominal interventions.

Exploratory laparotomy was decided and performed under general anesthesia and moderate dilation of the small bowel was discovered. During arduous adhesiolysis, an intestinal volvulus caused by the Meckel diverticulum adhesions was unveiled. It had an unusual length of over 20 cm and was torsioned in pelvis through massive viscero-visceral and viscero-parietal adhesions (fig.1).

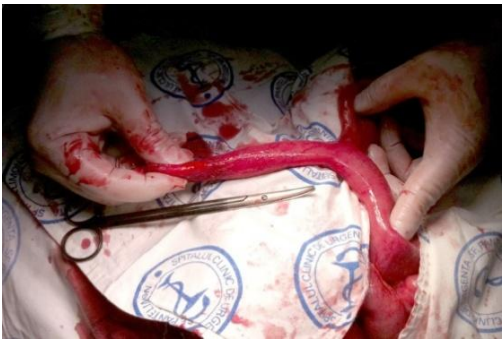

Fig. 1. Meckel's diverticulum after dissection and isolation

After cutting the adhesions and devolvulation, the diverticulum was resected using a linear stapler, fired at its base of implantation (fig. 2, fig. 3).

Fig. 2. Diverticulum resection using a linear stapler

Fig. 3. Final aspect of mechanical suture line

A peritoneal lavage was performed with dextran solution and mesenteric novocaine injection. The viability check confirmed that the intestinal loop regained its color and peristalsis. The patient recovered without any complications.

DISCUSSION

Meckel's diverticulum is usually diagnosed in the first years of life and after that the risk of the complications decreases with increasing age, with no predictive factors for the development of complications. Although the incidence of MD is equal in both sexes, complications are more frequent in men than in women, with a male-female ratio of about 3:1 (7, 8, 10).

Mackey (9) published a large retrospective study with a total of 402 patients with a diagnosed MD over a period of fifty years. Of all complications, 70.1% occurred in patients younger than 40 years of age. According to Ludtke (8), most diverticular complications were seen in children younger than 2 years of age. Leijonmarck (11) found a lifetime risk of complications from MD of 3.7% at 16 years, 2% at 30 years and almost zero when older. The more recently published Mayo clinic experience with 1,476 patients of Park (10) found significantly more symptomatic MD in patients younger than 50 years of age.

Adults develop obstruction or, less frequently, symptoms of inflammation. Hemorrhage is less common and is usually the result of heterotopic gastric or pancreatic mucosa causing ulceration. Small bowel obstruction due to Meckel's diverticulitis may be caused by entangled loop of small bowel around a fibrous cord, intussusception, volvulus, or incarceration within a hernia sac. Obstruction is usually demonstrable on plain films of the abdomen and the cause of the small bowel obstruction might be shown by CT. (5)

Due to the rarity of cases in adults, Meckel's diverticulum is still misdiagnosed preoperatively. The surgeon should always consider this if a patient has abdominal pain and/or vomiting and physical examination and ultrasonography findings are not suggestive of appendicitis or air-fluid levels are found on abdominal X-ray. If no surgical pathology is found during laparotomy, it is advisable to carefully inspect the small intestine, particularly the last segment, where Meckel's diverticulum is most commonly discovered.

CONCLUSIONS

The proper management of asymptomatic Meckel's diverticulum is still controversial. It is difficult to predict which fortuitous diagnosed patients can become symptomatic. Morbidity rates after resection of incidentally found MD are much lower than those after resection of symptomatic MD. The risk for future complications of a non-resected MD must be weighed against the risk of complications after a resection in order to justify a prophylactic approach.

The discovery of a Meckel's diverticulum complication in a mid thirties patient represented an intra-operatory surprise and is the peculiarity of the case.

NEWS

NANOFIBERS: AN IMPORTANT ALTERNATIVE IN THE TREATMENT OF WOUNDS CAUSED BY BURNS

Nanofibers and incorporation of antimicrobial compounds in these scaffolds are an important alternative way to control skin infections. The most common technique to prepare nanofibers is electrospinning. Nanofibers are produced from different polymers, treated in a specific manner to form threads with diameters from a few micrometers to nanometers. Also these structures can be used as drug delivery systems. The possibility to incorporate antimicrobial compounds to nanofibers, open a new perspective in biomedical engineering. Release of antimicrobial compounds, or other compounds that can accelerate the healing process, can be controlled by selecting polymers of specific composition. A localized delivery system is required to control the level and the rate of antimicrobial compounds delivered to the wounds. An example of drug delivery system is the incorporation of tanic acid on the surface of chitosan nanofibers, generated by electrospinning process. The antibacterial activity of chitosan is based on the damaging interaction of this polycation with the negatively charged surfaces of bacteria. In the same time, tanic acid inhibits bacterial growth for *Escherichia coli*, *Staphylococcus aureus* and *Pseudomonas aeruginosa*. With the involvement of scientific community, electrospinning became one of the most powerful tools for fabricating nanomaterials with a wide range of applications. (Xua F, Wenga B, Gilkersonb R et al. Development of tannic acid/chitosan/pullulan composite nanofibers from aqueous solution for potential applications as wound dressing. *Carbohydr. Polym*, 2015; 115: 16-24).

THE MEDICO-PSYCHO-SOCIAL IMPLICATIONS OF PREGNANCY DURING ADOLESCENCE (Abstract): The issue of maternity in adolescence is an important one due to the increasing number of adolescent mothers in our country, as well as in other countries, because of the risks involved by a pregnancy at this age, especially from a medical perspective, but also from a social one. **Material and methods**: The current study was conducted between 2012 and 2017 on a group of 103 adolescent mothers aged between 12 and 19 years of age, with a total of 109 children admitted to the Pediatric Recovery Department of Iasi "Sf. Maria" Emergency Hospital for Children. **Results**: The distribution of adolescent mothers by age was: 12%-12 years old, 10%-13 years old, 11% -14 years old, 12%-15 years old, 13%-16 years old, 14%-17 years old, 15%-18 years old, 15%-19 years old. Consideration was given to the existence of acute illnesses during the pregnancies for the mothers included in the study, the background, the level of education, the jobs and the marital status of the young parents, the birth weight of children, the Apgar score, the complications of the newborns, the Rh incompatibility between mother and child, etc. **Conclusions**: These data raise the need for an over-specialization – Infantile Obstetrics – that should deal with the issue of pregnancy in adolescents. In order to have a lower level of unwanted consequences on mother and fetus the close collaboration between the pediatric and the obstetrics sectors is very important for the pregnancy at this age group. **Keywords**: ADOLESCENT MOTHERS, PREGNANCY IN UNDERAGE WOMEN, ADOLESCENCE AND PREGNANCY.

Adolescent pregnancy is one of the most important public health issues today. It is a global phenomenon with both social and medical implications. It is defined as the occurrence of pregnancy in females under the age of 19 years. Annually, 16 million adolescents give birth to children and about 2 million of them are under the age of 15 years. In Romania, approximately 13 million newborns from mothers under the age of 19 were recorded in 2013. According to the National Institute of Statistics, around 90,000 girls aged 12-18 became mothers in 2009-2012 (1). UNICEF

data show that Romania is one of the top countries in Europe in terms of number of teenage births (2).

Pregnancy during adolescence involves several medical complications along the pregnancy as well as in the postnatal period, due to the immaturity of the organism at this age and the lack of medical education caused by the low level of schooling or poverty, which prevents the access to specialized medical consultations – most of the expectant mothers go to a doctor when they are in labor or they simply do not know they are pregnant until the second trimester (3, 4). What is even worse is that adolescents sometimes become multiparous mothers, which means even more medical complications. In addition, Romania is among the countries with the highest number of teenage pregnancies. The phenomenon is not so widely known, and the importance given to this issue is not as big as it should be (1, 3).

MATERIAL AND METHODS

The current study was conducted between 2012 and 2017 on a group of 103 adolescent mothers aged between 12 and 19 years of age, with a total of 109 children admitted to the Pediatric Recovery Department of Iasi "Sf. Maria" Emergency Hospital for Children. The data was processed using *Microsoft Excel* 2010.

Several variables were considered: the sex of the newborn, the background, the mother's age, the marital status, the level of education, the occupation, whether the pregnancy was medically monitored, the caesarean indication, the number of pregnancies, the number of deliveries, acute illnesses, chronic illnesses discovered during the pregnancy, the presence of risk factors, the place of birth, the mode of delivery, the presentation, the APGAR score at 1 minute and need to repeat it, the gestational age of the newborn, its weight and length at birth, the compatibility between mother and fetus, the presence of jaundice and its therapy, the type of diet, the treatments administered in the maternity hospital, the anthropometric data on admission to the Pediatric Recovery Department, the type of diet, the mode of administration, the weight gain obtained in the Pediatric Recovery Department, the number of days of hospitalization, pathogen carriage on admission to the Pediatric Recovery Department, treatment, the antibiogram conducted.

RESULTS

Most of these young mothers were secondary school students (58%), 21% were high-school or vocational school students, 21% graduated only 4-6 grades or are illiterate. Most pregnancies were not monitored from the health perspective (79%), some of the pregnant teenagers did not see a doctor before the moment of the delivery, while the rest of them, 21%, attended prenatal counseling, but rarely and very rarely. We also considered mothers' capacity to provide financial support to their newborns. Thus, 85% of mothers became homestay mothers after their children were born, dropping out of school; 15% continued their studies, but none of them had a job. Sometimes, during pregnancy or labor, there may be conditions that require the obstetrician to perform the caesarean section-thus, 76% had no indication for a caesarean section, while the rest of 24% required a caesarean section. 61% of mothers had another pregnancy in the past, 28% had 2 previous pregnancies, 9% had 3 previous pregnancies and 2% had 4 previous pregnancies (fig. 1).

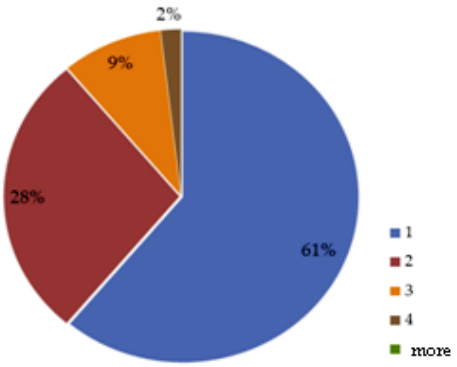

Fig. 1. Number of pregnancies among adolescent mothers included in the study

The number of deliveries for these mothers was also monitored. 71% of them had a previous delivery, 23%-had 2 previous deliveries and 6% had 3 previous deliveries. Consideration was given to the existence of acute illnesses during the pregnancies of the mothers included in the study: 91 of them had no acute illness, 3 of them had urinary tract infection, one of them had ureterohydronephrosis, one of them had pregnancy-induced hypertension, 3 of them had vulvovaginitis and 3 of them had anemia. Since a pre-existing pathology can influence the current pregnancy, the chronic diseases of these mothers were noted, as follows: 97 of them had no history of pathologies, 3 had mental retardation, one had neoplasm, one had lues and one had chronic anemia. 88% did not show risk factors, 2% consumed ethnobotanical substances, 5% smoked, 2% took medicines without medical indication and 3% drank alcohol. Regarding the place of delivery, 66% of deliveries took place at the "Cuza-Voda" Obstetrics and Gynecology Clinical Hospital in Iasi, 10% took place at the "Elena-Doamna" Obstetrics and Gynecology Clinical Hospital, 19% took place in other maternity hospitals in the Moldavian area and 5% were medically assisted in the ambulance. In terms of the type of delivery, 76% of the adolescent mothers delivered their babies naturally, the remaining 24% delivered their babies by caesarean section. There were various fetal presentations – 82% of the babies had a cephalic presentation, 13% had a pelvic presentation and 5% had a transverse presentation. APGAR scores were monitored one minute after birth: 7%-APGAR of 9-10, 54%-APGAR of 7-8, 16%-APGAR of 5-6, 12%-APGAR of less than 4; in 7% of the newborns, doctors were unable to identify the APGAR score. APGAR scores five minutes after birth: 13%-APGAR of 9-10, 61%-APGAR of 7-8, 14%-APGAR of 5-6, 3%-less than 4; in 9% of the newborns, doctors were unable to identify the APGAR score. The newborns of adolescent mothers were classified according to the gestational age and weight criteria: LBW-61%, VLBW-20%, ELBW-7%, ILBW-12%. For the length at birth, the statistical results are: 21%-between 32 and 40 cm, 50%-between 40 and 45 cm, 28%-between 45 and 50 cm and only 1% over 50 cm. The statistical data also included the presence / absence of maternal and fetal compatibility, with the following findings: compatibility in 41% of cases, incompatibility in 17% of cases and unknown in 42% of cases. In 69% of newborns, jaundice was present, while in 31% it was absent. 71% of the cases needed phototherapy, while in 29% of the cases it was not necessary. The newborn's diet in the maternity hospital was also considered to be of interest and was included in the statistical data: natural feeding in 1% of cases, mixed feeding in 18% of cases and artificial feeding in 81% of cases. At the time of admission to the Pediatric Recovery Department, the following investigations were per-

formed: 2%-nasal exudates, 1%-pharyngeal exudates, 1%-eye discharge, 14%-gastric aspiration; in 82% of the children, no investigations for pathogen carriage were performed. The germs identified in the investigations were: *Klebsiella spp.*-9%, E. coli-9%, *Pseudomonas aeruginosa*-6%, *Enterobacter spp.*-3%, *S. aureus*-5% and unidentified in 68 % of cases. In 30% of cases, antibiotic therapy and symptomatic treatment were performed. Weight on admission in the Pediatric Recovery Department: 27%-between 1,700 and 2,000 grams, 67%-between 2,000-2,500 grams and 6%-between 2,500-2,700 grams. In the Pediatric Recovery Department, the feeding mode was: 50%-gavage and bottle feeding and 31% of the cases –bottle feeding exclusively. The type of infant nutrition in the Pediatric Recovery Department was predominantly artificial (fig. 2).

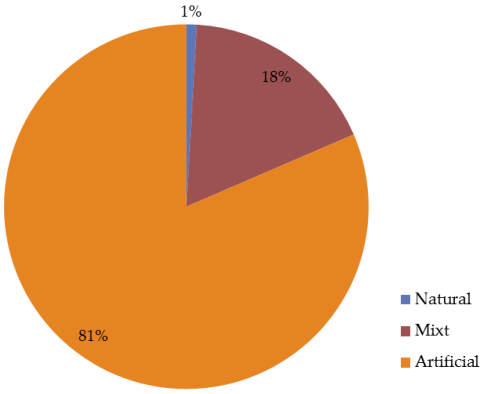

Fig. 2 The type of feeding received by the new born in the Maternity Hospital

The weight on discharge from the Pediatric Recovery Department was also monitored: 20%-between 2,000 and 3,000 grams, 58%-between 3,000 and 4,000 grams, 21%-between 4,000 and 5,000 grams and 1%-over 5,000 grams. The weight gain was also statistically determined in the Pediatric Recovery Department: 29%-between 100 and 1,000 grams, 53%-between 1,000 and 2,000 grams, 17%-between 2,000 and 3,000 grams and 1%-over 3,000 grams. The number of days of hospitalization within the department: 25%-between 9-30 days, 49%-30-60 days, 23%-60-90 days and 3%-more than 90 days. The sex distribution of neonates from teenage mothers includes 46% males and 54% females. In terms of place of origin, most of the teenage mothers come from rural areas: 75%. The distribution of teenage mothers by age groups: 35%-between 12 and 14 years, 39%-between 15 and 17 years, 26%-between 18 and 19 years.

DISCUSSION

A study conducted in 2011 in the US showed that pregnancy among adolescents and especially among those who are unmarried has medical and socio-economic effects on mother and child (1, 5). In another study conducted in India, all adolescent mothers were married. A child was generally conceived about 4-8 months after marriage (6, 7). A study conducted in Turkey showed that young mothers also give birth to children following sexual abuse, and built-up stress increases the risk of premature birth. The biological age of mothers shows the predominance of the age group between 17 and 19 years of age (8, 9). A study conducted in Timisoara showed that the predominant age at which adolescents become mothers is 16-17 years old (1). According to a study conducted in New York, teenage girls who get pregnant do not complete their middle school or high school studies, while those who continue their high school studies also show the desire to do post-secondary studies (1, 2).

Another study conducted in Romania shows that most adolescent mothers have completed their middle school education, but they do not continue with high school education (8). According to a study conducted in Finland and published in 2013, most adolescent mothers included in their database frequently participated in antenatal checks and tests (10). Another study conducted in Timisoara showed that the newborns generally came from pregnancies that were not medically monitored and that most of them were premature (6). A study conducted in Korea showed that pregnant teenagers saw an obstetrician very seldom compared to pregnant women who were not underage. 15% of the teenage mothers never sought any prenatal care service throughout their pregnancy. Regarding the teenage mother's occupation, most of them (85%) were homestay mothers, while the remaining 15% were students. Teenage mothers whose husbands did not work were more prone to be underweight compared to those whose husbands worked. Adolescent pregnancy is associated with socio-economic decline-most pregnancies occur in developing countries and in poor families (4, 7). A 8-year study conducted in the North Eastern part of Moldavia, published in 2014, showed that the number of cesareans was higher among adolescent mothers (natural birth: caesarean delivery ratio was 1:3). The cesarean distribution by age groups among adolescents shows that these girls are not physically prepared to become mothers (8, 10).

CONCLUSIONS

From our research we concluded that a pregnancy during adolescence is based on unstable ground, both from a psychosocial point of view (poor social and economic conditions, most of the young women belong to ethnic groups with early marriage, elderly partners, abuses, alcohol and drug consumption, the influence of the entourage and the media) and from a medical point of view – an immature body that supports a pregnancy (adolescence represents the period of sexual development paralleled by incomplete maturation, with the development of the gonads and the appearance of secondary sexual characters). The impact of pregnancy during this period is reflected both by the social impact on the mother (resulting in school dropout, repercussions on the mental state, depression, anger, stigmatization by others) and by several medical consequences both for the mother and for the fetus: improper conditions for development in intrauterine life – restricted intrauterine growth, abortion in intrauterine life – birth defects, low birth weight, prematurity, anemia, increased risk for malformations, predisposition to infection, impaired psychosomatic development, growth / speech difficulties, behavioral disorders and emotional dysfunctions. To have a lower level of unwanted consequences on mother and fetus, a close collaboration between the pediatric and the obstetrics sectors is very important for the pregnancy in adolescents.

NEWS

SURGICAL MANAGEMENT OF PERI-IMPLANT FEMORAL FRACTURES

Peri-implant fractures represent an important problem for the health system due to their increased incidence, the high average age of the affected population and the exorbitant costs that the treatment implies. As the number of implants used in orthopedics increases, it is inevitable that associated fractures become even more common. A significant increase is the number of trochanteric fracture nailing procedures accompanied by peri-implant femur fracture complications. A group from Czech Republic study and analyzed 849 patients with per trochanteric fracture, which had surgically managed with short nail and then analyzed those patients who suffered postoperative peri-implant fractures. Peri-implant fractures were divided into 3 groups according to the established classification, which served as a therapeutic guide. Following her study, they identified 21 postoperative femoral fractures (2.5%). They found 4 fractures(2 with locked nails and 2 with unlocked nails) in the distal portion of the femur, and 17 peri-implant fracture that occurred in the area of the nail and just below the nail tip. Of the 17 postoperative femoral fractures only one patient had distal dynamic locking. Based on this the risk of peri-implant fracture after unlocked distal nailing is higher than after locked nailing. In conclusion peri-implant fractures are a distinct topic in fractures. Trochanteric fractures with internal fixation and distally unlocked short nails does not prevent peri-implant fractures of the femur.We would draw attention to the potential risks associated with the omission of distal locking (Jiří Skála-Rosenbaum, Valér Džupa, Radek Bartoška, Pavel Douša, Petr Waldauf, Martin Krbec. Distal locking in short hip nails: Cause or prevention of peri-implant fractures. *Injury* 2016; 47(4): 887-892).

IMPROVED EXPERIMENTAL BURN MODEL ON RABBITS (Abstract): **Objective**: The goal of our study was to find an easy and suitable skin burn model for rabbits, to identify the temperature and contact time to reach a deep 2nd degree burn, and to find the best wound dressing fixation method. **Material and Methods**: We used New Zealand male rabbits as experimental models. On a pilot study, with a copper device heated to temperatures between 43-48 Celsius degrees, the burn was inflicted using contact times of 3, 4, 5, and 7 seconds. The burn depth was evaluated histological. Twenty-four rabbits were used to evaluate four dressing fixation methods: regular dressing with retention bandages; skin stapler; collars and body resin cast. **Results**: A 2nd degree deep burn was obtained at 43 degrees for 4 seconds. The retention elastic bandages were removed within hours and the skin staplers were removed with teeth leaving wounds on the skin. The collars were more successful but produced superficial neck lesions. The body resin casts were the most successful. **Conclusions:** The best contention method was the body resin cast. **Keywords**: SKIN BURN MODEL, RABBIT, DRESSING CONTENTION METHOD, BODY CAST

We aimed at finding the ideal experimental burn model to identify an animal with skin properties similar to humans and possibility of good wound dressing contention. On *Pubmed*, most experimental models are rats (1-5), Guinea pigs (6), rabbits (7-12) and pigs (13). In the last 15 years of searching on *Pubmed*, we have found few articles dealing with rabbit skin burn models. Finding a suitable burn model in animals is not an easy task. A review of the literature revealed several studies that attempted to describe a model of skin burns in rodents, most commonly using Wistar rats. Most did not explain how the dressings were kept in place without hurting the animal. Our goal was to find the proper temperature to produce a deep 2nd degree burn and to identify the best dressing contention method for rabbits.

MATERIAL AND METHODS

The study was performed on New Zealand male rabbits. The experiment was approved by the Ethics Committee of our institution and by the University of Agri-

cultural Sciences and Veterinary Medicine Ethics Committee and is part of a research national grant project.

Study design

A) We investigated the ideal temperature to reach a 2nd degree deep skin burn

Five male rabbits with an average weight of 2.5 kg were used to identify the ideal temperature to reach a deep 2nd degree skin burn. For the entire period, the animals were fed with rabbit food and water *ad libitum*. All procedures were performed under general anesthesia with intramuscular Ketamine 50 mg/kg and Xylasine 5 mg/kg.

Each rabbit had hair removed on each flank. A very fine and short hair of 0.20mm remained on the skin. For removing this hair, we used a commercial depilatory cream. The contact time with the cream was 25 minutes, according to the manufacturer's instructions. The cream was then removed and the skin was washed with water and then dried (fig. 1). For the next 24 hours no procedures were performed, allowing time for the skin irritation to disappear.

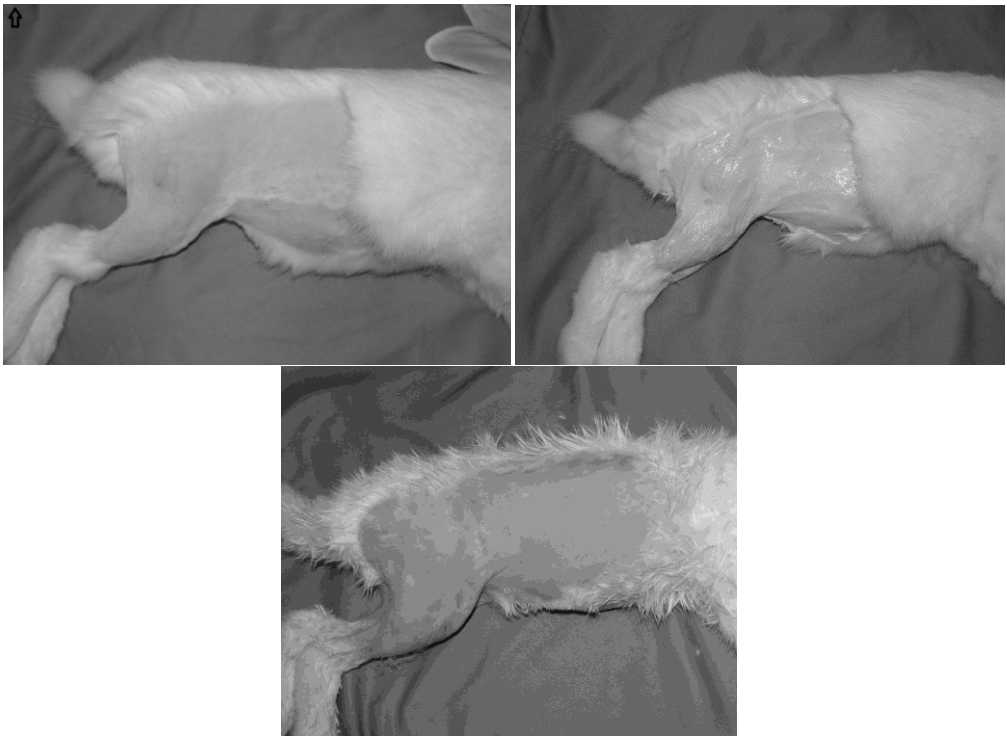

Fig. 1. Preparing the skin for the burn to be inflicted
A. The hair is removed with an electric shaver; B. The depilatory cream is in place; C. The skin appearance immediately after washing. Note some skin irritation.

The area to be burned was marked with a permanent skin-marker. Each animal had four burns, two on each flank (fig. 2). A 350 g copper device was used to inflict the burns (fig. 3). The device was introduced in boiling water and kept for 30 seconds. The temperature was measured using an infrared thermometer (Fluke 62 mini infrared

thermometer, accuracy: ±1ºC). When the device reached the desired temperature, it was applied. Because the copper has a better thermal conductivity compared with other materials, the temperature decreased slowly with an average of 1ºC per three seconds at room temperature.

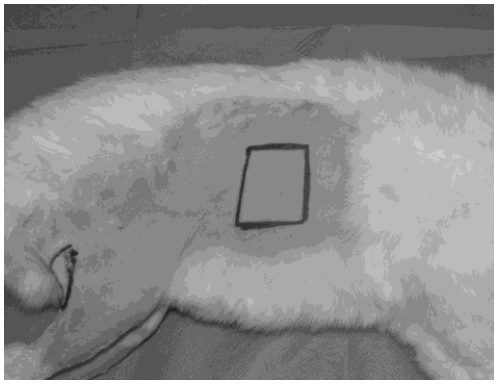

Fig. 2. The skin area to be burned is marked

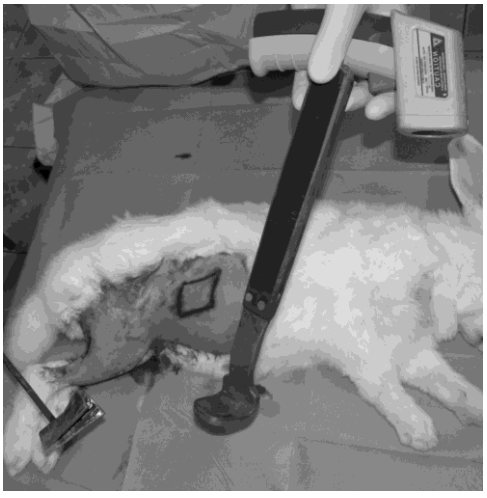

Fig. 3. The device used for the burn. The temperature was infrared measured.

All the procedures were performed under aseptic conditions, after cleaning the skin with diluted Povidone Iodine solution. No additional pressure was applied manually, except for the device's own weight. The device's copper volume was 19.28 cm^3 and the contact surface was 14.4 cm^2. Using contact times of 3, 4, 5 and 7 seconds and the device's temperatures of 43°C, 44°C, 45°C, 47°C, and 48°C (for each timing), burns were inflicted on the marked areas (two on each flank). The time between measuring the device's temperature to skin application was less than one second on a digital stopwatch.

The wounds were covered with dry gauze to keep them clean. On the third day, biopsies were taken from the burned areas to evaluate the depth. From each burned area one biopsy was taken.

B) Evaluation of the best dressing contention method

We compared four dressing contention methods on 24 New Zealand white male rabbits with an average weight of 2.5 kg, separated into 4 groups. Each rabbit's flank was inflicted with a burn.

Group I: We used the simplest method: dressing and retention bandages circumferentially (Peha Haft®, Hartman) (fig. 4). Each dressing was planned to be changed every 2nd day.

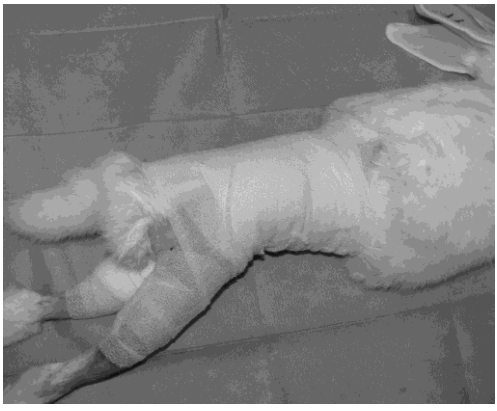

Fig. 4. Group I: Retention bandages placed circumferentially

Group II: The dressing was fixed with skin staplers (fig. 5) and retention bandages circumferentially (Peha Haft®, Hartman) applied on top. Each dressing was planned to be changed every 2nd day.

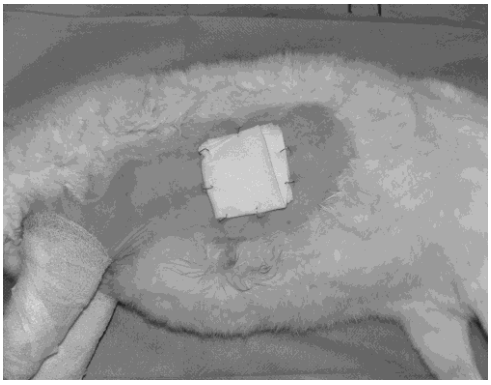

Fig. 5. Group II: The dressing fixed with skin staplers

Group III: The same as described in group II plus collars (fig. 6). Each dressing was planned to be changed every 2nd day.

Fig. 6. Group III: The collar in place

Group IV: The same as in group II, with fewer skin staplers and a body resin cast on top. The cast was placed circumferentially with narrower openings compared to the middle part. After the resin hardened, the cast was cut longitudinally and the sides connected with Omnifix® (Hartman) (partial elastic adhesive dressing) to allow better thoracic movement during respiration (fig. 7). The dressings were changed every 2nd day under general anesthesia for a period of 2 weeks.

Fig. 7. Group IV: Body resin cast placed circumferentially

RESULTS

A) The ideal temperature to reach a deep 2nd degree skin burn

The skin biopsies collected were histological evaluated and it was found that a deep 2nd degree burn can be obtained at 43° C for 4 seconds (fig. 8). Since the burn surface is not uniform, we considered a deep 2nd degree burn if more than 75% of the area was involved.

B) Evaluation of the best dressing contention method

Group I: The dressing fell down within hours after the rabbit woke up. The dressings were set again, but under a bit more tension. It was hard to find the proper tension in the retention bandages. This way, the dressings were in place, but four of the rabbits died 24 hours later. The autopsy revealed hemorrhagic ulcers in the stomach and bowel, most probably due to post-traumatic stress and administration of NSAIDs. Pleural effusion and pulmonary edema was associated. The treatment with

ketoprophen was stopped to the other groups and Phytomenadione and Omeprazole was initiated for the next days.

Group II: The dressings were in place for a longer time (hours up to one day). In the end all rabbits were able to remove them with the teeth.

Group III: The collars were useful and stopped the rabbits from removing the dressing for the next 48 hours. All the rabbits were very agitated and had superficial neck wounds at the site of collar. Their movements were highly restricted.

Group IV: This was the best contention method. After the first 48 hours, the cast was shortened in four rabbits, in order to prevent pressure sores at the hip joint.

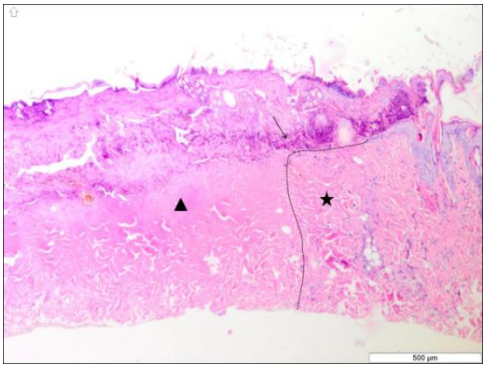

Fig. 8. Histopathology of full thickness skin damage, with ulceration and fibrinoleukocytic exudate. Severe, interstitial inflammatory infiltrate in the papillary dermis dominated by neutrophils, lymphocytes, and macrophages, delimiting the lesion (arrow). In the upper dermis there is linear fibroblastic and collagen proliferation along with newly formed blood vessels. Loss of normal architecture with homogenization of the collagen bundles in the reticular dermis (triangle). Perilesional normal skin (star) is delimited by dotted line. Hematoxylin and eosin stain, Bar=500µm.

After the dressings fell down twice in groups I-III, the contention method was changed to body resin casts and all animals (groups I-IV) were involved in a further study on topical creams for burn wounds.

DISCUSSION

Several types of burn models are described in the literature, most focusing on thermal injuries. Such injuries could be obtained after direct contact with hot water or with a hot surface. The contact temperature and the time are the main factors influencing the burn depth. There is a wide variety of reported contact temperatures and time to reach a 2nd degree burn.

Knabl et al (7) reported partial skin thickness burn on 9 New Zealand rabbits using an aluminum stamp of 85g heated up to 80°C and 14 seconds contact time. No details about the methods of dressing fixation were described. They recommend using rabbits of the same strain and weight in the anagen hair growth phase for better evaluation. Von Bullow et al (8) described a skin burn model on 10 New Zealand rabbits. Full thickness burns were achieved by the application of heated brass probes at 100°C for more than 30 seconds on the backs of the rabbits. No details about the weight and volume of the probe are described. According to the same author (8), superficial partial thickness burns can be produced with a contact time of 7 seconds. There are no data about the type of dressing. In their study on 15 rabbits, Aksoy et al (9) obtained 3rd degree skin burn injuries using a brass plate weighting 500 g, with a surface diameter of 3.5 cm. Before applying it to the skin, the instrument was left in boiling water at 100°C for 15 minutes. A contact time of 15 seconds was used to obtain a full thickness burn injury. It was mentioned that no topical antimicrobial treatment was applied. In this

study a delayed wound healing model was obtained by removing the *panniculus carnosus* layer, and three weeks later a 3rd degree burn was inflicted on the skin flaps.

Wang et al (10) obtained a full thickness burn area after 10 seconds of contact with 90-93°C water. The dressings on the burned areas were fixed with the tie-over method. No details about follow-up of wound dressing were reported. In another study on 16 New Zealand male rabbits where no burns were inflicted but full thickness wounds were performed to check different topical agents, the wounds were covered with a self-adhering wrap-around bandages. The rabbits were checked twice a day for the bandages to be in place and the dressings were changed daily without anesthesia.(11). The same type of dressing fixation was used by Jurjus et al in their study on deep 2nd degree skin burns obtained using an aluminum stamp heated to 80° and a contact time with the skin of 25 seconds (12). Unlike the study mentioned before, these dressings were changed after sedating the animals.

A possible explanation for this great variety of temperature and time can be explained by using different instruments for obtaining the burn, each with a different capacity for releasing the heat. Heated brass (1, 8, 9, 13), heated copper instruments (3), aluminum instruments (6, 7, 12), or even contact with hot water (10) were all tested to obtain an experimental burn model. It is important to know the time that elapsed from measuring the device's temperature until the inflicted burn. We chose to use a copper device because it has better thermal conductivity compared to other nonferrous metals or iron.

We decided to use rabbits for this experimental research, because they are larger than other rodents, easy to handle, and allow good follow-up. When working on small animals for burn models, some results can be negatively affected by the burn size. The contraction can be significant enough to alter the wound evaluation. In small animals the burn size can be a limiting factor for the experiment. Researchers dealing with different models of burns know that maintaining the dressings in place for a longer period of time (days) is a difficult task.

CONCLUSIONS

According to our results, this burn model seems to be better than those existing on rabbits and offer details about obtaining a deep 2nd degree burn and describes a good contention method. The best contention method was the body resin cast. We hope this information will be useful for those researchers working on rabbits.

DECLARATION OF INTEREST

Lucian Fodor is currently receiving a grant (PN-II-RU-TE-2011-3-002) from CNCS-UEFISCDI. Raluca Sobec, Codrin Dobreanu, Marius Fodor, Cristian Magdas are members of the same grant team. For the remaining authors none were declared.

CYTOLOGICAL ANALYSIS OF THE PERIODONTAL POCKET IN PATIENTS WITH AGGRESSIVE PERIODONTITIS AND CHRONIC PERIODONTITIS

Oral exfoliative cytology includes the study and interpretation of the features cells exfoliated from the oral mucosa. The aim of a study realized by a group of argentinian researchers was to analyze cytological changes in the periodontal pocket of patients with different clinical stages of aggressive periodontitis and chronic periodontitis. Patients, aged between 24-54 years, of whom 41 were diagnosed with aggressive periodontitis, 40 with chronic periodontitis, sub-classified as mild, moderate and severe periodontitis, and 40 healthy individuals who were the control group. For the cytological study were taken samples of the epithelium of the periodontal pocket. Superficial and intermediate cell values were significantly greater in patients with aggressive periodontitis than in patients with chronic periodontitis or the control group. Histiocyte number was higher in patients with chronic periodontitis than in those with aggressive periodontitis, and differed significantly in both types of periodontitis compared to the control group. There were significant differences in polymorphonuclear neutrophil leukocytes when both types of periodontitis were compared to the control group. Microbial flora was statistically higher in patients with chronic periodontitis, and there were differences between patients with periodontitis and the control group. The cytological study demonstrated that patients with aggressive periodontitis had greater tissue damage, shown by the increase in intermediate and superficial cells of the epithelium of the periodontal pocket compared to the group of healthy subjects and to a lesser extent, to patients with chronic periodontitis. Only superficial cells made it possible to differentiate the sub-stages of the disease (Cecilia EC, Myriam AK, María EL. Cytological analysis of the periodontal pocket in patients with aggressive periodontitis and chronic periodontitis. *Contemp Clin Dent*, 2014; 5(4): 495-500).

THE PSYCHO-EMOTIONAL PROFILE OF THE HIV-POSITIVE NAÏVE PATIENT (Abstract) **Aim:** The paper aims to outline the naïve HIV-positive patient's profile, in terms of feelings and emotions post-diagnosis. **Material and methods**: The evaluation took place from January 2011 to December 2013 in the Psycho-social Assistance Office of the "Sfânta Parascheva" Infectious Diseases Hospital in Iaşi. We evaluated 146 patients newly diagnosed with HIV infection, both in terms of immunological and virusological and from a psychological perspective, using the Hamilton Anxiety Scale (HAMA), Beck Depression Inventory II (BDI) and the clinical interview. **Results**: In a period of 3 years (January 2011 - December 2013) we registered in the HIV/AIDS Regional Center in Iaşi, 146 new cases of HIV infection in adults, with distribution by years as follows: 46 in 2011, 45 in 2012, 55 in 2013; 39 cases were in Iaşi, 39 in Suceava, 26 in Botoşani, 18 in Neamț 18, 16 in Bacău and 6 in Vaslui. Of these, 51 were women and 95 men, aged between 24 and 46 years. From the immunological point of view, 11% of patients had values of CD4 > 500 (16 patients), 47 % between 500 and 100 (69 patients) and 42 % < 100 (61 patients). From a psychological perspective, the clinical interview revealed a state of fear in 68.5 % of cases (fear of death, fear of complications, fear of other people's reaction to the diagnosis), confusion in 62 % of cases (in terms of diagnosis, the mode of infection, the future), anger in 27 % of cases (against the source of infection, against themselves, against God or divinity), guilt and self-blame in 7 % of cases. Beck Depression Inventory (BDI) revealed moderate depression in 14% of patients; mild depression in 27% of patients and 58 % of patients presented no symptoms of depression. Regarding the anxiety scale HAMA, in 54 % of cases it showed mild anxiety, average anxiety in 28 % of cases, 14% severe anxiety and 3% (4 cases) very severe anxiety. **Conclusions**: Patients newly diagnosed with HIV are a vulnerable population with a specific psycho-emotional profile. Multidisciplinary knowledge - in medical, psycho –emotional and social terms – of the patient's characteristics and needs helps to support adherence to the antiretroviral therapy and improve the quality of life. **Keywords:** HIV/AIDS, NAIVE PATIENT, PSYCHOLOGICAL PROFILE, ANXIETY, DEPRESSION

The newly diagnosed HIV-positive patient (also known as naive) represents a challenge for both infectious diseases doctor and psychologist, in terms of proper management. In order to best treat the patient, it is important to establish a relation-

ship based on the knowledge and the understanding of his needs, expectations, and his distinct psycho-emotional profile (1).

On receiving the HIV-positive diagnosis, the patient experiences a series of specific emotions: first, denial of the disease; then anger towards himself and others; this is followed by bargaining or "negotiation" of different aspects of the disease; after that comes the depression, the sense of "losing everything"; the last stage is acceptance, when the patient fully understands the HIV diagnosis and accepts it in his life (2). In most countries being HIV-positive is associated with stigma and discrimination, and that is why many patients feel that having contracted this disease is shameful and that it leads to social rejection – losing friends, social status, and ultimately their value as human beings (1, 2).

This is why the moment after the first HIV-positive diagnosis is critical in a patient's evolution. It is very important that the infectious diseases doctor work with a specially trained psychologist that can offer support and guidance to the naive patient. The psychologist can help the patient fully understand the impact that HIV/AIDS will have on his social and personal life and can also offer assistance in coping with the antiretroviral therapy (ART). This is one of the most difficult aspects of living with HIV/AIDS – having to take ART for the rest of one's life, and also coping with side-effects (3, 4).

In order to assist the newly diagnosed HIV/AIDS patient and to create the doctor-patient and psychologist-patient relationship, it is essential to understand the psychological and emotional profile of the patient. This paper aims to outline the naïve HIV-positive patient's profile, in terms of feelings and emotions post-diagnosis

MATERIAL AND METHODS

The evaluation took place from January 2011 to December 2013 in the Psychosocial Assistance Office of the "Sfânta Parascheva" Infectious Diseases Hospital in Iași.

Newly diagnosed patients, also known as naive patients, were evaluated in terms of immunological and virusological status and were also interviewed by the psychologist. After the clinical interview, they were also evaluated using the Hamilton Anxiety Scale (HAMA) and the Beck Depression Inventory II (BDI).

The Hamilton Anxiety Scale is of the first rating scales developed to measure the severity of anxiety symptoms. It consists of 14 items, each defined by a series of symptoms. It is designed to measure both psychological anxiety (mental agitation and psychological distress) and somatic anxiety (physical complaints related to anxiety) (5, 6).

The Beck Depression Inventory is one of the most widely used instruments for measuring the severity of depression. It is a self-report inventory and it consists of 21 questions with multiple-choice (7, 8).

In a period of 3 years (January 2011 - December 2013) we registered in the HIV/AIDS Regional Center in Iași 146 new cases of HIV infection in adults, with distribution by years as follows: 32% in 2011, 31% in 2012, 37% in 2013 (fig.1).

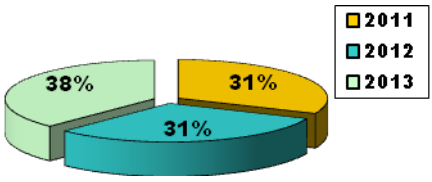

Fig. 1 Patient repartition in 3 years

Patients were admitted from all of the 5 counties in Moldova: 26.7% cases were in Iaşi, 26.7% in Suceava, 17.8% in Botoşani, 12.3% in Neamț, 10.9% in Bacău and 4.1% in Vaslui (fig. 2).

There was a higher percent of male patients – 65% men and 35% women (fig. 3), aged between 24 and 46 years.

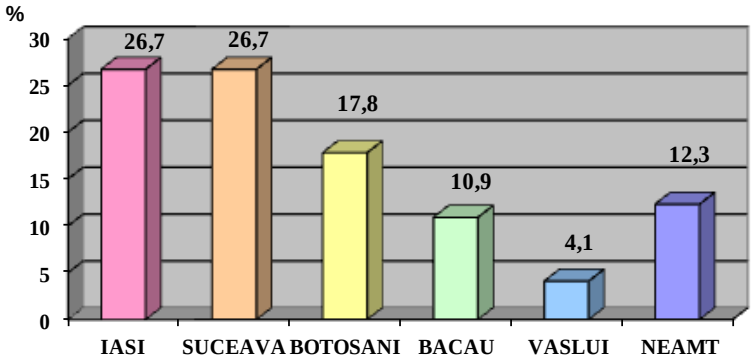

Fig. 2 Repartition in the Moldova area

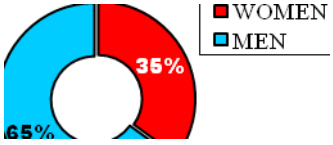

Fig. 3 Gender distribution

RESULTS

From the immunological point of view, 11% of patients had values of CD4 > 500 (16 patients), 47 % between 500 and 100 (69 patients) and 42 % < 100 (61 patients) (fig. 4).

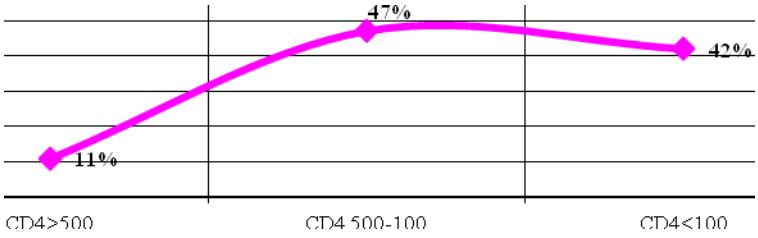

Fig. 4. CD4 cell count distribution

From a psychological perspective, the clinical interview revealed a state of fear in 68.5 % of cases (fear of death, fear of complications, fear of other people's reaction to the diagnosis), confusion in 62 % of cases (in terms of diagnosis, the mode of infec-

tion, the future), anger in 27 % of cases (against the source of infection, against themselves, against God or divinity), guilt and self-blame in 7 % of cases.

Beck Depression Inventory (BDI) revealed moderate depression in 14% of patients, mild depression in 27% of patients and 58 % of patients presented no symptoms of depression (fig. 5).

Regarding the anxiety scale HAMA, in 54 % of cases it showed mild anxiety, average anxiety in 28 % of cases, 14% severe anxiety and 3% (4 cases) very severe anxiety (fig. 5).

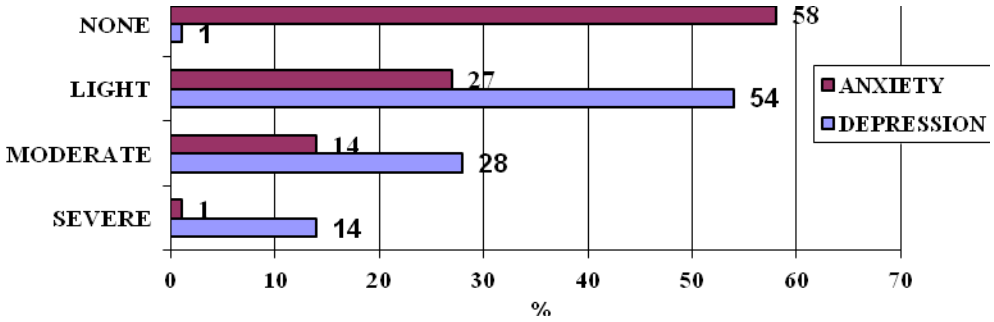

Fig. 5 Anxiety and depression evaluation

DISCUSSION

The number of new HIV/AIDS cases is continually increasing, with transmission mainly through unprotected sexual contact (homo- and heterosexual, prostitution) and use of unsterilized needles (drug users, tattoo and piercing) (9, 10).

In the North-Eastern part of Romania, the number of new HIV cases was large, with a rate of 35% per year, and many of the patients were in an advanced stage of the disease. The patients came from different backgrounds: multiple sexual partners, slow-progressers form the "pediatric cohort", homosexual men.

From a psychological point of view, they all had common emotional patterns: fear or lack of perspective for the future, lack of respect for one's self, sadness up to depression (11). Anxiety was high, and we believe this to be caused by both fear of dying and fear of social rejection.

A common emotion found in many of the patients in our study was guilt or shame. This is caused by a social phenomenon that associates HIV/AIDS with stigma, and leads to discriminatory behavior. In Romania, in spite of all the current existing information, AIDS is still, subconsciously, considered a shameful disease, contracted by marginalized populations that exhibit undesired behavior. With this in mind, the naive patient struggles to accept the positive diagnosis and not to consider him/herself as part of that discriminated group.

When establishing the best antiretroviral treatment, the infectious diseases doctor is obliged to offer the patient the best ART regimen catered to his or her needs. As specific as this treatment is, it only helps the patient at a molecular level. It is the psychologist's task to support the moral and emotional process of accepting the HIV diagnosis and beginning ART (12). The psychologist's expertise allows him to

guide the patient through all the five stages of acceptance of the diagnosis. This will have long term impact on the patient's adherence to therapy.

CONCLUSIONS

In our study, we highlighted the fact that patients newly diagnosed with HIV are a vulnerable population with a specific psycho-emotional profile.

Multidisciplinary knowledge - in medical, psycho –emotional and social terms – of the patient's characteristics and needs helps to support adherence to the antiretroviral therapy and improve the quality of life.

The psychologist's role is as important as the role of the infectious diseases doctor in managing the HIV-positive patient, due to his support and guidance in the continuous process of living with AIDS.

POLYCYTHEMIA VERA SYNDROME-AS A PROTROMBOTHIC STATE (Abstract): **The aim** of our study was to investigate whether the disorder of coagulation and fibrinolysis factors are mechanisms that contribute to the prothrombotic state in patients with polycythemia vera (PV) syndrome with or without cardiovascular disease (CVD), in order to identify the patients having high risk for thrombotic events. **Material and methods:** The study comprises 20 patients divided in 2 groups: 10 patients with PV syndrome (PV) and 10 pacients with PV and cardiovascular diseases associated (PV+CVD). The patients were tested by determining three factors of coagulation profile: protein S, free fraction (PS), antithrombin III (AT III) and Protein C (PC). **Results:** The level of the three parameters were found significantly modified in the both groups ($p<0.05$); comparing the results between the two groups of patients, in the second group (PV+CVD) the level of the parameters were significantly lower than in the first group (PV). **Conclusions:** In PV syndrome the risk for thrombosis is also due to the changes in coagulation factors. Patients with associated cardiovascular disease, present a more severe risk for trombothic events, so regarding the disorder of coagulation factors, this represent a major mechanism implicated in the etiology of thrombosis in these categories of patients. **Keywords:** THROMBOSIS, POLYCYTHEMIA VERA, PROTEIN S

Polycythemia vera (PV) is a clonal disorder arising in a multipotent hematopoietic progenitor cell that causes the accumulation of morphologically normal red cells, white cells, platelets, and their progenitors in the absence of a definable stimulus and to the exclusion of nonclonal hematopoiesis (1. 2). Described for the first time in 1892, polycythemia vera is not a new disease and while uncommon, with an incidence of at least 2 per 100,000 (3). Multiple factors are likely to contribute to the pathogenesis of thrombosis, including increased cell mass, possibly platelet number, activation of platelets and leukocytes and their interaction to form platelet leucocyte aggregates, in addition to prothrombotic circulating and endothelial factors. Endothelial activation may also have been due to elevated levels of vascular endothelial growth factor, which has also been reported to be elevated in PV (4. 5. 6). Activated leukocytes (neutrophils and monocytes) promote coagulation by release of granule contents, formation of aggregates with platelets. Subsequent effects include plate-

let leukocyte aggregates playing a pathogenic role in triggering monocyte tissue factor expression as well as superoxide anion and inflammatory cytokine release causing endothelial activation and damage. Besides the procoagulants mechanisms, the thrombotic risk is also amplified by the association of the other risk factors for thrombosis represented by advanced age, history of thrombotic vascular diseases, repeated phlebotomies, hypercholesterolemia and smoking (7, 8).

MATERIAL AND METHODS

The study comprises 20 adult patients, diagnosed according to Polycytemia Vera Study Group criteria, divided in 2 groups: 10 patients with PV syndrome (PV) and 10 pacients with PV with CVD associated (PV+CVD). Patients' age ranged from 61 to 80 years, significantly higher in the PV+CVD group ($p<0.05$). The old of the disease ranged from 1 to 4 years, significantly higher in the PV+CVD group ($p<0.01$).The patients were tested by determining three factors of coagulation profile: Protein S (PS), Antithrombin III (AT III) and Protein C.

RESULTS AND DISCUSSIONS

Protein S, Ag (PS): In the studied groups, the mean values of PS not significantly differ between genders, but in males from PV group, the mean values of PS are significantly lower than those observed in the PV+CVD group ($p<0.05$). In both studied group, it was observed a direct correlation between PS values and the patients' age; low values of PS were recorded in 66% of elderly patients from PV group and in 85% of elderly patients from PV+CVD group.

We have been observed a direct strong correlation between PS values and the age of the disease, both in the PV group ($r=0.76$) and in the PV+CVD group ($r=0.88$).

On the studied groups, comparing PS values, we have been observed the following characteristics:

- PS had the most homogeneous individual values in the PV+CVD group (12.15 CV%);
- in PV+CVD group, all of the patients had the PS values below normal limit (65%), significantly more cases compared with PV group (just 14 cases over limt) ($\chi^2=4.60$; GL=1; $p=0.027$);
- the mean values of PS are statistically significantly lower in PV+CVD group compared with PV group ($t=5.54$; GL=38; $p<0.001$). (fig. 1, 2, 3).

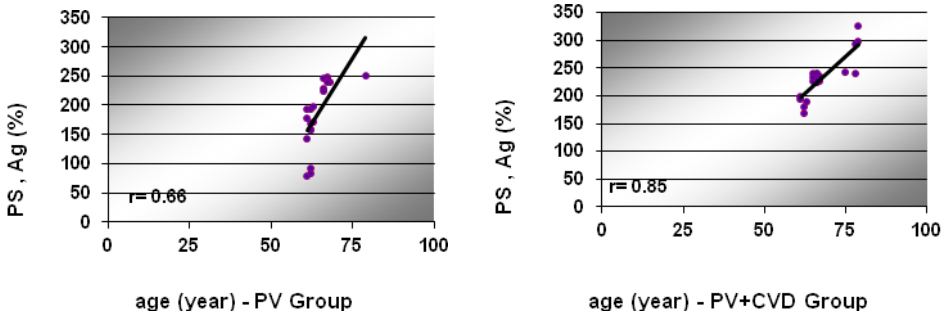

Fig. 1. Correlations between PS, Ag values and patients' age

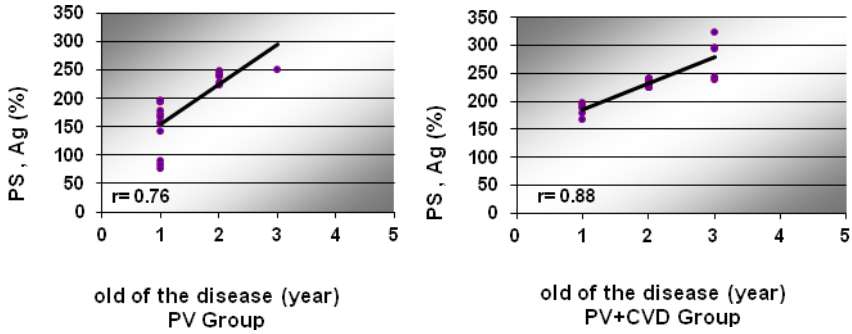

Fig. 2. Correlations between PS, Ag values and the old of the disease

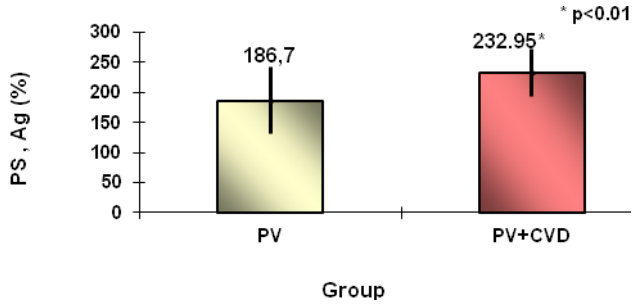

Fig. 3. The mean values of PS, Ag in the studied groups

Antithrombin III, Ag (AT III): On the studied groups, the mean values of AT III did not significantly differ between genders. On both studied groups, it was observed a direct correlation between AT III values and the patients' age; low values of AT III were recorded in 85% of elderly patients from PV group and in 89% of elderly patients from PV+CVD group.

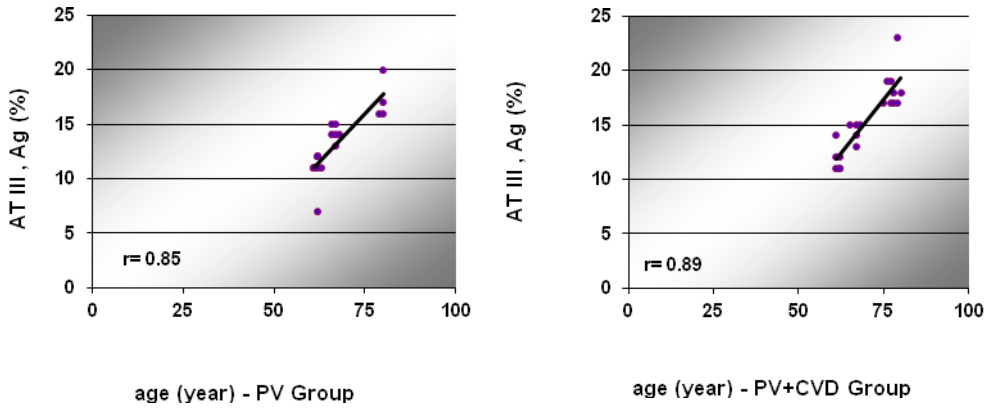

Fig. 4. Correlations between AT III, Ag values and patients' age

It was observed a direct strong correlation between AT III values and the age of the disease, both in the PV group (r=0.92) and in the PV+CVD group (r=0.89).

On the studied groups, comparing AT III values, we have been observed the following characteristics:

- the AT III individual values have a large dispersion, but the most homogeneous individual values was found in the PV+CVD group (12.66 CV%);
- we found the AT III levels below normal limits (65%) in all of the 20 patients from PV+CVD group and in 19 patients from PV group, without registering a significant statistically differences between these groups (χ^2=1.03; GL=1; p=0.311);
- the mean values of AT III are significantly lower in PV+CVD group compared with PV group (t=2.78; GL=38; p<0.05) (fig. 4, 5, 6).

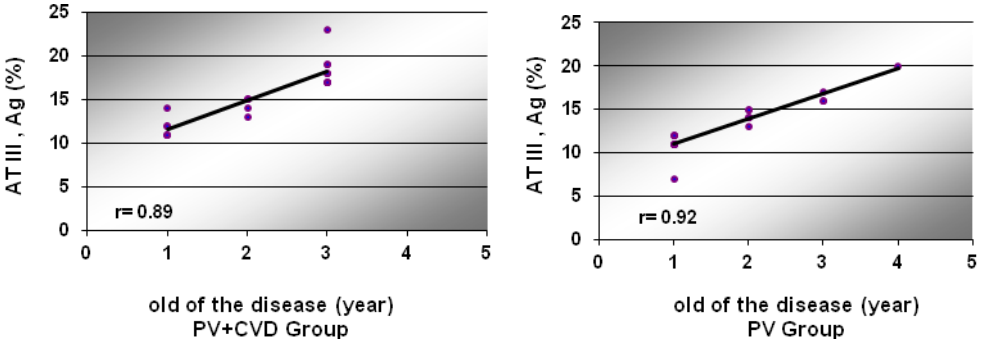

Fig. 5. Correlations between AT III, Ag values and the old of the disease

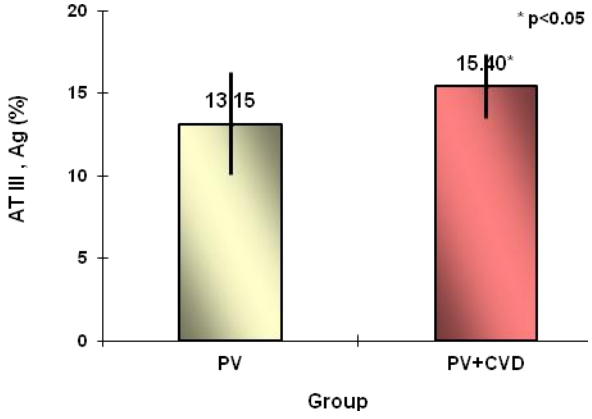

Fig. 6. The mean values of AT III, Ag in the studied groups

Protein C, Ag (PC): In the PV group, the mean values of protein C, Ag differ significantly between genders (p<0.05); in the PV+CVD group, in women, the values of this parameter are significantly lower compared with the values observed in women, from PV group (p<0.05). In both studied groups, it was observed an indirect

correlation between protein C values and the patients' age; low values of protein C were recorded in 79% of elderly patients from PV group and in 88% of elderly patients from PV+CVD group.

We also have been observed a strong indirect correlation between protein C values and the old of the disease, in both, in the PV group (r=0.84) and in the PV+CVD group (r=0.89).

On the studied groups, comparing protein C values, we have been observed the following characteristics:

- The variation of individual protein C, Ag values are large, but the most homogeneous series of values were found in PV+CVD group (14.49 CV%);
- We found the protein C, Ag level below normal limit (65%), in 18 patients from PV+CVD group and in 17 patients from PV group, without registering significant statistically differences between these groups (χ^2=0.23; GL=1; p=0.633);
- The mean values of protein C are significantly lower on PV+CVD group compared with PV group (t=2.42; GL=38; p<0.05) (fig. 7, 8, 9).

DISCUSSION

Thrombosis and bleedings are the major causes of morbidity and mortality in PV. Large vessel arterial thrombosis in PV involves the cerebral, coronary and peripheral arterial circulations, while microcirculatory disturbances may cause erythromelalgia and digital ischemia. This hypercoagulable state in the group of patients with PV, could in part be explained by the known hypercoagulable condition associated with malignancy, by increases in white blood cells (WBC) count, but polymorphonuclear (PMN) enzyme involvement is possible. Activated PMN release reactive oxygen species and intracellular proteases, which can act on the endothelial cells and platelets and may modify the hemostatic balance toward a prothrombotic state. Endothelial activation may also have been due to elevated levels of vascular endothelial growth factor, which has also been reported to be elevated in PV (9). Leukocyte elastase and cathepsin G can induce detachment or lysis of endothelial cells and can modify endothelial cell functions involved in thromboregulation-that prevent thrombin-induced prostacyclin production, induce plasminogen activator inhibitor release and proteolyze endothelial surface components such as thrombo-modulin (10). Furthermore, the potential thrombogenic effects of PMN-derived proteases include the direct potent platelet activation elicited by cathepsin G. Elastase can directly proteolyze and inactivate natural inhibitors of blood coagulation, including protein C, protein S, tissue factor pathway inhibitor, antithrombin, and heparin cofactor II. This inactivation may contribute to local progression of coagulation reactions at the inflammation sites (11).

CONCLUSIONS

In PV syndrome the risk for thrombosis is also due to the changes in coagulation factors. Patients with associated cardiovascular disease, present a more severe risk for trombothic events, so regarding the disorder of coagulation factors, these represent a major mechanism implicated in the etiology of thrombosis in these category of patients. We may hypothesize that hypercoagulable state associated with malignancy, increases in WBC count, endothelial dysfunction, and reduced levels of physiologic anticoagulants (antithrombin III, proteins C and S) and decreased fibrinolytic activity that in part may be secondary to increased plasma levels of plasminogen activator inhibitor could explain, the pathogenesis of the thrombo-philic state in PV.

NEWS

SERUM REACTIVITY TO *DEMODEX*-ASSOCIATED *BACILLUS OLERONIUS* PROTEINS IN ROSACEA PATIENTS

There is increasing evidence that suggests the role of *Bacillus oleronius*, isolated from within *Demodex folliculorum* mite in the induction of rosacea. A group of researchers tried to determine the correlation between the level of sebum and the density of *D. folliculorum* and the serum reactivity to the 62 and 83 kDa proteins of *B. oleronius* in patients with erythematotelangiectatic rosacea. Serum reactivity to *B. oleronius* proteins was detected in 82.6% of the rosacea patients compared to 26.9% of controls. In this group of patients, the level of sebum was lower and the density of *Demodex* populations on their faces was statistically higher than in controls, suggesting a potential role for this bacterium in the aetiology of rosacea (Jarmuda S, McMahon F, Zaba R *et al*. Correlation between serum reactivity to Demodex-associated Bacillus oleronius proteins, and altered sebum levels and Demodex populations in erythematotelangiectatic rosacea patients. *J Med Microbiol*. 2014; 63(Pt 2):258-62. doi: 10.1099/jmm.0.065136-0).

SELF-MEDICATION WITH ANTIMICROBIAL DRUGS AMONG UNIVERSITY STUDENTS IN A NORTHEAST REGION OF ROMANIA (Abstract): Self-medication with antimicrobial drugs is an important problem in the world and may lead to serious consequences for healthcare systems. **Objective:** To evaluate the prevalence and patterns of self-medication with antimicrobial drugs among university students in a Northeast region of Romania. **Material and methods:** A cross-sectional questionnaire-based study was conducted to collect data from medical and non-medical students who lived in residence halls. Data were analyzed using descriptive statistics and the chi-square test, when applicable. **Results:** Out of the 320 questionnaires distributed, a total of 281 students completed and returned the questionnaires. Among these, 115 (41%) respondents admitted to have used at least one antibiotic in the six months prior to the survey, 44% of whom did not seek medical advice (irrational self-medication). The most common antimicrobial drugs used for self-medication were amoxicillin (37%), amoxicillin-clavulanate (33%), ciprofloxacin and penicillin (14%) and the most frequently reported reasons for self-medication were respiratory and oral infections (31%), common cold (25%), and genitourinary infections (20%). Some students mentioned the use of more than one antimicrobial drug, for more than one disease. **Conclusions:** self-medication with antimicrobial drugs is a relatively common practice among students in Romania. This suggests the need for interventions to prevent the irrational use of antimicrobial drugs, such as the implementation of national programs for public education regarding the risks and consequences for the health of irrational use of antimicrobials. **Keywords:** SELF-MEDICATION, ANTIMICROBIAL DRUGS, STUDENTS.

Self-medication is defined as the use of any type of drug to treat self-diagnosed disorders or symptoms, without seeking the advice of a physician, either for diagnosis, prescription or surveillance of treatment. The World Health Organization (WHO) introduced the term "rational" self-medication, which limits the use of medications without prescription only to over-the-counter (OTC) drugs, thus helping prevent and treat minor illnesses that do not require medical consultation and save medical resources for more severe cases (1). Health authorities for each country have to ensure that only safe drugs are made available OTC and that patients have all the information regarding the drug usage, contraindications and side-effects (2-4).

Self-medication with antimicrobial drugs, a form of irrational use of medi-

cines, is a common phenomenon in many countries, with major implications for the public health: emergence of resistant microorganisms, particularly in developing countries, increased risk of drug interactions and side effects, treatment failures and prolonged hospital stays, wastage of medical resources and increased morbimortality. Self-medication is more common among the youth and it is associated with several factors related to modern society, such as less time for seeking medical advice, increased costs of medical consultations, poor compliance to treatment and aggressive pharmaceutical publicity (5-11).

Self-medication practices vary widely in different populations and previous studies have shown that age, gender, economic status, education level and medical knowledge are important predictors of self-medication (12-15). Students are a population of great interest regarding self-medication practices since they represent a privileged segment of the population, with access to information. Moreover, the attitude of medical students regarding self-medication may reflect in their future medical practice.

To the best of our knowledge, in Romania there are no studies regarding the self-medication practices with antimicrobial drugs among university students. Therefore, a cross-sectional study was conducted to evaluate the prevalence and patterns of self-medication with antimicrobial drugs among medical and non-medical university students. We aimed to describe the most common antimicrobial drugs used for self-medication and the ailments students treat with antimicrobial drugs.

MATERIAL AND METHODS

This cross-sectional questionnaire-based study was conducted on a sample of students from residence halls of two universities ("Grigore T. Popa" University of Medicine and Pharmacy and "Alexandru Ioan Cuza" University) from Iași, in the Northeast of Romania, from October to December 2011. The students were selected by convenient sampling. The study was approved by the Ethics Committee of the "Grigore T. Popa" University and written consent was obtained from each participant after a briefing on the objectives of the study.

The including criteria were: medical or non-medical students enrolled in the above-mentioned universities, aged between 18 and 31 years old, both genders, healthy. The non-medical students group included students in the first 2 years of medical studies, who did not study pharmacology and therapeutics. Information regarding demographic characteristics (age, gender, type and year of university studies, social environment) and antimicrobial drugs use in the six months prior to the study were collected through anonymous, self-administered questionnaires with open- and close-ended questions. The questionnaires, written in Romanian language, were pre-tested and validated on a sample of 100 students to determine the application time and to clarify possible questions from the students. If antimicrobial drugs use was confirmed in the previous six months, supplementary information was asked: the name antimicrobial drug, duration of the treatment, the person who recommended the treatment and the disease treated with antimicrobial drugs. The collected data were registered in a database and analyzed using SigmaPlot 11, descriptive statistics and the chi-square test in order to test the difference between proportions. A p value of less than 0.05 was considered significant. Some of the questions had multiple

answers; therefore the sum total of percentages is not always 100%.

RESULTS

Of the 320 questionnaires distributed, 281 students completed and returned the questionnaires, with a response rate of 87.81%. The demographic data of medical students and non-medical students are presented in tab. I.

TABLE I

Demographic characteristics of the respondents

Variable		Medical (n=141)	Non-Medical (n=140)
Age (mean±SD, years)		23 ± 1	21 ± 1
Sex	Male	38	18
	Female	103	122
Social environment	Rural	27	52
	Urban	114	88

Out of the 281 respondents, 115 (41%) reported that they had used at least one antibiotic in the six months previous to the survey. Antimicrobial drugs were used without medical advice (irrational self-medication) by 51 students (44%), while 64 students (56%) followed medical advice. Irrational antimicrobial drugs use was reported by 27 students (53%) as a self-recommended treatment, by 16 students (31%) according to pharmacist advice and by 17 students (33%) according to a friend or relative advice. Some students mentioned the use of more than one antimicrobial drug. There was no significant difference between medical and non-medical students (p=0.81) regarding the use of antimicrobial drugs in the six months before the survey. However, in relation to the source that influenced irrational self-medication, self-prescription was mentioned by 38% of medical students compared to only 9% non-medical students (p=0.003). These findings show that medi-

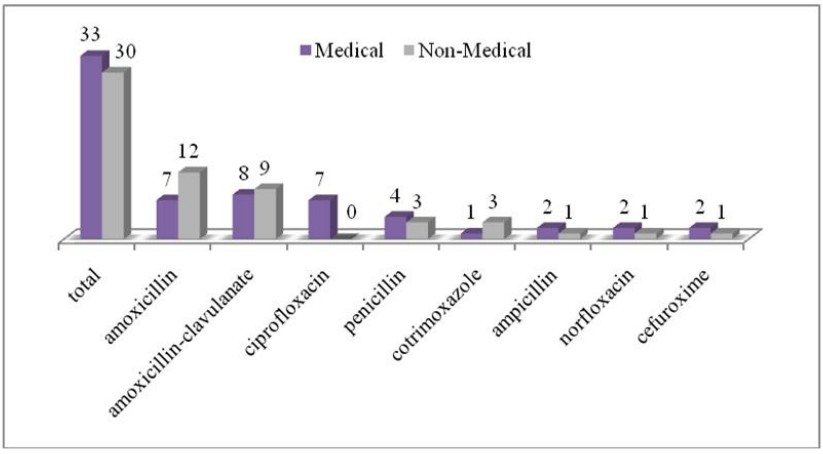

Fig. 1. The most commonly used antimicrobial drugs for self-medication (more than one antimicrobial drug were used by a person).

cal students are more confident in their knowledge regarding antimicrobial drugs use. Non-medical students mentioned pharmacists (19%) and friends or relatives (23%) for advice on antimicrobial drugs use compared to medical students, who mentioned taking the advice of the pharmacist and friends or relatives in 9%, respectively 7% of cases. There was a significantly higher prevalence of self-medication with antimicrobial drugs among students from urban areas (p=0.002) (fig. 1).

The majority of students reported self-medication with antimicrobial drugs for respiratory infections and oral infections (31%), common cold (25%), genitourinary infections (20%), while fewer students (8%) self-medicated for pain, fever, conjunctivitis, eczema or enterocolitis. Some persons mentioned more than one disease.

DISCUSSION

Despite the national regulations that restrict the dispensation of antimicrobial drugs without prescription, our study indicates a relatively high prevalence of irrational self-medication with antimicrobial drugs in the Northeast of Romania. Irrational use of antimicrobial drugs was reported in 44% of our students' population. This rate is lower than countries such as Ghana (70%) and similar to countries such as Turkey (44.1%) and China (47.8%) (10, 11, 14). Other studies on self-medication with antimicrobial drugs have focused on the general population and reported variable prevalence rates between 7.3% in Indonesia (5) and 77.9% in Greece (15).

Compared to the results obtained by Olayemi et al. (16), showing a very high (80%) prevalence of self-medication with antimicrobial drugs among students from Medical and Pharmaceutical sciences compared to 42.11% of students in Social Sciences and 27.78% of Engineering students, we found that medical students had a higher frequency (38%) of self-prescription of antimicrobial drugs compared to non-medical students (9%), who more frequently had followed the advice of the pharmacist or friends and relatives. Medical students from higher years of studies, attending courses of pharmacology and therapeutics, are generally more confident in their own knowledge regarding antimicrobial drugs use and, hence, mention self-recommended antimicrobial drugs more frequently. Of particular concern is the high percent of 31% of students advised by a pharmacist regarding the antibiotic use for self-medication. Though national regulations restrict the issuing of antimicrobial drugs without a prescription, it seems that regulatory authorities often lack resources to enforce them.

The main limitation of this study consisted in the self-administered nature of the questionnaires. Therefore, the data was based on information provided by students' recollection only. Since our study included only university students, who represent a well-informed group of individuals, our population sample may not be representative for the general population. Other limitations include the small sample group and its sampling frame based on convenience, which could be a source of possible bias.

CONCLUSIONS

The results of this study confirm that self-medication with antimicrobial drugs is a relatively common practice among medical and non-medical students in Northeastern Romania. Self-medication with antimicrobial drugs is associated with serious risks such as emergence of microorganism resistance, drug interactions and toxicity, wastage of medical resources and increase

in morbi-mortality. There is need for national education programs regarding the risks of irrational self-medication with antimicrobial drugs, particularly among students, who represent the young, well-informed population. Furthermore, we consider that there is need for a stronger enforcement of the regulations regarding the sale of antimicrobial drugs and the pharmaceutical publicity.

ACKNOWLEDGEMENTS

Special thanks to Dr. Ştefan Cristian Stănel for his help in developing the questionnaire and to the respondents of this survey.

DEVELOPMENT AND VALIDATION OF A SPECTROPHOTOMETRIC METHOD FOR QUANTITATIVE DETERMINATION OF NEW PRESERVATIVES FROM PHARMACEUTICAL FORMS (Abstract): **Aim**: A spectrophotometric UV-VIS fast, sensitive and simple method was developed for quantitative determination of two new antimicrobial preservatives (oxi-acetyl-mandelic acid and oxi-propionyl mandelic acid) and validated according to validation quides. **Material and methods**: The absorption spectra were recorded at 200–400 nm, and the absorbances were measured at 256 nm for oxi-acetyl mandelic acid and 258 nm for oxi-propionyl mandelic acid. Optimum working conditions were established and the method was validated. The developed and validated method was applied to determine these two preservatives from ointments, in which the preservatives were incorporated. **Results:** The method has a good linearity in the concentration range 0.1–1.5 mg/ml (for oxi-acetyl mandelic acid) and 0.1–1 mg/ml (for oxi-propionyl mandelic acid). The RSD for the precision of the method was 0.96328 for oxi-acetyl mandelic acid and 0.797612 for oxi-propionyl mandelic acid. The relative standard deviation was 0.726367% for oxi-acetyl mandelic acid and 0.726234% for oxi-propionyl mandelic acid. In the ointment samples, the concentration of oxi-acetyl mandelic acid and oxi-propionyl mandelic acid were within the limits specified by pharmacopoeia for ointments. **Conclusions:** The developed and validated spectrophotometric method, for the determination of oxi-acetyl mandelic acid and oxi-propionyl mandelic acid is simple, easy to perform, fast and cost effective. **Keywords:** VALIDATION, OINTMENTS, PRESERVATIVES, SPECTROPHOTOMETRIC METHOD, MANDELIC ACID

Mandelic acid is known as an antiseptic, being active against some pathogens (*Staphylococcus aureus*, *E. coli*, *Proteus* sp., *Aerobacter* sp. etc.). It is used in urinary infections (oral use), or dermic infections (inflammatory acne), for external use. Starting from this acid, we synthesized some mandelic acid derivatives, two of them (oxi-acetyl mandelic acid and oxi-propionyl mandelic acid) presenting high antimicrobial activity compared to mandelic acid.

For these two derivatives, oxi-acetyl mandelic acid and oxi-propionyl mandelic acid, were carry out some studies: there were confirmed their chemical structures (by elemental analysis, UV-VIS, IR, RMN ^{1}H spectral analysis), there were estab-

lished the minimum inhibitory concentrations (MCI=125 μg/ml for oxi-acetyl mandelic acid and MCI=500 μg/ml for oxi-propionyl mandelic acid) and lethal dose 50%, after oral administration (LD_{50}=800 mg/kg for oxi-acetyl mandelic acid and LD_{50}=3000 mg/kg for oxi-propionyl mandelic acid) (1, 2).

This paper presents the development of a fast and sensitive spectrophotometric UV-VIS method for oxi-acetyl mandelic acid and oxi-propionyl mandelic acid determination. The spectrophotometric method was validated according to validation quides and applied to oxi-acetyl mandelic acid and oxi-propionyl mandelic acid determination from pharmaceutical forms (ointments) (3, 4, 5).

MATERIAL AND METHODS

Apparatus:

- Jasco V530 spectrophotometer, quartz cells (1=1 cm);
- IKA-Werke basic ultrasonic bath.

Materials and reagents:

- oxi-acetyl mandelic acid, new synthesized preservative, obtained in faculty lab, for which we have validated the structure and established the MCI, the results have been previously published in journals;
- oxi-propionyl mandelic acid, new synthesized preservative, obtained in faculty lab, for which we have validated the structure and established the MCI, the results have been previously published in journals;
- absolute ethanol (p.a.) (Merck KGaA);
- cetyl alcohol, lanolin, vaseline, sunflower seed oil were produced by Redox, Bucureşti, România.

There were prepared oxi-acetyl mandelic acid and oxi-propionyl mandelic acid stock solutions and then were obtained suitable dilutions in absolute ethanol. Taking into account that those two preservatives are active at low concentrations, the determination was performed at concentrations close to the active ones. The absorption spectras were recorded between 200–400 nm, and the absorbances were measured at 256 nm for oxi-acetyl mandelic acid and 258 nm for oxi-propionyl mandelic acid in a 1 cm cell versus a blank of absolute ethanol.

The developed method was validated by studying the following parameters: linearity, detection limit, quantification limit, precision, in accordance with the bioanalytical method validation guidelines (3, 4, 5).

The developed and validated method was applied to determine these two preservatives from pharmaceutical forms (ointments). According to MCI`s, the preservatives were embedded in ointments in 0.0125 g% concentration for oxi-acetyl mandelic acid and in 0.05 g% concentration for oxi-propionyl mandelic acid. The ointments were prepared by the formula presented below:

Rp/	
Cetyl alcohol	5 g
Sunflower seed oil	20 g
Lanolin	5 g
Vaseline	20 g
Oxi-acetyl mandelic acid	0.0125 g
Distilled water q.s. ad	100 g

Rp/	
Cetyl alcohol	5 g
Sunflower seed oil	20 g
Lanolin	5 g
Vaseline	20 g
Oxi-propionyl mandelic acid	0.05 g
Distilled water q.s. ad	100 g

These two preservatives were extracted from ointments with gently heated absolute ethanol and, after filtration; the samples were spectrophotometric analyzed at 256 nm for oxi-acetyl mandelic acid and at 258 nm for oxi-propionyl mandelic acid, respectively.

RESULTS AND DISCUSSION

The method was validated by studying the following parameters: linearity, detection limit, and quantification limit, precision.

Linearity. There were prepared stock solutions of oxi-acetyl mandelic acid, respectively oxi-propionyl mandelic acid, from which were obtained the working solutions in a concentration range of 0.1–1.5 mg/ml (for oxi-acetyl mandelic acid) and 0.1–1 mg/ml (for oxi-propionyl mandelic acid). For each concentration, three determinations were performed and the average value of absorbance was calculated for each range (tab. I).

TABLE I

The average values of absorbance are graphically represented according to concentrations (fig. 1 and fig. 2).

Statistical analysis of experimental data leads to regression line equations, presented in table II. There were calculated the standard error of regression curve (SE), the Person correlation coefficient (r^2), the detection limit (LOD) and the quantification limit (LOQ). In tab. III are prezented the statistical data.

In conformity with the obtained data, the developed method was linear in the range of the studied concentration.

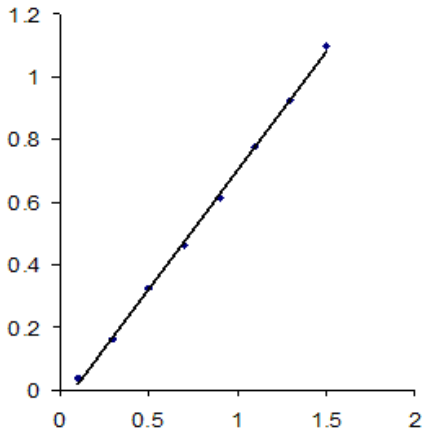

Fig. 1. Regression line for oxi-acetyl mandelic acid determination

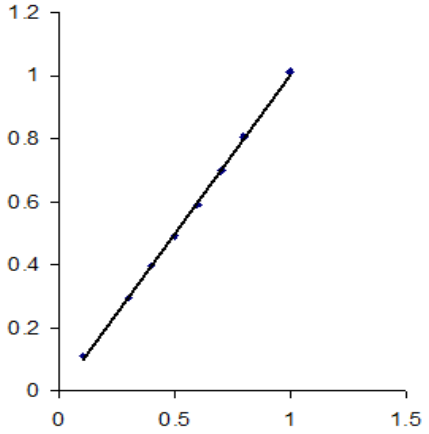

Fig. 2. Regression line for oxi-propionyl mandelic acid determination

TABLE II

Regression line equations for the two preservatives determination

Substance	Regression line equations
Oxi-acetyl mandelic acid	Absorbance = 0.75867x - 0.05671
Oxi-propionyl mandelic acid	Absorbance = 1.00851x - 0.00396

TABLE III

	Oxi-acetyl mandelic acid	**Oxi-propionyl mandelic acid**
Person coefficient (r^2)	0.99897	0.99920
Standard error	0.012876	0.008863
Intercept	- 0.05671	- 0.00396
Slope	0.75867	1.00851
Detection limit (LOD) mg/ml	0.05	0.03
Quantification limit (LOQ) mg/ml	0.17	0.08

Precision of the system and method. Precision of the system was studied for the 1.3 mg/ml concentration of oxi-acetyl mandelic acid and 0.6 mg/ml concentration of oxi-propionyl mandelic acid, for 10 assays performed in the same conditions. The results and the statistical analysis for standard deviation (SD) and relative standard deviation (RSD %) are presented in table IV.

Processing data lead to a relative standard deviation RSD=0.96328% for oxi-acetyl mandelic acid and RSD=0.797612% for oxi-propionyl mandelic acid, compared to the maximum of 2% proposed by the European standards, so the systems are considered to be precise.

TABLE IV
System precision

	Oxi-acetyl mandelic acid	**Oxi-propionyl mandelic acid**
Det. no.	**Absorbance**	**Absorbance**
1	0.9234	0.5917
2	0.9231	0.5998
3	0.9111	0.6001
4	0.9323	0.6013
5	0.9101	0.5928
6	0.9321	0.6032
7	0.9278	0.5925
8	0.9109	0.5922
9	0.9215	0.5912
10	0.9311	0.5922
Average	**0.92234**	**0.5957**
Standard Deviation (SD)	**0.008885**	**0.004751**
Relative standard deviation (RSD) %	**0.96328**	**0.797612**

The precision of the method was investigated in a range of 20% compared to interest concentration, grouped on a number of 3 assays in 3 concentrations levels. Using the regression line equation the concentrations and recovery were calculated (tab. V).

From statistical analysis we obtained a relative standard deviation RSD= 0.726367% for oxi-acetyl mandelic acid and RSD=0.726234% for oxi-propionyl mandelic acid, compared to the maximum of 5% proposed by the european standards, so the proposed method is precise.

The analysis of the two preservatives from ointments. The presence of the oxi-acetyl mandelic acid and oxi-propionyl mandelic acid was carried out by comparing the spectras obtained after extraction with the standards ones. The obtained data, after the two preservatives quantification from the ointments were compared with the limits recommended by pharmacopoeia (tab. VI) (6, 7).

The experimental data shows us that the concentrations of oxi-acetyl mandelic acid and oxi-propionyl mandelic acid from the studied ointments are in the recommended ranges for ointments in pharmacopoeia (6, 7).

CONCLUSIONS

A simple, fast and sensitive UV-VIS spectrophotometric method was developed and validated for the assay of two new preservatives (oxi-acetyl mandelic acid and oxi-propionyl mandelic acid). The valida-

tion was performed according to validation guides. The developed and validated spectrophotometric method was applied to determine these two preservatives from pharmaceutical forms (ointments). The mean recovery in the ointments of the two preservatives was in the range of 98.56–101.60%.

RAMAN SPECTROSCOPY FOR DIFFERENTIATION OF CAUSATIVE AGENTS OF ONYCHOMYCOSIS

The discriminative power of Raman spectroscopy for differentiation of important dermatophytic and non-dermatophytic agents of onychomycosis in human nail was analyzed in a study by Smijs *et al.* An ex vivo nail model was used to determine the capacity of Raman spectroscopy to distinguish between *Trichophyton rubrum*, *T. mentagrophytes*, *T. tonsuran*s, *Scopulariopsis brevicaulis* and *Candida albicans*. For this purpose, Raman spectra (200/sample) were taken from 50-µm slices of infected nail using a 2500 High-Performance Raman Module and 785-nm diode laser. Analysis of spectra showed differences between the dermatophytes (with *T. rubrum* being most different) and between dermatophytes the non-dermatophytes *S. brevicaulis* and *C. albicans.* In conclusion, Raman spectroscopy allows for specific and non-invasive differentiation of causative organisms of onychomycosis (Smijs TG, Jachtenberg JW, Pavel S, Bakker-Schut TC et al. Detection and differentiation of causative organisms of onychomycosis in an ex vivo nail model by means of Raman spectroscopy. *J Eur Acad Dermatol Venereol*. 2013. doi: 10.1111/jdv.12324).

2. Discipline of Primary Health Care and Epidemiology

SOME OBSERVATIONS ON OPTIMIZATION OF PRE-HOSPITAL EMERGENCY MEDICAL SERVICES FROM THE CITY OF IASI, ROMANIA (Abstract): In the Iasi City, with a population of 825,100 inhabitants, the number of requests for ambulance service has increased steadily for the past 17 years. One of the determining factors could be the development of the primary health care prevention. **Material and methods**: We take into study some factors which consider influencing the reorganization of emergency medical systems in the Iasi City territory. **Results**: According to the spatial analyzes, distribution of health units in Iasi City is concentrated type, developing in the downtown area, where there is also a high accessibility to health care services. There are some areas with a high population density, have low accessibility to hospital units, due to the presence of spatial network railroad as a spatial barrier, limiting interaction with other areas of the city. **Conclusions**: The analysis of optimization concept of Medical Services in a city like Iasi is about the challenge to understand the impact of the population health towards the development and organizing the territory, and, interrelated, how we can improve the population health by the best possible organization. **Keywords**: AMBULANCE SERVICE, HEALTCARE, EMMERGENCY CARE UNIT, CENTRAL PLACES THEORY

The evolution of the health status of the population is a phenomenon that could not be anticipated, but factors that influence it positively or negatively could be identified. Thus, situation is contradictory: although we live in a time when innovations in healthcare are increasingly diverse, living standards higher than that of previous periods, we are witnessing a growing demand for emergency medical services.

The Ambulance Service of Iaşi (A.S.I.) is a strategic medical unit, with legal personality and its specific work on standby 24 hours from 24, 365 days per year. A.S.I. is subordinated to the Department of Public Health Iasi. A.S.I. provides pre-hospital emergency care, both at application and during transport of patients (sick, injured, pregnant women) to the hospital. In addition, A.S.I. provides ambulatory care at the request, but also non-medical transportation. A.S.I. answers telephone calls coming from people and various medical units, with an average of 150 requests in 24 hours to about 4,500 requests a month, with a distribution of structurally relatively equal.

There is a higher share of major emergencies (disaster emergencies, collective and individual emergencies), followed by those of second degree and medical transport.

MATERIAL AND METHODS

Pre-hospital emergency medical services and medical transportation are provided of County Ambulance Service of Iasi (C.A.S.I.), for a population of 825,100 inhabitants (in 2008), of which 393,389 urban and 431,711 rural population. To better resolve requests, C.A.S.I. has organized ambulance substations in 9 towns in the county (Paşcani, Hîrlău, Tg. Frumos, Bivolari, Răducăneni, Podu Iloaie, Mircești, Vlădeni, Țibănaşi).

We take into study some factors which consider influencing the reorganization of emergency medical systems in the Iasi City territory.

RESULTS AND DISCUSSION

The number of requests for ambulance service has increased steadily for the past 17 years. One of the determining factors could be the development of the primary health care prevention.

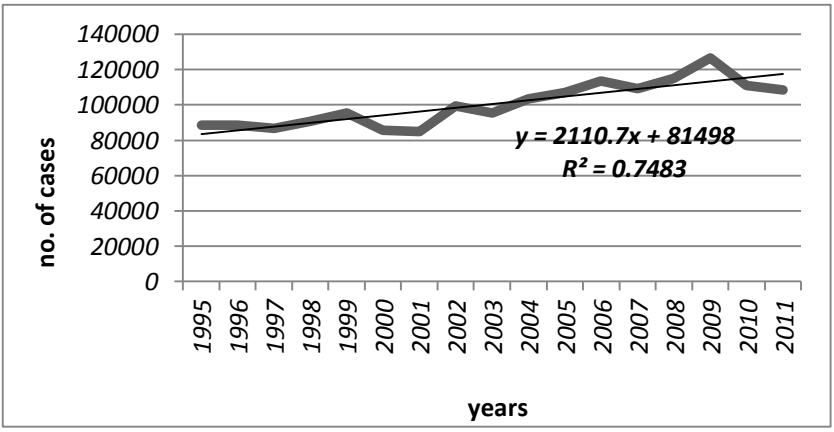

Fig. 1. Evolution of the number of requests in Iaşi (1995-2011) (source: C.A.S.I.)

TABLE I

The evolution of the ambulances number during the period 2006-2012 (source: C.A.S.I.)

Year	2006	2007	2008	2009	2010	2011	2012
C1/C2	2	2	2	3	3	3	4
B1/B2	14	16	19	19	17	17	18
A1/A2	10	11	9	9	8	8	8
Unclassified	16	16	10	10	8	8	8

The situation of fleet of ambulances is not good, according to European standards, if we consider the optimal number of ambulances reported to the population served (an ambulance with stretcher to 5000 inhabitants). Thus, at the end of May 2012, the situation was as follows: 38 ambulances, of which 4 are Resuscitation and Intensive Care Ambulances (C1/C2) and 18 are Emergency Ambulances and Resuscitation (B1/B2), 8 unassisted ambulance transport (A1/A2) and 8 unclassified (T1/T2) with crew formed by healthcare specific activity of 1, 2 or 3 people, including: physicians, nurses and ambulance drivers. These ambulances are sent to the area to resolve the 150 requests on average in 24 hours, a number that increases by 30-40% in case of outbreak (tab. I).

Force medical personnel consisted of 12 physicians, 121 nurses and 91 ambulance drivers (drivers trained to be the third person who fills specialized emergency response crew of the ambulance), at the end of May 2012. Program staff is working four shifts (day and night, 12-24, 12-48). Of the 15 hospitals of Iasi County, nine of them take major and second degree emergencies of the entire county, such as: "St. Spiridon" University Emergency Hospital, "St. Mary" Emergency Hospital for Children, "Elena Doamna" and "Cuza Voda" Obstetrics and Gynecology Hospitals, Clinic Hospital of Neurosurgery, "C.I. Parhon" Hospitay, TB Hospital, "St. Paraskeva" Infectious Diseases Hospital, "Socola" Psychiatric Hospital".

According to the spatial analyzes, distribution of health units in Iasi City is concentrated type, developing in the downtown area, where there is also a high accessibility to health care services (fig. 2, 3).

At first glance, the two maps do not differ too much. The focus of accessibility around of medical services is observed. This fact respects *Central Places Theory* conducted by Christaller and Lösch (central places are the result of conscious choices of places optimal location). Even if in these cases central places are not chosen by default, the hospitals focus only in a specific area of the city offers a high degree of vulnerability of most outlying addresses or buildings. Thus, in case of emergency, a large proportion of Iasi remains in areas which could consider not accessible or accessible to a longer time interval, comparatively with emergency medical facilities. In addition, the costs to serve that population are increased.

We measured ease of movement or reaching the place from the population addresses - barycenters buildings, respectively - to the nearest hospital. The situation would be different if we take into account that every hospital has one highly specialized profile. We have achieved this mapping by using the Network Analyst function. Neighborhoods in the northwest, west and southeast, such as Pacurari, Canta, Dacia, Nicolina, CUG, Bucium, with a high population density, have low accessibility to hospital units, due to the presence of spatial network railroad as a spatial barrier, limiting interaction with other areas of the city.

The problems of Pre-hospital Emergency Medical System (EMS). Despite the well-established structure of the Romanian health system (primary care, local clinics, hospitals, emergency care unit ECU, and pre-hospital medical units), in the emergency medical services gaps appear different from the education of the public, to the treatment and resolution of cases.

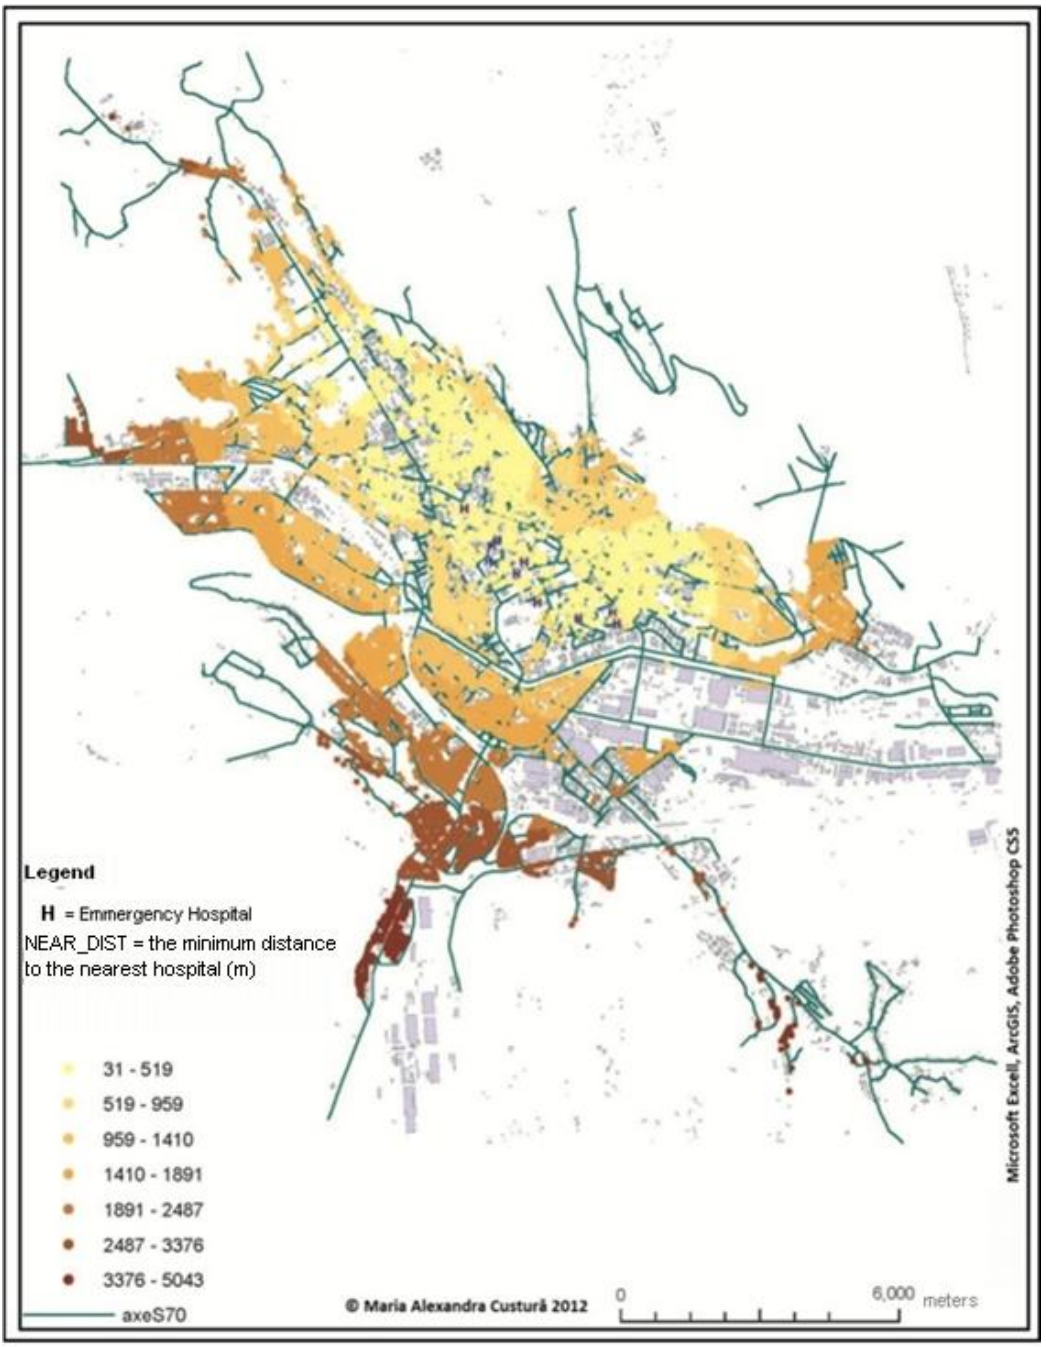

Fig. 2. Accessibility of public addresses to the nearest hospital (Iasi, Romania)

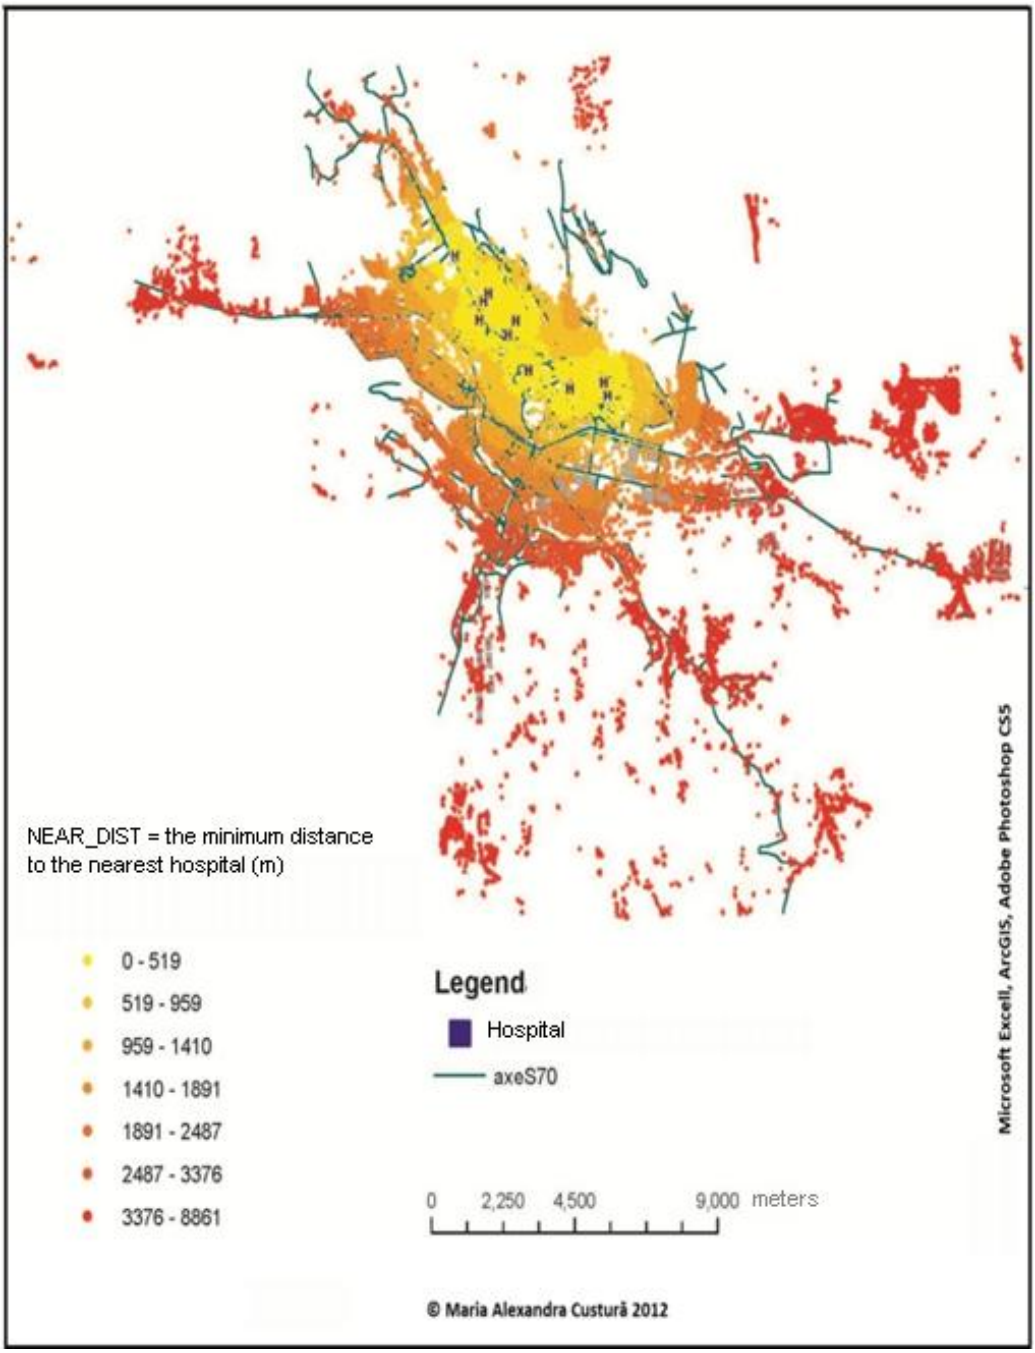

Fig. 3. Accessibility of central points of buildings (barycenters) to the nearest hospital (Iasi, Romania)

Education of the population is the way to prevent and treat some diseases, the attitude to the disease and how they require and expect to be given pre-hospital first aid. Western European countries have placed great emphasis on education of the population, leading to a better functioning of ECU and a growth of the population state of health (the prevention of major emergencies - secular people learning first aid medical).

In addition to public education, another problem is the lack of cases screening at the level of the primary health care, leading to overuse of pre-hospital emergency services for cases that can be resolved in family physician's office. The lack of a complex hospital unit where various cases could be admitted, fully equipped for diagnosis and treatment, leads to situations of patients' transfer, that endanger the state of it, and their resource consumption and wastage, both of those material and human.

Infrastructure is an impediment to the proper conduct of business by covering large distances, congestion because the permanent works to rehabilitate it. In addition to road infrastructure, that informational is insufficiently used. Another weakness of the Romanian medical system is the ratio between healthcare personnel and the deserved population, including the situation of the ECU also.

CONCLUSIONS

The concept of optimization underlies real need of improve Medical Services and, thus, the population welfare. Therefore, the analysis of this issue is about the challenge to understand the impact of the population health towards the development and organizing the territory, and, interrelated, how we can improve the population health by the best possible organization. This understanding requires not only the knowledge of the medical system problems or territory, but also the interdependencies that occur between the two.

ANTIMICROBIAL RESISTANCE IN SEPTIC-PURULENT INFECTIONS

V. Prisacari, I. Berdeu
Department of Epidemiology
State Medical and Pharmaceutical University "Nicolae Testemitanu",
Republic of Moldova, Chisinau

ANTIMICROBIAL RESISTANCE IN SEPTIC-PURULENT INFECTIONS (Abstract): Evaluating the spread of antibiotic-resistant microorganisms from a multi-profile hospital. **Materials and methods:** There were analyzed 3940 strains of antibiotic-resistant microorganisms from patients with septic-purulent infections. **Results:** From the total, 51.44% samples of isolated strains showed resistance to antibiotics, including Gram negative (61.66%), and Gram positive ones (40.25%). A higher degree of resistance showed strains of *Acinetobacter spp*. (86.87%), *P. rettegeri* (83.40%) and *K. pneumoniae* (73.35%). Etiological structure of septic-purulent infections, as well as the degree of resistance, has proved to be varied, depending on the hospital profile unit. Isolated strains showed a higher resistance to penicillins and cephalosporins. **Conclusion:** Microorganisms isolated from patients with nosocomial septic-purulent infections have showed a higher resistance to antibiotics. **Keywords:** SEPTIC-PURULENT INFECTIONS, MICROORGANISMS, ANTIBIOTICS, RESISTANCE.

Nosocomial septic-purulent infections are characterized by poly etiological character, and highly resistant bacteria to antibiotics, due to uncontrolled use of antibiotics (1, 2, 3, 4, 5, 6).

Microorganisms with a high and broad spectrum of resistance to chemotherapeutics are involved in the etiological structure of nosocomial infections, thus requiring using reserve antibiotics or combinations of antibiotics, which are much more expensive. (4, 5, 7, 8). To develop the tactics of using antimicrobial drugs and the strategy of their purchase, our research aimed at accumulating information about the spread of antimicrobial resistance in some hospital settings.

MATERIAL AND METHODS

The paper refers to transversal epidemiological studies carried in 2010 based on the retrospective analysis of 3940 strains of microorganisms isolated from patients with septic-purulent infections (SPI) hospitalized in the National Center for Emergency Medicine. Study of antimicrobial resistance was performed by disk diffusion method and program WHONET – 5.6 was used for the epidemiological analysis.

RESULTS

The study revealed that the 3940 strains isolated from patients with SPI belonged to 51 species. This fact demonstrates the strong poly etiological character of this pathology, the Gram-positive microorganisms prevailing - 2237 (56.78%). From all strains, Gram-negative microorganisms represented 1624 (41.22%) and fungi constituted 79 (2.01%).

Our research showed the following predominance in the general etiological structure of SPI: *S. epidermidis* – 21.45%, *S. aureus* – 17.03%, *E. coli* – 11.14%, *E. faecalis* – 10.38%, *K. pneumoniae* – 5.36%, *P. aeruginosa* – 6.47%, *Acinetobacter sp*. – 3.07% and microorganisms from genus *Proteus* – 4.5%.

TABLE I

Etiological structure and antibiotic sensitivity / resistance of microorganisms isolated from patients with SPI

Etiological structure of SPI in relation to the hospital profile of departments has proved to be varied. Gram-positive strains were predominant (52.38%, 72.69%, 94.57%, 69.33%) in trauma, maxillo-facial surgery, neurology and cerebrovascular diseases departments. In general surgery (septic and aseptic), anesthesiology, reanimation and intensive care unit, urology and neurosurgery departments Gram-negative strains were predominant (56.92%, 53.22%, 65.08%, 54.55%, 55.77%) (tab. II).

Analysis of antibiotic resistance of isolated strains (tab. I) revealed that from the overall testing (28159), it was recorded resistance to antibiotics in 14484 samples (51.44%). Gram negative microorganisms showed a higher degree of resistance (61.66%) compared to Gram positive ones (40.25%).

A higher degree of antibiotic resistance exhibited *E. faecalis* strains (58.86%) and *S. epidermidis* (43.90%). The majority of Gram-negative strains had an increased resistance to antibiotics, especially *Proteus, Enterobacter, Klebsiella and Pseudomonas*. *Acinetobacter sp*. have proved to be the most resistant strains (86.87%).

Analysis of antibiotic resistance of strains in relation to the group of antibiotics showed a higher resistance to penicillins (65.40%), cephalosporins (79.40%), including the first generation cephalosporins (74.76%), second generation (93.30%), third generation (73.80%) and fourth generation (85.50%). Sensitivity of microorganisms to these groups of antibiotics constituted: 34.60%, 20.60%, 25.24%, 6.70%, 26.20% and 14.50%, respectively.

Gram-negative microorganisms showed a higher resistance compared to Gram-positive ones (61.66%), especially to penicillins (79.78%), cephalosporins of I, II and IV generations - (89.60%, 93.60% and 85.40%) and were sensitive to penems (81.14%), aminoglycosides (51.60%) and quinolones (54.80%). Gram-positive microorganisms isolated from patients with SPI also showed a higher resistance to penicillins (57.47%), cephalosporins (65.85%), cephalosporins of I, II and IV generations (66.10%, 84.40%, 87.50%), and a higher sensitivity to aminoglycosides (87.65%), quinolones (77.94%), penems (61.54%) and oxazolidinones (93.10%) (tab. III, fig. 2).

Analysis of resistance in relation to species of the isolated strains (fig. 2 and 3). Of *S. aureus* strains, 64.70% were resistant to cephalosporins (64.70%), especially II (87.50%) and IV generation (80.00%). A higher sensitivity was recorded to aminoglycosides (90.36%), oxazolidinones (94.90%) and quinolones (85.87%).

Strains of *S. epidermidis* showed a higher resistance to penicillins (61.97%), second generation cephalosporins (82.60%), first generation cephalosporins (66.40%), IV generation cephalosporins (65.20%), also to macrolides (53.95%) and glycopeptides (60.0%), and an increased sensitivity to penems (88.24%), aminoglycosides (86.45%) and quinolones (71.92%).

Strains of *S. pyogenes* showed an obvious resistance to cephalosporins (85.70%) and a higher sensitivity to quinolones (96.70%), lincosamides (92.60%), macrolides (70.70%) and oxazolidinones (93.80%).

Strains of *E. faecalis* have revealed a higher resistance to penicillins (67.92%), lincosamides (76.70%), macrolides (68.90%) and glycopeptides (68.30%). These organisms werealso sensitive to beta-lactamase +inhibitors (78.80%), penems (87.50%), nitrofurans (80.00%) and oxazolidine (80.80%).

Acinetobacter sp. strains showed an increased resistance to quinolones (81.60%), aminoglycosides (72.80%), cephalosporins of all generations (98.30%), especially to III generation (97.85%) and II generation (97.80%) and to penicillins (95.30%). These strains showed sensitivity only to penems (47.50%).

E. coli strains have also proved to be highly resistant, especially to penicillins (73.90%), beta-lactam+inhibitor (66.70%), cephalosporins (73.00%), monobactams and tetracyclines (100.0%), and sensitive to penems (85.70%), aminoglycosides (62.40%) and quinolones (75.26%).

Strains of *E. aerogenes* have proved to be highly resistant to penicillins (88.30%), cephalosporins (87.50%), aminoglycosides (66.05%) and sensitive to penems (91.70%), nitrofurans (57.10%) and quinolones (47.80%).

E. cloacae strains showed resistance to penicillins (80.43%), cephalosporins II generation (90.0%), cephalosporins III generation (80.70%), aminoglycosides (51.15%) and sensitivity to penems (90.0%), quinolones (56.80%) and phenicols (61.10%).

Strains of *K. pneumoniae* have proved to be resistant especially to penicillins (97.10%), cephalosporins of all generations (92.95%), especially to cephalosporins I and II generations (96.10% and 97.70%), nitrofurans (83.30%), quinolones (59.80%) and sensitive to aminoglycosides (40.60%) and phenicols (51.80%).

From all strains of *P. aeruginosa*, resistant to penicillins have proved to be 77.90%, to cephalosporins (95.90%), to monobactams (97.00%), to nitrofurans (66.70%) and sensitive to penems (85.65%) and aminoglycosides (53.68%).

TABLE III

Evaluation of the sensitivity / resistance of microorganisms isolated from patients with SPI in relation to the group of antibiotics

Group of antibiotics	Microorganisms								Total			
	Gram positive				Gram negative

From the strains of the genus *Proteus*, a higher resistance was recorded at *P. rettegeri*, especially to penicillin (96.67%), quinolones (81.90%), cephalosporins (96.26%), aminoglycosides (71.90%), and sensitivity to penems (61.54%).

Strains of *S. marcescens* have shown a high resistance, especially to penicillins (80.00%), cephalosporins (86.60%), the second generation cephalosporins (95.65%), and had sensitivity to penems (50.00%), aminoglycosides (75.80%) and quinolones (65.30%).

CONCLUSION

Our research showed that septic-purulent infections were characterized by etiologic polymorphism and resistance to antibiotics, especially in Gram negative (61.66%) compared to the Gram-positive ones (40.26%). The most resistant to antibiotics have proved to be *Acinetobacter sp.* (86.87%), *P. rettegeri* (83.40%), *K. pneumoniae* (73.35%), *P. aeruginosa* (60.0%) and *S. marcescens* (58.0%). Strains isolated from patients with SPI showed high resistance to penicillins and cephalosporins, which are the antibiotics most commonly used in medical practice, which resulted in a permanent monitoring of the antibiotic resistance and administration of antibiotics in relation to the antibiogram results.

MONOAMINE OXIDASE-A INHIBITION REVERSES ENDOTHELIAL DYSFUNCTION IN HYPERTENSIVE RAT AORTIC RINGS (Abstract). **Aim.** Monoamine oxidases (MAOs) are mitochondrial enzymes, with 2 isoforms, A and B that convert biogenic amines to their corresponding aldehydes via a reaction that produces hydrogen peroxide. Since MAO-A is the predominant form at vascular level we hypothesized that MAO-A-dependent H_2O_2 production may contribute to the development of endothelial dysfunction and, MAOs inhibition could improve the vascular function, respectively. **Material and methods.**To this aim aortic rings were isolated from female adult spontaneously hypertensive rats (SHR) and their corresponding (Wistar-Kyoto) controls. The effect of MAO-A inhibitor, clorgyline (10µmol/l) on endothelium-dependent relaxation (EDR) in response to acetylcholine and endothelium-independent relaxation in response to sodium nitroprusside, was studied in isolated phenylephrine-preconstricted aortic segments in the presence of indometacine (10µmol/l). **Results.**In hypertensive group EDR was significantly decreased – maximal relaxation (% of KCl, mean±SD) being 37±3.5 in SHR vs. 3.7±1.8 in controls. If experiments were done in the presence of clorgyline, EDR in control segments was unaffected. However, the compound restored normal EDR in aortic segments from hypertensive rats (maximal relaxation - % of KCl, 13.7±2.3). **Conclusions**. Inhibition of the MAO-A isoform might be useful in restoring endothelium-dependent relaxation in this experimental model of hypertension in rat.
Keywords: ENDOTHELIAL DYSFUNCTION, EXPERIMENTAL HYPERTENSION, MONOAMINE OXIDASE.

Cardiovascular disease is a leading cause of morbidity worldwide and endothelial dysfunction (ED) represents both a widely investigated underlying mechanism and a therapeutic target. Accumulated lines of evidence indicate that increased production of reactive oxygen species (ROS) significantly contributes to ED pathogenesis. Four enzymatic systems have been systematically investigated as major sources of ROS generation by vascular cells: NAD(P)H oxidases, xanthine oxidase, uncoupled eNOS and mitochondrial respiratory chain (1). However, recent data have incriminated monoaminooxidases (MAO) with two functional isoforms, A and B, as another important source of deleterious hydrogen peroxide (H_2O_2) production (2). In particular, increased activity of myocardial MAO-A has been reported to contrib-

ute to ventricular dysfunction associated with postischemic reperfusion, and also to the maladaptative hypertrophy within the evolution of heart failure (3). Moreover, with respect to vasculature, MAO-A mediated ROS production has been shown to induce mitogenic signaling in smooth muscle cells by a process that may involve the activation of matrix metalloproteinase 2, which likely contributes to vascular wall remodeling (4). Enhanced MAO-A protein expression and consecutive generation of H_2O_2 in the cerebral arteries have been also demonstrated to be responsible for the exaggerated *in vitro* tension development induced by serotonin, in the isolated basilar arteries of SHR (5).

The unfavorable effects of MAO activation are antagonized by a couple of available selective MAO inhibitors (MAOI) that can be divided in: i) irreversible MAOI, such as clorgyline for MAO-A and selegiline for MAO-B and ii) reversible MAOI, such as moclobemide for MAO-A and lazabemide for MAO-B, respectively (6).

In the light of these new findings that consider MAO an important source of H_2O_2 not only in the brain, as widely recognized (7) but also in the heart, the aim of the present study was to determine whether inhibition of MAO-A, the predominant isoform in the cardiovascular system, could improve the vascular relaxation in hypertensive and normal rat vessels. We hypothesized that, similarly to ischemia/reperfusion injury and hypertrophy, the activity of this enzyme is increased in pathological conditions associated with ED, such as experimental hypertension, with the subsequent generation of a large amount of H_2O_2, that might cause a decrease in nitric oxide (NO); in this respect, MAO inhibition might correct the endothelial dysfunction by improving the NO-dependent vasodilatation.

MATERIAL AND METHODS

All experimental procedures used in this study were conducted in accordance with the Directive 2010/63/EU on the protection of animals used for scientific purposes. The experimental protocol was approved by the Ethics Committee of the University for Medicine and Pharmacy of Timişoara, Romania.

Animals were fed *ad libitum* and housed under standard conditions (constant temperature and humidity of 22.5 ± 2° C and 55 + 5%, 12-h light/dark cycle). Twenty-four hours prior to the experiment solid food was withdrawn with no limitation in water supply.

Experiment protocol. Experiments were performed in vascular preparations (thoracic aortas) isolated from SHR and control female rats weighing 250-350 g (n = 6/group). The arterial segments were carefully cleared of connective tissue to not damage the intimal surface and cut into 2-3 mm wide rings. The rings were suspended between two parallel stainless steel hooks in two individual jacketed organ baths containing Krebs-Henseleit buffer (composition in mM: NaCl 118, KCl 4.7, CaCl2 2.5, MgSO4 1.2, KH2PO4 1.2, NaHCO3 25, and glucose 11.1), gassed with a mixture gases of 95% O2 and 5% CO2 and maintained at 37°C. The upper hook was connected to a force transducer for isometric tension recording. The amplified analog signal from the force transducer was digitized using a data acquisition system (Digidata 1200B, Axoscope 10, and Molecular Devices Ltd).

The rings were equilibrated for 60 minutes at 37°C under 1.75 cN passive tension and the buffer was replaced every 15 min. To confirm the viability of vascular smooth muscle, vessel rings were contracted twice with KCl. A relaxation re-

sponse to acethylcholine, an endothelium-dependent vasodilator, of 15% or more from the stable tension induced by KCl was considered as functional endothelium. After washout and return to baseline the tissues were pre-contracted with 10-5 M phenylephrine (PE). Cumulative concentration-response curves (10^{-9} to 10^{-5} M) for: acetylcholine (ACh), as endothelial-dependent response, and sodium-nitroprusside (SNP), as endothelial-independent response, were recorded in the absence vs. the presence of MAO-A inhibitor (Clorgyline, 10^{-5} M). Indometacin (10^{-5} M), as inhibitor of cyclooxygenase, was present in the organ baths throughout the experiments in order to eliminate the influence of prostaglandine synthesis on vasodilator response.

Relaxation response of each vascular ring was assessed by measuring the reduction in vascular tone at cumulative doses of the vasodilator agent and expressed as percentage change from the stable tension produced by PE.

Statistical analysis. Acquired data were statistically processed using *GraphPad Prism 5* and *Microsoft Office Excel 2003* software (Microsoft Corporation). Central tendencies of the variables obtained from n different rings were expressed as mean (M) and the dispersion as the standard deviation (SD). Statistical comparison between two groups of averages was performed using t test.

In order to assess overall vascular reactivity, we chose to calculate the following variables in the equation for a Hill-type sigmoidal relationship: i) the estimated maximum response, ii) the concentration required to achieve 50% of maximum response (EC50 (-log [M]) and the iii) dose-response slope. In order to compare the dose - response curves, F test was used.

RESULTS

The rings isolated from SHR develop a pronounced attenuation of endothelium dependent-relaxation (EDR). In control segments, EDR was unaffected in the presence of the MAO-A inhibitor, clorgyline (10μmol/l). In contrast, the irreversible MAOI partially restored normal EDR in aortic rings harvested from SHR rats (fig. 1).

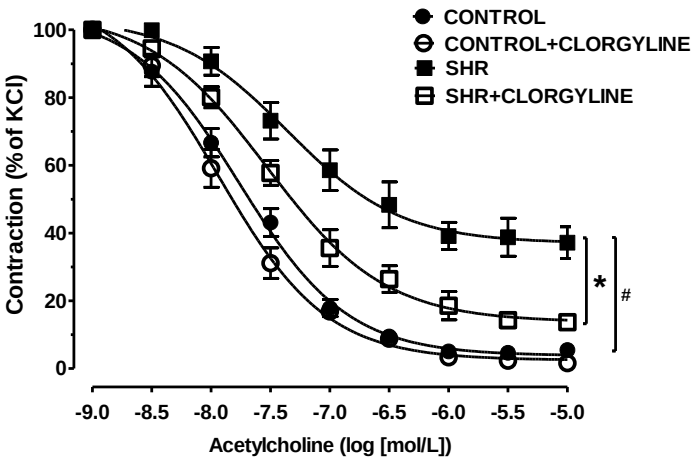

Fig.1. Acethycholine dose-response curve of aortic rings in SHR vs. CONTROL in the presence vs. the absence of the MAO A inhibitor, clorgyline (10 μmol/l) (*, # $p<0.0001$)

The relaxation induced by sodium nitroprusside was similar in both experimental groups, regardless the presence or the absence of clorgyline (fig. 2).

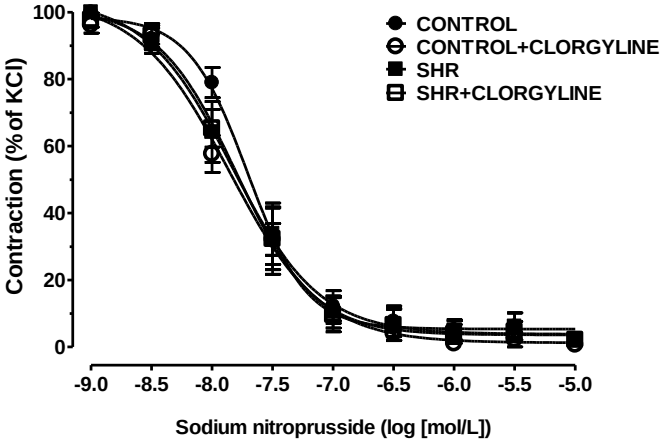

Fig. 2. Sodium nitroprusside dose-response curve of aortic rings in SHR *vs.* CONTROL, +/- clorgyline(10 μmol/l) in the presence of indometacin (10 μmol/l).

Preincubation with L-NAME, a potent eNOS inhibitor caused a significant reduction in relaxation response in SHR group as compared to control; also, relaxation in the rings from SHR group treated with clorgyline was improved as compared to the non-treated rings. This observation suggests that the mechanism underlying the improvement of relaxation could be NO-dependent (fig. 3).

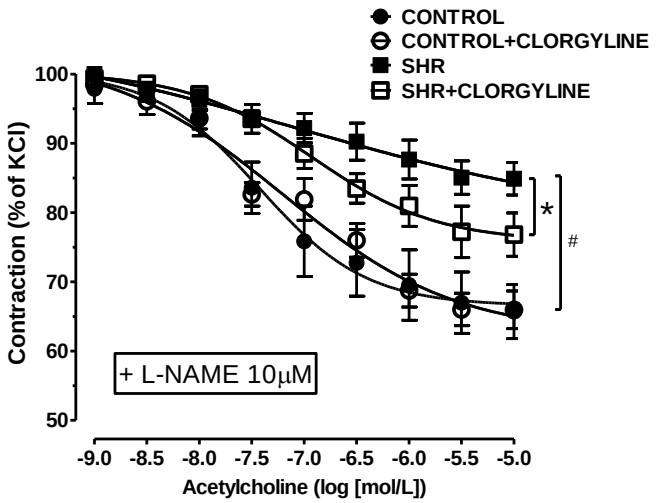

Fig. 3. Acetylcholine dose-response curve in aortic rings from SHR *vs.* CONTROL, +/- clorgyline (10 μmol/l) in the presence of L-NAME (10 μmol/l) and indometacin (10 μmol/l). (*, # $p<0.001$)

DISCUSSION

Increased production of radical species has been constantly associated to various pathologies, including hypertension, atherosclerosis, diabetes (8, 10). ROS-induced endothelial dysfunction is a well establishedpathomechanism but currently this phenomenon was attributed to the increased formation of the highly reactive superoxide anion (11), not to H_2O_2 with the former being considered the only responsible for scavenging NO (with the generation of peroxynitrite required for eNOS uncoupling). However, since hydrogen peroxide is freely diffusible through cellmembranes, it can further activate inflammation, induce apoptosis and promote endothelial dysfunction (12).

The roles of MAOs, in terminating the action of neurotransmitters in the central and peripheral nervous system and in the oxidation of dietary amines in extraneuronal tissues have been extensively studied (6,7). Thus, it has been shown that in vitro or in vivo application of L-deprenyl, an irreversible MAO-B inhibitor, produced vasodilatation via an increase in the amount of NO in brain tissue and cerebral blood vessels (13). NO inhibits mitochondrial monoamine oxidase activity and decreases outer mitochondria membrane fluidity, yet, the mechanism by which NO inhibits MAO remains unknown at present. However, it seems likely that the effect of NO on MAO activity is by a direct interaction of the compound or a metabolite with the protein (14, 15).

In the present study we focused on the role of MAO-A in the development of endothelial dysfunction in an experimental model of genetically induced hypertension. Ex vivo blockade of MAO A with clorgyline improved endothelium-dependent relaxation in vessels from hypertensive animals. Of note, this effect was not present in vessels isolated from the control animals. This observation strongly suggests that inhibition MAO activity in basal conditions do not interfere with vascular reactivity, most probably due to minimal generation of H_2O_2.

However, catabolism of monoamines results not only in H_2O_2, but also in production of ammonia, a much less investigated by-product (3). Generation of NH_3 could also explain the deleterious effects of MAO activation in vascular cells. NH_3 is known to be a mediator of cerebral vascular dysfunction in hepatic encephalopathy. Ammonia stimulated the formation of ROS by cerebral endothelial cells (16, 17) and reduction of ammonia levels in a liver failure model, improved endothelial function (18).

The present study has at least two limitations: first, MAO activity and H_2O_2 generation were not quantified and the experiments were restricted to the functional analysis of isolated vessels without addressing the effects of *in vivo* MAO inhibition. However, systemic MAO inhibition in this model is not suited to address the role of MAO in endothelial function. As MAOs are a main pathway of catecholamine degradation, the MAO inhibitor-induced accumulation of these vasoactive compounds may increase the already present hypertensive response and further promote vascular dysfunction (19). Also, it must be pointed out that information concerning the pharmacokinetics of MAO inhibitors is quite scarce. For instance, it is not clear whether the plasma concentrations achieved in patients treated for neurological disorders are in the range of the dosages tested in this study. Systematic pharmacokinetic studies

are undoubtedly necessary to establish the dose regimen necessary to achieve and maintain the concentrations of the circulating compounds in the micromolar range.

MAO inhibitors are currently used in psychiatry and neurology for the treatment of anxiety and depressive disorders, Parkinson's and Alzheimer's diseases, respectively (6). Therefore, no major problem should exist for their introduction in clinical studies concerning heart disease. Of note, MAO inhibition was already used in the late '60s in the treatment of angina pectoris (20, 21), although obviously the involvement of mitochondria and ROS generation was not even in its infancy. In a recent paper, Li et al demonstrated a therapeutic effect of an antidepressant medication (selective serotonin uptake inhibitor) in ameliorating experimental heart failure (22). If evidence will be provided for common novel pathways contributing to these co-morbid pathologies maybe, indeed, in the future antidepressants will be able to heal both minds and hearts (23). In this light, further studies addressing the potential role of MAO inhibitors in reversing an impaired vascular dysfunction are clearly warranted.

CONCLUSIONS

Inhibition of MAO-A improved the vasodilator response to Ach in hypertensive rat aortas whereas no effect was observed in control animals. Therefore, the MAO-A inhibitor, clorgyline, might be useful in restoring endothelium-dependent relaxation in situations of increased vascular oxidative stress and endothelial dysfunction.

NEUROSURGICAL APPROACH IN ORBITAL PATHOLOGY - UNICENTRIC STUDY (Abstract): Orbital pathology represents a unique entity because is located in a border region that requires neurosurgery, ophthalmology and oncology collaboration. The modern surgery includes the orbital surgery and skull base surgery. **Material and Methods:** This study presents neurosurgical approaches in 17 cases of orbital pathology in a period of 4 years in the Neurosurgery Department of Emergency Hospital "Prof. Dr. N. Oblu" Iaşi. In most cases our team performed a fronto-temporal and pterional approach with orbital roof resection and tumor ablation. In our study there were 10 women (58.8%) and only 7 men (41.1%). 16 patients presented with exophthalmia, head each (8 patients), diplopia (3 patients), amblyopia (4 patients), ptosis (1 patients), rinoreea (1 patients) and nerveVII paresis (2 patients). **Results:** Postoperative there were remissions of exophthalmia and the other symptoms and there were not registered any complications**. Conclusions**: However the technique and cranial approach can be evaluated on case-by-case situation and depends on the location and extension of the lesion. The goals were patient safety, symptoms remission and tumor removal. **Keywords:** ORBIT, TRANSCRANIAL APPROACH, EXOPHTHALMOLOS.

Over a 4 years period there were admitted 17 patients with intra-orbital pathology and they went under surgery with microsurgery or macro surgery ablation of the lesions. In 15 cases our team performed an intracranial approach to the orbital region and in 2 cases an anterior approach to the lesion. The objectives were total removal of the tumor and symptoms remission.

MATERIAL AND METHODS

The study presented 17 patients with orbital tumors diagnosed on CT and MRI scan since 2007 until the end of 2010 with 10 women and 6 men with ages between 12-77 years old. All except one patient presented with exophthalmia. In most cases our team performed a pterional approach with frontal or orbital extension or both (7 cases) and a fronto-temporal approach with orbital extension (8 patients). For the other 2 cases an anterior approach was used. In one of these cases, a patient presenting with rinoreea, a median trans-facial ap-

proach with Le Fort osteotomy was made.

For the pterional approach the patients were positioned in supine position with the head tilted backwards by 20 degrees and turned 30-35 degrees to the lateral. Skin incision was made from zygomatic arch 1 cm in front of tragus, curving anteriorly, behind hairline (1, 11). We also need to perform orbital roof craniotomy for tumor macro or microsurgery ablation. Medially between the dorsal superior rectus and levator muscle and medial rectus muscle was located the optic nerve (7). When working near it, great care should be taken to avoid injury the central retina artery or ciliary nerve. It was not performed an orbital roof reconstruction after this (1, 7). One of the goals is total ablation of the tumor.

In 8 cases we use fronto-temporal approach with the head positioned rotated on 60^0 from vertical. Skin incision was made curved with anteriorly concavity from zygomatic arch to the medial line and 3 cm down on the medial line. The craniotomy was made in 4 holes. Performing orbital roof craniotomy was obtained visual access to the orbital tumor (1, 11). Our study comprised 10 females (58.8 %) and 7 males (41.1 %). 16 patients presented with exophthalmia, head each 8 patients, diplopia 3 patients, amblyopia 4 patients, 1 patients with ptosis, 1 with rinoreea and 2 patients with nerve VII paresis.

The predominated side of the tumors was left 58.8% (10 cases) and right 35.2 % (6 cases) and one case was bilateral. In 9 cases tumors were only in orbital region in 2 cases were orbital pathology with intracranial extension and in 6 cases were skull bases pathology with orbital extension. We encountered 3 cases of lachrymal gland adenoma, 3 cases of orbital non-Hodgkinl lymphoma, 1 cases of fibroma, 3 cases of skull base meningioma, 2 cases of carcinoma metastasis, 1 cases of orbital fibrosclerosis, 2 cases of hemangioma, 1 cases of orbital cavernoma and 1 cases of mucocele. For the most cases there was performed a transcranial approach with macroscopic resection of the tumor.

TABLE I
Pathology cases

PATHOLOGY	CASES
Lachrymal gland adenoma	3
Orbital non-Hodgkinl lymphoma	3
Fibroma	1
Skull base meningioma	3
Carcinoma metastasis	2
Fibrosclerosis	1
Hemangioma	2
Cavernoma	1
Mucocele	1

In 7 cases we used pterional approach with the total resection of the lesion in 71.4 % (5 cases) and subtotal in 28.5 % (2 cases). In 4 cases the lesions had orbital extension. In 4 cases our team used microsurgical technique with 3 cases of total removal of the tumor; in one cases with skull base meningioma with orbital extension the resection was subtotal. In 3 cases was performed a macroscopic technique with total removal of the tumors in all cases.

In 8 cases we use fronto-temporal approach and the total resection was in 75% (6 cases) and subtotal in 25% (2 cases). The extension of the lesion intracranial was in 2 cases and in 2 cases was skull base pathology with intra orbital extension and in 4 cases only orbital pathology. In all cases we used a macrosurgical technique.

In 2 cases the approach was anterior with macro- and microsurgical technique, the tumor resection was subtotal in both cases. The tumors had only orbital location without cranial extension.

Two patients with skull base meningiomas presented recurrence of the tumor and we performed a second intervention for complete tumor ablation.

Exophthalmia was resolved in all cases. N. VII paresis did not resolve after tumor resection. No patient died as a result of the surgical procedures (tab. II).

RESULTS

TABLE II

Clinical data of the patients with orbital pathology

No	Age	Sex	Side	Pathology	Surgical approach	Intervention	Intracranial extension	Intra-orbital extension	Degree of Resection
1	68	F	R	Pleomorphic adenoma of lacrimal gland	F-temporal	Macrosurgical	-	/	Total
2	77	F	R+L	Bilateral orbital Non-Hodgkin Lymphoma	F-temporal	Macrosurgical	-	/	Total
3	12	M	L	Fibroma	Median trans-facial with Lafort osteotomy	Microsurgical	-	/	Subtotal
4	60	F	R	Pleomorphic adenoma of lacrimal gland	F-temporal	Macrosurgical	-	/	Total
5	68	F	L	Carcinoma Metastasis	Left Pterional	Macro surgical	/	+	Total
6	67	F	L	Meningioma	Left Pterional	Microsurgical	/	+	Total
7	35	M	L	Hemangioma	Left Pterional	Microsurgical	/	+	Total
8	31	F	L	Meningioma	Left Pterional	Microsurgical	/	+	Subtotal
9	64	F	R	Non-Hodgkin Lymphoma	F-temporal	Macrosurgical	+	/	Total
10	68	M	R	Non-Hodgkin Lymphoma	Transpalpebral	Macrosurgical	-	/	Subtotal
11	55	M	L	Pleomorphic adenoma of lacrimal gland	Left Pterional	Macrosurgical	-	/	Total
12	37	F	R	Inflamatory fibrosclerosis	F-temporal	Macrosurgical	-	/	Subtotal
13	77	F	L	Carcinoma Metastasis	Left Frontal	Macrosurgical	/	+	Total
14	49	M	L	Cavernoma	F-pterional	Microsurgical	-	/	Total
15	40	F	R	Hemangioma	F-O-pterional	Macrosurgical	-	/	Total
16	56	M	L	Meningioma	F-temporal	Macrosurgical	/	+	Subtotal
17	56	M	L	Mucocele	F-temporal	Macrosurgical	+	/	Total

DISCUSSION

There are 2 types to approach orbital tumor pathology. One is anterior approach and the other one is trans-cranial approach. The anterior approach is used mainly by ophthalmologists and trans-cranial approach is used by neurosurgeons (3). The type of the approach aims the goals of the surgical treatment. However the tumors characteristics are important.

In 1913 Frazier (6) describes trans-cranial approach with orbital osteotomy, technique that suffered some modifications since then. In our study we used classical pterional approach with frontal extension in one case and fronto-temporal approach with classical craniotomy. Out team performed roof orbitotomy in 12 cases and roof and lateral wall orbitotomy in 2 cases. In 2 cases there was performed an anterior approach.

In trans-cranial approach the lesion resection was total in 80 % (12 cases) and subtotal in 20 % (3 cases). In anterior approach the lesion resection was subtotal (2 cases).

Although the approach is difficult, given the anatomical elements for a direct approach and tumor resection, we recommend a trans-cranial approach. In our study we found no significant differences between microsurgical technique and macro surgical technique.

Although surgical treatment remains the main treatment for most symptomatic orbital tumor pathology, lesions involving the skull base and the medial wall of the orbit are still difficult to treat. These lesions should be addressed by a multidisciplinary team. There is indication that good knowledge of the microanatomy of the orbit is necessary for a good outcome (7, 8).

CONCLUSIONS

For safety and better chance of total removal of orbital tumor pathology we recommend trans-cranial approach. However the technique and cranial approach can be evaluated on case-by-case situation and depends on the tumor location and extension. The goal is patient safety, symptoms remission and tumor removal.

TUBERCULOSIS MENINGO-ENCEPHALITIS WITH POSITIVE CSF FOR KB AND SLOWLY FAVORABLE EVOLUTION. CASE REPORT (Abstract) **Background:** Meningo-encephalitis produce by Koch bacillus is a disease including various symptoms, with often atypical onset and evolution, and with an etiological diagnosis being rarely established. It therefore remains a disease with severe prognosis, despite adequate treatment. **Case report:** a 47 years old male from Neamt County, with chronic otitis in his recent medical history, comes to the emergency room for fever, severe headache, confusion, equilibrium disorders, influenced health status, and meningeal irritation signs. Given his otitis and antibiotic therapy received in recent medical history, the patient was initially diagnosed and treated for beheaded bacterial meningitis (348 elements/mm³, 89% lymphocytes, 5% granulocytes, proteinorrhachia 1.54 g/l). Clinical and paraclinical evolution was poor with persistent fever and headache, impaired mental state, and the spinal puncture showed increased pleocytosis (725 elements/mm³), lymphocytosis (78%), increased proteinorrhachia (2.12 g/l), and low levels of glycorrhachia and chlororrhachia. Tuberculosis meningoencephalytis was suspected (confirmed after 3 weeks through cultures on Lowenstein-Jensen medium: positive for *Mycobacterium tuberculosis*), and a tuberculostatic treatment associating four drugs and intravenous Ciprofloxacin was started. Although the treatment included substances against cerebral edema and neurotrophic agent, his evolution showed persistent headache syndrome. We noticed very slow decrease in CSF pleocytosis (after a month) of treatment the patient still had 240 elements/mm³, 85% lymphocytesand 15% granulocytes. Moreover, due to hepatic toxicity a reduction of the tuberculostatic doses was needed. **Conclusions:** The beginning of the tuberculosis infection symptoms is often surprising, with clinical signs regarding secondary determinations (meningoencephalitis), association with another infection (otitis – wrong diagnosis), as well as persistent yet slowly favorably evolving symptoms, both clinically and paraclinically (CSF parameters). The etiological agent is extremely rarely isolated, due to a very slow growth of the Koch bacillus on special culture mediums and also because such diagnosis is not often considered before starting the treatment. **Key words:** TUBERCULOSIS MENINGO-ENCEPHALITIS, PERSISTENT SLOWLY FAVORABLE CLINICAL AND BIOLOGICAL EVOLUTION.

Tuberculosis meningo-encephalitis is one of the most severe sites of tuberculosis infection evolution, being an extremely polymorphic disease, with frequently atypical onset and evolution and with an etiological diagnosis being rarely established,

with severe prognosis, despite adequate treatment. Tuberculosis still represents a very severe health problem, with high prevalence and mortality rates, frequently because of the lack of a fast and safe diagnostic algorithm (which often leads to late specific treatment), atypical onset and increasingly higher incidence of tuberculosis in the general population.

CASE REPORT

We present the case of a 47 years old male patient from Neamţ County who came to our clinic for fever, severe headache, confusion, equilibrium disorders, impaired health status, and positive signs of meningeal irritation.

His medical history included a chronic otitis during the previous months.

The onset of the disease was about 10 days before hospitalization and manifested itself through severe occipital headache, confusion status, equilibrium disorders, impaired general state. He went to Târgu Neamt Hospital where was evaluated by a neurologist, his native cranio-cerebral computer tomography being normal. He received treatment for cerebral edema, but the patient started to have fever and he was therefore transferred to the Infectious Disease Department of Târgu Neamţ . Chest X-ray showed a triangular heterogeneous opacity with opaque bands from center to periphery under the left hillum, for which antibiotic treatment was started (Amoxicillin- clavulanatum, then Ceftazidime + Gentamicin), with unfavorable evolution, persistent fever, headache and confused mental state, for which he was transferred to our clinic.

On admission: normal weight, subfebrility, influenced general state, confusion (partial temporo-spatial disorientation, hemodynamic and respiratory stable state, HR 88/min, BP 125/75 mmHg, diffuse headache, positive signs of meningeal irritation).

The paraclinical tests revealed normal white cells count (8720/mm³), neutrophilia (94.1%), HSR 25 mm/h, mild hepatic cytolysis (ASAT 67UI/L). The chest X-ray revealed a small zone of fibrosis of approximately 1.5 cm in diameter in the medial right pulmonary field. A lumbar puncture was performed, which revealed clear CSF, pleocytosis (348 elem/mm³, 89% lymphocytes, 5% granulocytes, high protein-rrhachia (1.54 g/l), low glycorrhachia (0.25g/l) and normal chlorurorrhachia (7.04g/l).

Because of the otitis in his recent medical history and previous antibiotic therapy administered at Târgu Neamţ Hospital, it was thought to be beheaded bacterial meningitis and treated with Ceftriaxon 4g per day + Ciprofloxacin 400 mg per day, treatment against cerebral edema (Dexametazon, Manitol), group B vitamins, drugs against fever and antalgic agents.

Seven days after admission the patient still had mild fever, non-severe confusion, influenced general state. The lumbar puncture was repeated and revealed increased pleocytosis (725 elem/mm³), 78% lymphocytes, 20% granulocytes, high proteinorrhachia (2.12 g/l), low glycorrhachia (0.29 g/l) and low clorurorrhachia (6.80 g/l). We suspected a tuberculosis meningoencephalitis (confirmed after 3 weeks by positive culture on Lowenstein-Jensen medium for *Mycobacterium tuberculosis*), so we started tuberculostatic treatment including four agents (Pyrazinamide 2g + Isoniazid 300 mg + Ethambutol 1,6 g + Rifampicin 750 mg) together with intravenous Ciprofloxacin.

The evolution was slowly favorable

with persistent headache, mild cerebral edema despite neurotrophic therapy, remission of fever and confusion, and a very slow CSF pleocytosis decrease (tab. I).

TABLE I
Evolution of CSF parameters from admission to discharge

	Admission	Day 7	Day 17	Day 33	Day 45
Elem/mm³	348	725	264	240	160
Sediment	Lf 89% Gr 5% Mf 6%	Lf 78% Gr. 20% Mf 2%	Lf 83% Gr.12% Mf 5%	Lf 85% Gr.15%	Lf 90% Gr. 10%
Ziehl Nielsen coloration	Negative				
Latex agglutination	Negative				
Bacterial cultures	negative				
Cultures on Lowenstein-Jensen medium	*M. tuberculosis*				
Proteinorrhachia	1.54	2.12	2.95	1.58	1.20
Glycorrhachia	0.25	0.29	0.30	0.40	0.60
Clorurorrhachia	7.04	6.80	7.04	6.93	7.00

The evolution was also marked by the appearance of hepatotoxic side effects, supported by the increased transaminase levels, which determined us to decrease the Rifampicin doses.

After one and a half month from admission to our clinic, the patient was discharged in good general state, without fever, good temporal and spatial orientation, but with a persisting mild headache, the native computer tomography performed being normal. We recommended the patient to continue his tuberculostatic treatment under monitoring from the TBC outpatient clinic in his town.

DISCUSSION

Tuberculosis meningitis is caused by tuberculosis infection dissemination in the meningeal structures, favored by bacteremia and *Mycobacterium tuberculosis* proliferation, in immunodepressed individuals. Tuberculosis meningitis remains a disease with severe prognosis, being the most life-threatening site of tuberculosis infection, with a high rate of mortality and important neurological sequelae (1, 2)

Despite global efforts to manage the tuberculosis infection, its prevalence has been increasing, with 9.4 millions of infected patients worldwide in 2008, and the highest incidence of 139:100000 inhabitants in Africa (3). When tuberculosis cases are quickly detected and treated, there is better control of this illness and the transmission risk decreases inversely proportional to time of treatment. Most likely, the dynamics of tuberculosis infection is strictly related to the fast detection of each case, thus reducing the transmission period (3).

There are some peculiar aspects in the modality of tuberculosis infection onset in this case, i.e. clinical symptoms in secondary sites of infection (meningo-encephalitis) or absence of personal epidemiological contact. Also, there was no pulmonary involvement in his medical history, as the X-rays performed, both at Târgu Neamţ and in our clinic, revealed no indication of any active pulmonary disease.

The presence of otitis in his recent medical history was misleading for diagnosis setting, as it made us suspect another bacterial cause of meningitis and hence delayed specific treatment delivery.

The etiological agent is extremely rarely isolated, due to the difficulties related to the growth of the Koch bacillus on special culture mediums and also due to the slow susceptibility index of this etiology before treatment. Since *Mycobaterium tuberculosis* takes a long time to be isolated on special mediums, and given the low number of positive reactions revealed by Ziehl Neelsen stain, it is often recommended to initiate the tuberculostatic therapy if such condition is suspected and not to wait for positive culture results.

Persistent headache and mild cerebral edema may be considered complications of tuberculosis meningitis despite a normal computer tomography.

The prognosis of the disease in this case may also be influenced by the secondary hepatic side effects which, when associated with digestive symptoms (nausea, vomiting, lack of appetite, abdominal discomfort), may influence the patient's adhesion to the treatment, especially if it is a long-term treatment. The large amount of pills to be taken every day is often another problem of therapy adherence and hence disease prognosis.

CONCLUSIONS

The tuberculosis infection onset was surprising, with clinical manifestations in secondary sites (meningo-encephalitis), the association of concomitant otitis (misleading), and the persistent yet slowly favorably evolving symptoms, from both the clinical and CSF parameters viewpoints. The isolation of the etiological agent is extremely rare, due to the difficult growth of the Koch bacillus on special mediums and also to the small susceptibility for this diagnosis, especially at the beginning of the disease, when the clinical and biological signs are atypical.

PERFORMANCE OF DIFFERENT METHODS OF ESTIMATING RISK SCREENING FOR CHROMOSOMAL ANOMALIES (Abstract): In the last 10 years, several studies have been carried out on additional ultrasound markers in the first trimester of pregnancy in order to improve detection rate of fetal numerical chromosome abnormalities (aneuploidy) and to reduce the rate of false-positive diagnosis. The purpose of this study was to evaluate the performance of various recommendations for which amniocentesis was performed followed by FISH testing in the diagnosis of aneuploidy. These evaluations were conducted in order to determine whether ultrasound aspects are associated with fetal aneuploidy and to estimate the risk level of individual markers using probability estimation analysis. **Material and methods**: The study has been carried out at the Clinical Hospital of Obstetrics and Gynecology "CuzaVodă" Iaşi, at the Laboratory of cytogenetic - prenatal diagnosis, during January 2004 – December 2011, on a target group of 1406 pregnant women. As part of this study, 1411 amniocentesis were performed. **Results**: increased efficiency of screening for fetal aneuploidy in the first trimester of pregnancy is obtained through combined method (maternal age over 35 years, increased nuchal translucency and the presence of double test risk) which has 100% detection rate and a rate false-positive result of 0%. The efficiency of this method is provided also by the relatively high risk (RR = 17.2) and its specificity (Sp = 100%). Making the assessment following the study false positive rate, it appears that a good method of risk assessment for aneuploidy is the combined evaluation of increased nuchal translucency (NT) with maternal age over 35 years (specificity 99.5%, a detection rate of 40% false positive rate of 0.45% and a relative risk of 7.09 for the presence of aneuploidy). **Conclusions**: The achievement of a correct prenatal diagnosis and the increase of the method efficiency, requires a correct selection of cases with aneuploidy risk assessment, based on the results of ultrasound and biochemical (double test risk) investigations correlated with advanced maternal age or previous presence of aneuploidy of children (Down syndrome, Edwards syndrome, Patau syndrome, Klinefelter syndrome and triplo X). **Key words**: FETAL NUMERICAL CHROMOSOMAL ABNORMALITIES, SCREENING METHOD, PRENATAL DIAGNOSIS

Orice sarcină porneşte de la posibilitatea existenței unei malformații cromozomiale. Pentru a calcula riscul individual, este necesară evidențierea riscului a priori ce depinde de vârsta maternă şi corelarea acestuia cu o serie de teste screening efectuate în puncte cheie ale sarcinii. Anii '70 au adus în prim plan corelarea riscului de trisomie 21 cu vârsta maternă avansată, dar costurile şi riscurile ridicate asociate amniocentezei au impus limitarea indicației acesteia doar pentru gravidele peste 40 de ani. Consecutiv, grupul de risc crescut a beneficiat de o reducere a vârstei materne la 35 de ani. Anii '90 s-au caracterizat prin combinarea vârstei materne şi a valorii translucenței nucale la 11-13+6 săptămâni de gestație ceea ce a permis identificarea a aproximativ 75% dintre fetuşii afectați cu o rată de screening pozitiv cotată la 5%. Asocierea translucenței nucale şi a biochimiei serice materne în primul trimestru de sarcină, reprezentată de dublu test (β hCG liber şi PAPP-A) determină identificarea a circa 85-90% din fetuşii afectați (1,2).

Echipa condusă de Kypros Nicolaides a stabilit liniile generale ale *screening*-ului prenatal în ultimii ani. Astfel, dacă inițial se considera că esențiale sunt morfologiile de trimestru I şi II, actualmente se promovează ideea că esența diagnosticului prenatal se află în ecografia de 11-13 săptămâni (3).

Scopul studiului a fost acela de a evalua performanța diferitelor metode de *screening* pentru care s-a practicat amniocenteză urmată de efectuarea testului FISH în vederea diagnosticării anomaliilor cromozomiale numerice fetale. Ca şi indicații au fost evaluate: vârsta maternă avansată, markeri ecografici fetali (translucența nucală crescută), markeri serici materni (dublu test cu risc crescut). Această evaluare a fost realizată pentru a determina dacă aspectele ecografice, biochimice şi vârsta maternă avansată sunt asociate cu aneuploidiile fetale, pentru a estima gradul de risc a markerilor individuali folosind analiza probabilității de estimare.

În ultimii 10 ani au fost realizate mai multe studii suplimentare privind markerii ecografici din primul trimestru de sarcină pentru a îmbunătăți rata de detecție a aneuploidiilor şi de a reduce rata de diagnostic fals-pozitiv (4).

MATERIAL ŞI METODĂ

Studiul s-a efectuat în Spitalul Clinic de Obstetrică şi Ginecologie „Cuza Vodă" Iaşi, în Laboratorul de citogenetică - diagnostic prenatal, în perioada ianuarie 2004 – decembrie 2011 pe un lot care a inclus un număr de 1406 de gravide. În cadrul studiului au fost practicate 1411 amniocenteze sub ghidaj ecografic în vederea efectuării testului FISH care permite detectarea anomaliilor numerice ale cromozomilor 21, 13, 18, X şi Y.

Amniocentezele au fost efectuate de medici cu experiență din cele trei Clinici ale Spitalului Clinic de Obstetrică şi Ginecologie „Cuza–Vodă" Iaşi, astfel încât să se obțină suficient lichid amniotic de la prima încercare, evitându-se astfel repetarea procedurii, scăzând riscul pentru complicații.

Studiul statistic a abordat două aspecte: statistica descriptivă şi statistica analitică. Statistica descriptivă prezintă clasificarea şi sintetizarea datelor de observație. Aceasta concentrează informația existentă în datele respective cu ajutorul anumitor indicatori statistici ce exprimă caracteristici sau tendințe ale fenomenului studiat. Analiza corelației statistice a permis identificarea unor dependențe specific statistice şi adaptate la formele complexe şi variate din medicină. În urma aplicării testelor statistice

s-au luat în discuție principalii parametrii de interes, iar în funcție de valorile acestora s-au stabilit concluziile.

REZULTATE ŞI DISCUȚII

Performanța diferitelor metode de screening în primul trimestru de sarcină privind aneuploidiile fetale

Vârsta maternă este un criteriu de screening sărac, deoarece un număr mare de copii cu aneuploidii (frecvent sindrom Down) sunt născuți de femei mai tinere de 35 de ani. Colegiul American de Obstetrică şi Ginecologie (The American College of Obstetricians and Gynecologists - ACOG) nu mai recomandă utilizarea vârstei materne de 35 de ani ca un punct critic pentru practicarea amniocentezei (5,6).

Screening-ul bazat pe **vârsta maternă** pentru un cut-off de 35 de ani permite definirea grupului cu risc crescut pentru aneuploidii fetale (anomaliile cromozomiale numerice). Vârsta maternă avansată (n= 628) a avut o rată de detecție a anomaliilor cromozomiale numerice de 5,10% (n=32). Analiza gradului de asociere a vârstei materne peste 35 de ani cu prezența aneuploidiilor a demonstrat prin rezultatul testului Yates faptul că nu există o asociere semnificativă, aspect ce demonstrează că vârsta maternă avansată nu este un factor de predicție semnificativ în apariția unei sarcini cu anomalie cromozomială numerică (χ^2=1,02, r=-0,129, p=0,2609; 95%CI).

Evaluarea raportului de şansă (OR= 0,77) şi a riscului relativ (RR=0,78) susține încă odată concluzia potrivit căreia vârsta maternă avansată nu este un factor de predicție semnificativ în estimarea unei sarcini cu aneuploidie, riscul relativ având valoare subunitară.

Utilizând rezultatul testului FISH ca metodă *gold standard*, s-au calculat sensibilitatea, specificitatea, valorile predictiv pozitive şi predictiv negative dar şi acuratețea privind utilizarea vârstei materne avansate ca metodă de evaluare a riscului pentru prezența aneuploidiilor. Valoarea predictiv pozitivă a vârstei materne a fost de 5,1%, iar valoarea predictiv negativă a fost de 93,49%. Sensibilitatea testului a fost de 38,55% şi este mai mică comparativ cu specificitatea vârstei materne (55,12%), aspect ce demonstrează încă odată că în cazul gravidei cu vârstă peste 35 ani putem să ne aşteptăm la rezultate fals pozitive însă acuratețea fiind mică acestea nu se corelează semnificativ cu vârsta maternă peste 35 de ani.

Translucența nucală crescută a fost evidențiată în 3,33% din cazuri (n=47).

Translucența nucală crescută a avut o rată de detecție a aneuploidiilor de 19,15% (n=9). Corelația dintre translucența nucală crescută şi prezența anomaliilor cromozomiale numerice a evidențiat (testul neparametric Pearson) faptul că există o asociere semnificativă, aspect ce demonstrează faptul că translucența nucală crescută este un factor de predicție semnificativ pentru prezența anomaliilor cromozomiale numerice (χ^2=15,45, r=0,61, p=0,00008, 95%CI). Raportul de şansă (OR=4,13) şi riscul relativ (RR=3,53) demonstrează prezența unui risc crescut pentru anomalie cromozomială numerică în cazul prezenței translucenței nucale crescute, în lotul analizat acesta fiind de 3,53 ori mai mare comparativ cu riscul prezent în cazul absenței translucenței nucale crescute. Valoarea mare a specificității (97,14%) indică faptul că probabilitatea de a avea o anomalie cromozomială numerică în contextul prezenței translucenței nucale crescute este mare. Rata rezultatelor fals pozitive în cazul translucenței nucale crescute a fost de 2,86%.

În lotul de studiu 12,33% din cazuri (n=174) au prezentat **dublu test** cu risc crescut, dintre acestea doar 5,75% au fost însoțite de aneuploidie cromozomială (n=10).

Rezultatele au demonstrat faptul că prezența dublului test cu risc crescut nu prezintă o asociere semnificativă cu prezența anomaliilor cromozomiale numerice, aspect ce demonstrează faptul că dublul test cu risc crescut nu este un factor de predicție semnificativ pentru prezența anomaliilor cromozomiale numerice (χ^2=0,0065, r=-0,01, p=0,935 95%CI). Raportul de şansă (OR=0,97 → 0,46-1,99; 95%CI) şi riscul relativ (RR=0,97 → 0,51-1,85; 95%CI) demonstrează prezența unui risc mic pentru anomalie cromozomială numerică în cazul dublului test cu risc crescut. Valoarea specificității (87,65%) indică faptul că probabilitatea de a avea o anomalie cromozomială numerică în contextul rezultatului de risc crescut dat de dublu test este moderată şi mai mică comparativ cu probabilitatea de estimare a prezenței translucenței nucale crescute (97,14%). Rata rezultatelor fals pozitive este de 12,35%, valoare de asemenea mai mare comparativ cu cea calculată în cazul translucenței nucale crescute.

Evaluarea metodelor combinate de screening în primul trimestru de sarcină.

Asocierea vârstei materne ≥ 35 ani şi translucenței nucale crescute ca metodă de predicție în aneuploidiile fetale

Vârsta maternă avansată şi prezența translucenței nucale crescute a fost identificată în 0,71% din cazuri (n=10). Rata de detecție a anomaliilor cromozomiale numerice în cadrul metodei de screening combinate (vârstă maternă ≥35 ani + translucență nucală crescută) a fost de 40% (n=4). Gradul de asociere a rezultatelor pozitive (risc crescut) a testului combinat (vârstă+TN) cu prezența anomaliilor cromozomiale numerice demonstrează faptul că această evaluare combinată este un factor de predicție semnificativ pentru prezența anomaliilor cromozomiale numerice (χ^2=15,423 r=0,83 p<<0,05 95%CI) (tab. I).

Evaluarea raportului de şansă (OR= 21,18 → 2,59-45,75; 95%CI) şi a riscului relativ (RR=7,09 → 3,22-15,61; 95%CI) demonstrează prezența unui risc foarte mare pentru anomalie cromozomială numerică în cazul asocierii vârstei materne peste 35 de ani şi translucenței nucale crescute (tab. III). Valoarea foarte mare a specificității (99,5%) indică faptul că probabilitatea de a avea anomalie cromozomială numerică în contextul evaluării combinate date de vârsta maternă avansată şi translucența nucală crescută este mare. Rata rezultatelor fals pozitive este de 0,45%, valoare de asemenea mică comparativ cu cele calculate în cazul analizei individuale a vârstei materne avansate şi translucenței nucale crescute (tab. II).

Asocierea vârstei materne ≥ 35 ani, translucenței nucale crescute şi dublu test cu risc crescut ca metodă de predicție în aneuploidiile fetale

Rata de detecție a anomaliilor cromozomiale numerice în cadrul metodei de screening combinate (vârstă maternă ≥35 ani + translucență nucală crescută + dublu test cu risc crescut) a fost de foarte mare, în lotul de studiu fiind întâlnit un singur caz, acesta fiind asociat cu aneuploidie cromozomială (trisomie 18). Corelarea rezultatelor pozitive (risc crescut) a testului combinat (vârstă+TN+dublu test) cu prezența anomaliilor cromozomiale numerice a evidențiat (testul neparametric Yates) faptul că există o asociere semnificativă, aspect ce demonstrează faptul că această evaluare

combinată este un factor foarte bun de predicție pentru prezența anomaliilor cromozomiale numerice (χ^2=3,51, r=0,87, p=0,00006, 95%CI) (tab. I). Datorită numărului foarte mic de cazuri nu a putut fi evaluat raportul de şansă. Evaluarea riscului relativ (RR=17,2 → 13,94-21,21; 95%CI) demonstrează prezența unui risc foarte mare pentru anomalie cromozomială numerică în cazul asocierii vârstei materne peste 35 de ani, translucenței nucale crescute şi dublu test cu risc crescut (tab. III).

În evaluarea performanței metodei de screening privind evaluarea combinată - vârstă maternă avansată, translucență nucală crescută şi dublu test cu risc crescut, numărul mic de cazuri din lotul de studiu a avut o influență semnificativă asupra rezultatelor. Astfel, prezența unui caz unic a determinat o specificitate mare a metodei (100%), însă a scăzut semnificativ acuratețea metodei la 94,19% şi sensibilitatea acesteia (1,2%) (tab. II). Aceste rezultate ce privesc sensibilitatea şi acuratețea nu sunt concordante cu specificitatea metodei, în situația studiată neexistând un compromis favorabil ce ar demonstra faptul că această metodă este performantă. O metodă prezintă o bună putere discriminatorie atâta timp cât atât sensibilitatea, cât şi specificitatea au valori mari, dar sensibilitatea nu atinge nivele maxime.

Asocierea vârstei materne ≥ 35 ani şi dublu test cu risc crescut ca metodă de predicție în aneuploidiile fetale

În lotul de studiu asocierea vârstă maternă ≥ 35 ani şi dublu test cu risc crescut a fost întâlnită în 4,75% din cazuri (n=67). Rata de detecție a anomaliei cromozomiale numerice în cadrul metodei de screening combinate (vârstă maternă ≥35 ani + dublu test cu risc crescut) a fost de 10,45% (n=7). Analiza gradului de asociere a rezultatelor pozitive (risc crescut) a testului combinat (vârstă+dublu test) cu prezența anomaliilor cromozomiale numerice a evidențiat (testul neparametric Yates) faptul că nu există o asociere semnificativă, aspect ce demonstrează faptul că această evaluare combinată nu este un factor de predicție semnificativ pentru prezența anomaliilor cromozomiale numerice (χ^2=1,18 r=0,32 p=0,103 95%CI) (tab. I). Evaluarea riscului relativ (RR=1,85 → 0,89-3,85; 95%CI) demonstrează prezența unui risc mic pentru prezența anomaliilor cromozomiale numerice în cazul asocierii vârstei materne peste 35 ani şi dublu test cu risc crescut (tab. III).

Studiul a relevat o valoarea mare a specificității (95,48%) acest fapt indicând că probabilitatea de a avea anomalie cromozomială numerică în contextul evaluării combinate date de vârsta maternă avansată şi dublu test cu risc crescut este de 95,48%. Rata rezultatelor fals pozitive este de 4,52% (tab. II).

TABELUL I

Prevalența factorilor de risc implicați în aneuploidiile fetale

Metoda de screening	Aneuploidie fetală		χ^2	r	p
	absentă	prezentă		*95%CI*	
Vârstă maternă (≥ 35 ani)	94,90%	**5,10%**	1,265448	-0,1295	0,26063

TABELUL III

Parametrii predictivi ai metodelor de screening privind aneuploidiile fetale

Metoda de screening	Raport de şansă		Raport de risc	
	OR	95%CI	RR	95%CI
Vârstă maternă (≥ 35 ani)	0,77	(0,48-1,24)	0,78	(0,51-1,20)
Translucența nucală (TN)	4,13	(1,78-9,29)	3,53	(1,88-6,61)
Dublu test	0,97	(0,46-1,99)	0,97	(0,51-1,85)
Vârsta maternă + dublu test	1,95	(0,78-4,61)	1,85	(0,89-3,85)
Vârsta maternă + TN	21,18	(2,59-45,75)	7,09	(3,22-15,61)
Vârsta maternă + TN + dublu test	-	-	17,20	(13,94-21,21)

Eficiența ridicată de screening pentru aneuploidii fetale realizat în primul trimestru de sarcină o deține metoda combinată (vârstă maternă peste 35 ani, prezența translucenței nucale crescute şi dublu test cu risc crescut) ce are rata de detecție de 100% şi o rată a rezultatelor fals-pozitive de 0%. Eficiența acestei metode este dată şi de riscul relativ ridicat (RR=17,2) şi specificitatea metodei (Sp=100%) (fig. 1).

Evaluând în funcție de rata rezultatelor fals pozitive din studiu reiese faptul că o metodă bună de evaluare a riscului pentru aneuploidii este evaluarea combinată a translucenței nucale crescute (TN) cu vârsta maternă peste 35 ani. Rezultatele indică pentru această metodă o specificitate de 99,5%, o rată de detecție de 40%, o rată a rezultatelor fals pozitive de 0,45% şi un risc relativ pentru prezența aneuploidiilor de 7,09 (RR=7,09).

Indicația unică având în vedere vârsta maternă avansată sau dublul test cu risc crescut reprezintă cele mai slabe metode de screening privind anomaliile cromozomiale numerice (Sp – vârstă maternă=55,12%, Sp – dublu test=87,65%).

Indicația unică privind translucența nucală crescută reprezintă o metodă de screening bună, având în vedere faptul că în lotul analizat specificitatea metodei a fost de 97,14%, rata rezultatelor fals pozitive a fost de 2,86% iar riscul relativ de 3,53 (RR=3,53) (fig. 1).

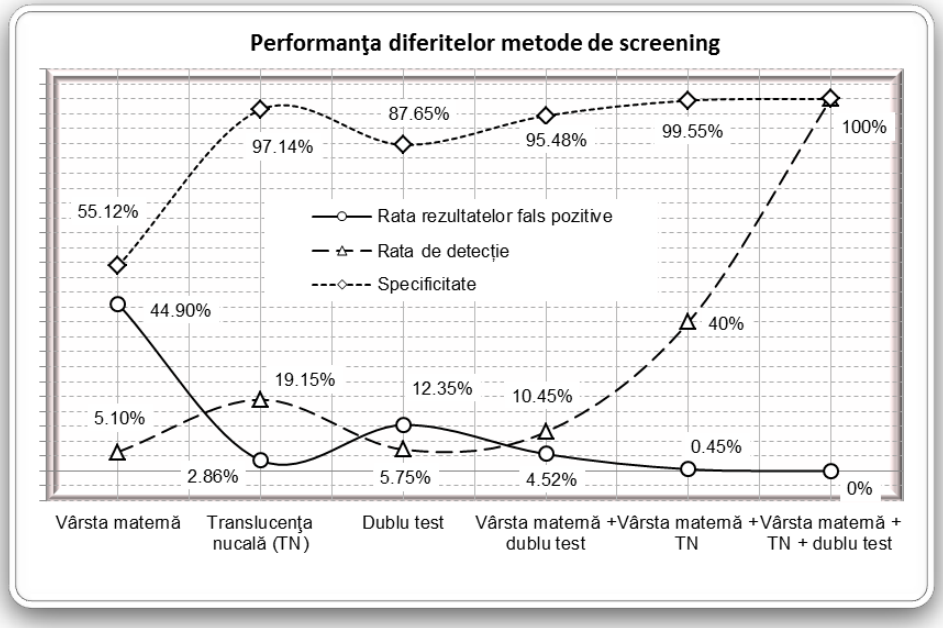

Fig.1. Performanțele diferitelor metode de screening privind aneuploidiile fetale

CONCLUZII

Pentru realizarea unui diagnostic prenatal corect şi creşterea eficienței metodei este necesară o selecție corectă a cazurilor cu risc de aneuploidie pe baza rezultatelor evaluării ecografice şi a celei biochimice (dublu test cu risc crescut) în corelație cu vârsta maternă avansată sau prezența în antecedente a unor copii cu aneuploidie (sindrom Down, sindrom Edwards, sindrom Patau, sindrom Klinefelter sau triplo X).

Alături de siguranță şi precizie, precocitatea reprezintă dezideratul unei metode de diagnostic prenatal fiabile.

În evaluarea performanței metodei de screening privind evaluarea combinată - vârstă maternă avansată, translucență nucală crescută şi dublu test cu risc crescut, numărul mic de cazuri din lotul de studiu a avut o influență semnificativă asupra rezultatelor. Astfel, prezența unui caz unic a determinat o specificitate mare a metodei (100%), însă a scăzut semnificativ acuratețea metodei la 94,19% şi sensibilitatea acesteia (1,2%). Aceste rezultate ce privesc sensibilitatea şi acuratețea nu sunt concordante cu specificitatea metodei, în situația studiată neexistând un compromis favorabil ce ar demonstra faptul că această metodă este performantă.

Evaluând în funcție de rata rezultatelor fals pozitive din studiu, reiese faptul că o metodă bună de evaluare a riscului pentru aneuploidii este evaluarea combinată a translucenței nucale crescute (TN) cu vârsta maternă peste 35 ani. Rezultatele indică pentru această metodă o specificitate de 99,5%, o rată de detecție de 40%, o rată a rezultatelor fals pozitive de 0,45% şi un risc relativ pentru prezența aneuploidiilor

de 7,09 (RR=7,09).

Indicația unică având în vedere vârsta maternă avansată sau dublul test cu risc crescut reprezintă cele mai slabe metode de screening privind anomaliile cromozomiale numerice (Sp – vârstă maternă=55,12%, Sp – dublu test=87,65%).

Indicația unică privind translucența nucală crescută reprezintă o metodă de screening bună, având în vedere faptul că în lotul analizat specificitatea metodei a fost de 97,14%, rata rezultatelor fals pozitive a fost de 2,86%, iar riscul relativ de 3,53 (RR=3,53).

NOUTĂȚI

REGLAREA TRANSCRIPȚIEI GENICE PRIN INTERMEDIUL TFO

Oligonucleotidele formatoare de triplex (*Triplex-forming oligonucleotides* -TFOs) au rol reglator al expresiei genice prin inhibarea transcripției. Prin încorporarea situs-specifică a timidinei, TFO sunt inactivate şi formarea triplexului TFO:DNA este blocată. După expunerea de scurtă durată la radiații UV, timidina este îndepărtată, iar TFO sunt activate, ducând la inhibarea transcripției genice. În plus, încorporarea deoxicitidinei la nivelul secvențelor inhibitorului TFO permite dezactivarea indusă de lumină a TFO şi activarea fotochimică a a expresiei genice. Acestea sunt primele exemple de foto-reglare a TFO şi aplicațiile sale în activarea sau dezactivarea fotochimică a expreisie genice. (Govan J, Uprety R, Hemphill J, Lively MO, Deiters A. Regulation of Transcription through Light-Activation and Light-Deactivation of Triplex-Forming Oligonucleotides in Mammalian Cells. *ACS Chem Biol*. 2012 Apr 27. [Epub ahead of print]).

HEPATOCYTES' FUNCTION AND ADIPOKINES IN PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE DEPENDING ON THE ACE (rs4646994) AND PPAR-γ2 (rs1801282) GENES' POLYMORPHISMS (Abstract): Non-alcoholic fatty liver disease (NAFLD) is a pathology characterized by accumulation of fat (steatosis) found in at least 5% of hepatocytes, and is a multifactorial disease including a genetic component. **Aim:** To analyze the association of polymorphism of the ACE (I/D) and PPAR-γ2 (Pro12Ala) genes with functional activity of hepatocytes and adipocytokines content in patients with NAFLD. **Material and methods:** The study involved 96 patients with NAFLD and obesity (OB): men-41.67%, women-58.33%. Liver function was studied by the activity of organ-specific enzymes. The polymorphisms of PPAR-γ2 (Pro12Ala) and ACE (I/D) genes were studied by PCR. **Results:** The leptin plasma level was 1.74-2.39 times higher in women compared to men with development of leptin resistance (LR) regardless of NAFLD type or OB degree, especially in the D-allele of the ACE gene carriers by 22.19% and 28.73%. **Conclusions:** This study shows existing associations of changes in hepatic function, lipid metabolism, and adipocytokines activity in NAFLD with the ACE (rs4646994) and PPAR-γ2 (rs1801282) genetic polymorphisms. ACE DD-genotype and PPAR-γ2 gene's Ala-allele associate with higher conjugated bilirubin, transaminases, and leucocytes. Secretory activity of adipose tissue is significantly higher by the content of pro-atherogenic leptin, with the development of leptin resistance in women, regardless of the NAFLD type and OB degrees, especially in D-allele carriers of the ACE gene. NAFLD with OB is characterized by reliable increase in leptin concentration, especially in Pro12 genotype carriers of the PPAR-γ2 gene, with increase in LR and decrease of anti-atherogenic adiponectin. **Keywords:** NON-ALCOHOLIC FATTY LIVER DISEASE, GENETIC POLYMORPHISM, ACE (I/D), PPAR-γ2 (PRO12ALA), LEPTIN, ADIPONECTIN, OBESITY.

Non-alcoholic fatty liver disease (NAFLD) is the most common liver disease in developed countries with incidence of 24% in Europe (1). The disease is closely related to metabolic syndrome, obesity (OB), insulin resistance (IR), type 2 diabetes mellitus (DM), arterial hypertension, and hyperlipidemia (2-5). IR reduces the level of adiponectin in blood plasma, and increases concentration of leptin, which is also found in NAFLD (6). Reduced secretion of adiponectin, an anti-atherogenic, anti-inflammatory and anti-fibrotic agent, combined with increased secretion of leptin possessing opposite effects, promotes the progression of NAFLD into non-alcoholic steatohepatitis (NASH), as proved by multiple studies, including path morphology (7-10).

NAFLD is diagnosed in 20-35% of adult population in developed countries; in obese women, aged over 40, fatty liver dystrophy occurs in 75% of cases. Even among liver donors with normal levels of transaminases, steatosis is diagnosed in 20%. According to the National Health and Nutritional Examination Survey (NHANES III), the incidence of fatty liver dystrophy is met in up to 16% of patients with normal body weight and up to 76% in patients with obesity (11-14).

The clinical significance of NAFLD and the lack of effective drugs for limiting or reversing the progression of the disease in patients with NASH are of considerable interest and determine the need for further study of the main mechanisms involved in the development and progression of the disease. The accumulation of fat in liver occurs as a result of the imbalance between intake and excretion of triglycerides (15). However, genetic factors for the development of this pathology, which may serve as early markers of functional and organic hepatocyte cellular disturbances, have been still understudied (14, 16).

Therefore, *the aim of this study* was to analyze the associations of the ACE (I/D), PPAR-γ2 (Pro12Ala) genetic polymorphisms with functional activity of hepatocytes and adipocytokine content in patients with NAFLD.

MATERIAL AND METHODS

This study conforms to international *bioethical standards* (European Convention on Human Rights and Biomedicine, the WMA Declaration of Helsinki on ethical principles of scientific medical research involving human subjects, GCP, EUC directive #609) and approved by Commission for Bioethics in Research of the Bukovinian State Medical University, Ukraine. All patients signed written permissions and obtained full information about the study prior to participation. The study involved 96 patients with NAFLD, 56 (58.33%) women and 40 (41.67%) men. The mean age was 53.70±5.34 yrs. Compensated type 2 diabetes mellitus (DM 2), lasting from 2-7 years, observed in 44 (45.83%) patients. Existing literature data was used as control.

NAFLD *diagnosed* in accordance with the EASL-EASD-EASO Clinical Practice Guidelines for the management of NAFLD (8). The OB degree was determined by body mass index (BMI) $\geq$30 kg/m^2 (6, 8). During previous year the subjects had alcohol intake less than: for men >50 g C_2H_5OH per week, for women >30 g C_2H_5OH per week.

The *liver function* was studied by the activity of detoxification and protein-synthetic function of hepatocytes indices, by the presence or absence of cytolysis signs, mesen-

chymal inflammatory syndrome, or cholestasis syndrome. Leptin and adiponectin were measured in ELISA (DRG ELISA, Germany). Leptin resistance (LR) was calculated as the leptin/triglycerides ratio (>2.7). Results were interpreted according to ESC/ESH 2013 recommendations.

Polymerase chain reaction (PCR) was used to study the polymorphism of PPAR-γ2 (Pro12Ala, rs1801282) and ACE (I/D, rs4646994) genes. DNA was isolated from peripheral venous blood lymphocytes using a set of DNA-sorb-V reagents. PCR was performed using Taq DNA polymerase and specific primers for PPAR-γ2 (forward 5'-GAAACTGATGTCTTGACTCATGGGTG-3' and reverse 5'-CAACCTGGAAGA CAAACTACAAGAGC -3') and ACE (forward 5'-GCCGGGGACTCTGTAAGCCA CTGC-3' and reverse 5'-CCTTGTCTCGCCAGCCCTCCCA-3') (7). Allele discrimination of the PPAR-γ2 gene was performed using restriction endonuclease Cse I (HgaI) (Fermentas, Lithuania). The amplification products of of the I/D polymorphism of the ACE gene and those of the restriction of PCR PPAR-γ2 genes Pro12Ala polymorphism were separated in horizontal electrophoresis in 3% agarose gel concentrated with 4 μL of ethidium bromide for 45-60 minutes, visualized using transilluminator with molecular weights marker 100-1000 bp.

Statistical processing was carried out using the *MS Excel, Primer of Biostatistics 6.05* and *Statistica 7.0* software. Logic regression used for establishing genetic dependencies.

RESULTS

Liver protein synthesizing function did not suffer in observed patients, regardless of the analyzed genes' polymorphic variants (tab. I). In ACE gene's DD genotype, the level of direct bilirubin, as well as the activity of AST, ALT, and leukocyte content were higher than in II/ID-genotypes. Conjugated bilirubin was higher by 22.24% and 20.55% ($p<0.05$), AST – 2.12 and 1.71 times ($p<0.05$), respectively; for ALT – 1.32 times ($p<0.05$); leukocytes by 14.56% ($p<0.05$). Ala-allele carriers had higher rates of AST, ALT as well as leucocytes compared to Pro12-genotype of the PPAR-γ2 gene – by 35.21%, 38.64%, 29.81% and 12.95%, respectively ($p<0.05$). The fasting glucose level was higher in all patients regardless of type 2 DM, requiring further study.

Activity of adipose tissue by the content of adipocytokines in plasma, depending on the NAFLD type and OB degrees, is presented in tab. II. Leptin level is higher in women, regardless of NAFLD type and OB degrees by 1.74-2.39 times ($p<0.001$). In men with non-alcoholic steatosis of the liver (NASL) concentration of leptin was 25.39% higher than in men with non-alcoholic steatohepatitis (NASH), $p_{NASH}<0.05$. In case of 3rd degree OB, leptin content was higher than in 1st and 2nd OB degrees, regardless of gender: in men by 48.99% ($p_{OB1}=0.022$) and 43.55% ($p_{OB2}=0.034$); in women by 53.34% ($p_{OB1}<0.001$) and 50.98% ($p_{OB2}=0.002$).

The rate of leptin resistance (LR) increased by 22.22% ($p<0.05$) in NASL patients and by 46.15% in NAFLD ($p=0.035$) and combined with the 3rd degree OB by 42.79% ($p=0.044$). Concentration (tab. II) of adiponectin in patients with 2nd and 3rd degrees OB was lower than in those with the 1st degree by 5.73% and 5.91% ($p<0.05$). The single-factor dispersion analysis confirmed association of NAFLD with high leptin content in men ($F=236.86$, $p<0.001$) and LR ($F=283.94$, $p<0.001$).

TABLE I

Biochemical indices of hepatocytes function in NAFLD patients depending on the PPAR-γ2 (Pro12Ala) and ACE (I/D) genes' polymorphisms

Indices	ACE gene genotype			PPAR-γ2 gene genotype	
	II	ID	DD	12Ala, ProAla	Pro12

p_{II}, p_{Ala} – reliability of differences between the values for a specific gene relative to the II homozygotes of the ACE gene and the carriers of the Ala-allele (12Ala+ProAla) of the PPAR-γ2 gene; p_{ID} – reliability of differences for a specific gene relative to ID-heterozygotes

TABLE II

Content of adipocytokines in patients considering the NAFLD type and degrees of obesity

Indices			Leptin, ng/mL	Adiponectin, ng/mL	Leptin resistance, U
NAFLD	NASH	M	30.38±3.92	75.88±2.50	20.09±2.37
		W	69.69±8.50 P_m<0.001		
	NASL	M	40.72±2.06 p_{NASH}<0.05	74.35±3.75	25.83±0,88 p_{NASH}<0.05
		W	71.01±9.21 p_m<0.001		
Obesity	OB I	M	22.23±3.77	77.88±1.81	17.92±2.31
		W	48.67±7.38 p_m<0.001		
	OB II	M	24.60±5.59	73.42±2.05 p_{OB1}=0.004	19.04±3.15
		W	51.13±6.44 p_m<0.001		
	OB III	M	43.58±7.66 p_{OB1}=0.022 p_{OB2}=0.034	73.28±2.53 p_{OB1}=0.018	33.28±6.07 p_{OB1}=0.035 p_{OB2}=0.044
		W	104.30±9.25 p_{OB1}<0.001 p_{OB2}=0.002 p_m<0.001		

OB I-III – obesity of the I-III degrees; M – men; W – women; p_{NASH} – reliability of differences between the indices relative to individuals with NASH by each separate index; p_{OB1} – reliability of differences between the indices relative to individuals with the first degree obesity by each separate index (including the content of leptin taking into consideration gender); p_{OB2} – reliability of differences between the indices relative to individuals with the second degree obesity by each separate index; p_M – reliability of differences between indices relative to men.

Obesity was associated with high leptin content in men (F=77.95, p<0.001) and women (F=341.43, p<0.001), with LR increase (F=103.17, p<0.001) and decrease of adiponectin (F=44.84, p<0.001).

In female D-allele carriers of the ACE gene, leptin level exceeded the one in individuals with II-genotype (tab. III) by 22.19% (p_{II}=0.048) and 28.73% ((p_{II}=0.036). In Pro12 genotype of the PPAR-γ2 gene, leptin level exceeded that of the Ala-allele carriers regardless of their sex (tab. III): in men 1.99 (p_{12Ala}=0.036) and 3.75 times p_{ProAla}=0.008), in women by 32.79% (p_{12Ala}=0.015) and 27.81% (p_{ProAla}=0.043). The rate of LR prevailed exclusively in male homozygous Pro-allele carriers, over Ala-allele carriers – 2.23 and 3.16 times (p<0.01), in contrast to women, where such dependences were not found, despite higher initial level of both leptin itself and the rate of LR.

TABLE III

The content of adipocytokines in NAFLD patients, depending on polymorphic variants of the ACE (ACE) and PPAR-γ2 (Pro12Ala) genes

Genotypes		Leptin, ng/mL		Leptin resistance, U		Adiponectin, ng/mL

DISCUSSION

Several studies focused on mechanisms of NAFLD development depending on polymorphisms of the genes involved in the regulation of lipids and carbohydrates metabolisms. Despite this fact, role of ACE and PPAR-γ2 genes in NAFLD remained unclear until recent times (3, 12).

Single-factor dispersion analysis confirmed association of I/D (rs4646994) polymorphism of the ACE gene with high leptin content and the LR rate both in men and in women, as well as reduction of adiponectin. Data concerning the ACE gene I/D polymorphism is similar to other European populations but present less I-allele compared to Asian populations. Similar associations of Pro12Ala polymorphism of the PPAR-γ2 gene were also established. Distribution of Pro12Ala polymorphism of the PPAR-γ2 gene in this study is similar to other European studies. In addition, Ala-allele was more frequent and Pro-allele less frequent than in both Asian and Equatorial races (7, 13, 17).

Similar data of adipose tissue secretory activity – the increased synthesis of leptin, increased LR, and decreased adiponectin in ProPro-genotype owners (PPAR-γ2 gene), were previously presented in several papers (7, 18). In our study, we found no association of the DM frequency depending on rs1801282 polymorphism of the PPAR-γ2 gene, unlike data found in Iranian population (19). While ACE is promising drug target for the management of NAFLD, no correlations of ACE gene polymorphism with risk factors and the disease severity in NAFLD were previously established (20), unlike our data.

CONCLUSIONS

This study shows existing associations of changes in hepatic function, lipid metabolism, and adipocytokines activity in NAFLD with the ACE (rs4646994) and PPAR-γ2 (rs1801282) genetic polymorphisms. ACE DD-genotype and PPAR-γ2 gene's Ala-allele associate with higher conjugated bilirubin, transaminases, and leucocytes. Secretory activity of adipose tissue is significantly higher by the content of pro-atherogenic leptin, with the development of leptin resistance in women, regardless of the NAFLD type and OB degrees, especially in D-allele carriers of the ACE gene. NAFLD with OB is characterized by reliable increase in leptin concentration, especially in Pro12 genotype carriers of the PPAR-γ2 gene, with increase in LR and decrease of anti-atherogenic adiponectin.

THORACO-ABDOMINAL INJURIES: THE GENERAL SURGEON'S PERSPECTIVE (Abstract): **Backround:** Thoraco-abdominal traumatic injuries affect the inferior part of the thoracic cavity and the superior part of the abdominal cavity. This study summarizes five years of our surgical department's experience in the diagnosis and management of thoraco-abdominal trauma patients. **Methods:** We examined records from our surgical and emergency room departments from January 1996 to December 2000, and selected patients with thoraco-abdominal injuries. **Results:** Fifty-five patients were treated who suffered coexisting trauma of the thoracic and abdominal cavity. Males represented the majority of patients and mean age was 38.2 years. Traffic accidents were the major cause (55%) followed by criminal acts of violence (32%) and falls (13%). The most common thoracic injuries were rib fractures (40%) and simple lung contusions (35%) and the abdominal organs most commonly injured were the spleen (35%), liver (25%) and kidney (20%). Surgical interventions were performed in 68% of patients, whereas the remaining patients were treated conservatively. **Conclusions:** Thoraco-abdominal injuries are characterized by high heterogeneity and can provide significant decision-making challenges. The accurate diagnosis of all coexisting injuries is critically important, as the diagnosis will determine surgical or non-operative management of these injuries. **Key words:** THORACIC, ABDOMINAL, TRAUMA, DIAGNOSIS, MANAGEMENT.

The aim of this study is to present the five-year experience of our surgical department in diagnosis and management of thoraco-abdominal traumatic injuries that affect the inferior part of the thoracic cavity and the superior part of the abdominal cavity. These injuries are characterized by high heterogeneity due to the variety of injury mechanisms that can be involved and the anatomy of this body part. Thoraco-abdominal injuries can provide significant decision-making challenges and the surgeon should be able to consider all possibilities in order to diagnose life threatening injuries (1, 2).

The organs located in the superior part of the abdominal cavity are the liver, spleen, stomach and parts of the pancreas

and kidneys, which are protected by the inferior ribs. However, the abdomen is more vulnerable to injury than the chest because there is little bony structure below the ribcage to protect internal organs from anterior and lateral impacts. Due to the elasticity of the thoracic cage, blunt impact of the upper abdomen can compress and injure abdominal organs with minimal or no injury to the bones. Compression of the abdominal cavity against a fixed object such as a safety belt or steering wheel results in a rapid increase in intraluminal pressure, which may in turn cause bowel rupture and tears or hematomas of solid organs without rib fractures (2, 3).

MATERIALS AND METHODS

We present our experience with patients who have had coexisting trauma of the thoracic and abdominal cavity. For this retrospective study, the records of our surgical department and the emergency department were examined from January 1996 to December 2000 to flag patients with thoraco-abdominal injuries. A total of 55 patients were treated in our department during this time frame.

All patients admitted to the trauma center were resuscitated utilizing Advanced Trauma Life Support (ATLS) protocols. Resuscitation consisted of rapid infusion of warm fluids and blood. All patients had recordable vital signs on admission to the Emergency Room and had suffered concomitant thoraco-abdominal traumatic injuries affecting the lower part of the thorax and one or more abdominal organs (fig. 1).

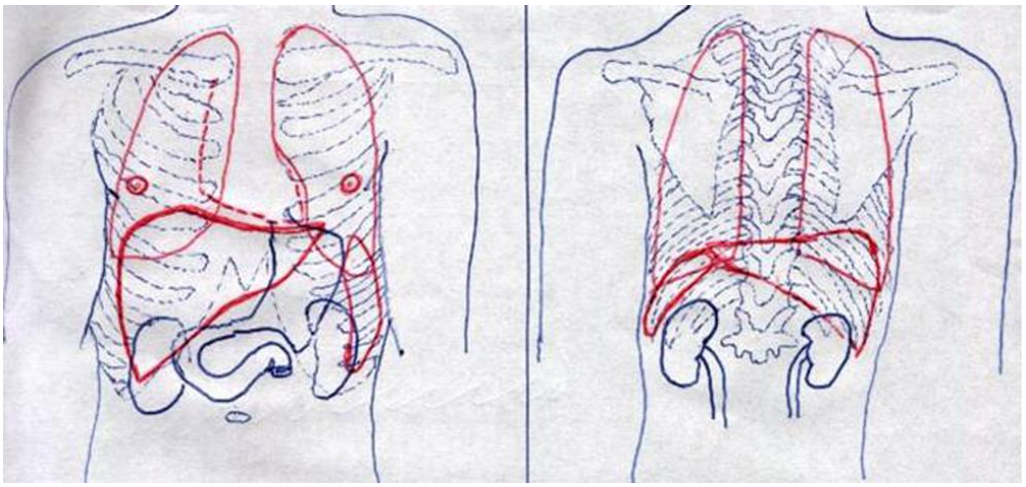

Fig. 1. Crude anatomy of the thorax and abdomen

The inclusion criteria for patients into our study were: 1) Injury of the lower chest (anterior ribs 5-10 and posterior ribs 9-12), including simple contusions of the thoracic wall, and 2) Simultaneous injury to an organ of the upper abdomen ranging from simple contusions to severe rupture of solid organs.

RESULTS

Males represented the majority of patients (85%) while females were less commonly represented (15%) with a male to female ratio of 5.7 to 1 (fig. 2). The patients ranged in age from 16 to 86 with a mean age of 38.2 years (fig. 3).

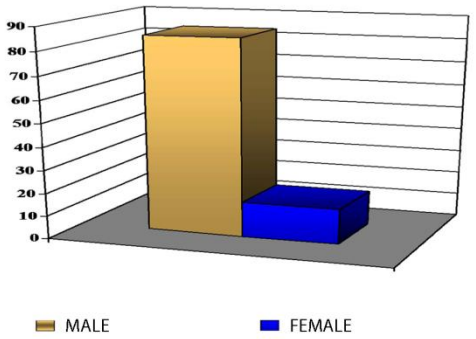

Fig. 2. Distribution of patients by sex

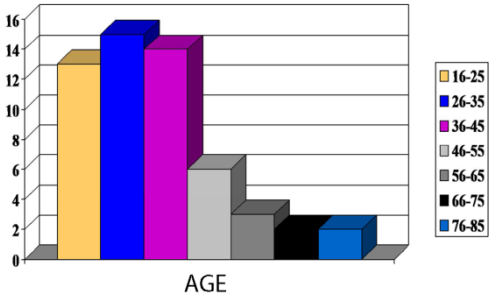

Fig. 3. Distribution of patients by age

Regarding the etiology of the injury, 55% of cases were caused by traffic accidents and 32% of cases were from criminal acts (of which 83% of these acts (15/18) involved injury by a lethal weapon, whereas the remaining 17% (3/18) were related to use of force). Falls accounted for the remaining 13% of total cases. Traffic accidents were further separated into car accidents (74%), bicycle accidents (16%) and pedestrians hit by automobiles (10%). In car accidents, about 2/3 of the patients were not using seatbelts.

The *mechanism* of *injury* is important in the management of a patient with a thoraco-abdominal injury. Three main groups of trauma mechanisms were recorded:

1. Blunt trauma of the inferior thoracic wall, where the kinetic energy of the power that injures the thorax is transmitted to the structures of the region (69% of cases),
2. Acute penetrating injuries (27% of cases), and
3. Combinations of both (4% of cases).

The injuries of the thoracic cavity were divided as follows: rib fracture (with or without hemothorax) (40%), rupture of chest wall (35%), and pulmonary fracture (with or without hemopneumothorax) (25%) (Table I).Injuries of the abdominal cavity were divided as such: spleen (35%), liver (25%), kidney (20%), diaphragmatic (6%) and combinationatorial injuries (14%) (i.e., diaphragm and inferior vena cava, diaphragm and stomach, or multiple injuries) (table I).

TABLE I

Thoracic injuries and abdominal injuries sustained by patients with thoraco-abdominal injuries.

Thoracic cavity	***Abdominal Cavity***
1. Rib fracture (with or without hemopneumothorax) (40%)	1. Spleen injury (35%)
2. Contusion of chest wall (35%)	2. Liver injury (25%)
3. Pulmonary contusion (with or without hemopneumothorax) (25%)	3. Kidney injury (20%)
	4. Diaphragmatic injury (6%)
	5. Combination (14%) - Diaphragm+vena vein - Diaphragm+stomach - Multiple injuries

Additionally, we recorded the following combinations: rib fracture with or without hemo/pneumothorax and spleen injury (26%), fracture of chest wall and liver injury (19%), rib fracture with or without hemo/pneumothorax and kidney injury (13%), fracture of chest wall and spleen injury (9%), fracture of chest wall and kidney injury (7%) and other combinations (26%) (table II).

TABLE II
Combined thoraco-abdominal injuries

Combination of thoraco-abdominal injuries
1. Rib fracture +/- hemo/pneumothorax & spleen injury (26%)
2. Contusion of chest wall & liver injury (19%)
3. Rib fracture +/- hemo/pneumothorax & kidney injury (13%)
4. Contusion of chest wall & spleen injury (9%)
5. Contusion of chest wall & kidney injury (7%)
6. Other combinations (26%)

Regarding the diagnostic modalities used for the patients with thoraco-abdominal injuries, we first used simple x-rays in 77% of cases, trauma exploration in 18% of cases and other tests (CT, U/S) for the remaining 5% of cases. As secondary diagnostic tests, we used U/S in 58% of cases, peritoneal lavage in 33%, CT in 5% and simple x-rays in 4% of cases. For tertiary diagnostic tests we used CT in 66% of cases, simple x-rays in 19% and other tests (angiography, urography, etc.,) in the remaining 15% of cases (table III).

Regarding trauma management, 68% of patients underwent exploratory laparotomy, or another major surgery. The specific interventions in the abdomen were: splenectomy (49% of cases), surgical hemostasis (38% of cases), nefrectomy (5% of cases) and diaphragm suturing (8% of cases). In the remaining 32% of cases, conservative management was chosen. The treatment of coexisting chest injuries was mostly conservative, since in only three cases (5%) a thoracotomy was required to control hemorrhaging of a large vessel in the chest. In 21% of patients (n = 12), Bülau drains were used for the treatment of hemopneumothorax (42%), pneumothorax (31%) and hemothorax (27%).

TABLE III
Diagnostic modalities used

1st diagnostic modality	
X-rays	77%
Wound exploration	18%
Others (US/CT)	5%
2nd diagnostic modality	
Ultrasound	58%
Diagnostic peritoneal lavage	33%
Computed tomography	5%
X-rays	4%
3rd diagnostic modality	
Computed tomography	66%
X-rays	19%
Others (angiography, urography etc)	15%

The average hospital stay was 13 days (min 6 days, max 27 days). Mortality rate was 5.5% (3 patients), which resulted from major injuries, such as rupture of the inferior vena cava or a section of the major hepatic vases.

DISCUSSION

Given our results over a five-year period, it is clear that thoraco-abdominal injury is a major challenge for the emergency trauma surgeon. Diagnostic errors often occur, as these injuries perplex even the most experienced trauma surgeons. An interesting observation of the current study is that car accidents are the major cause of thoraco-abdominal injury and are responsible for over half of the injuries, followed by acts of criminal violence, contrary to international experience, where the correlations are reversed (4).

The pre-hospital care, support of vital functions and hemodynamic stabilization of the patient have a crucial role in increasing survival for all trauma patients (2, 3). When the two largest cavities of the body are involved in trauma, this will lead the trauma surgeon to suspect serious abdominal injury, even in cases of simple contusions. Rapid assessment of physical signs of injury is a sine qua non, but it has been estimated that in many cases, clinical examination can be misleading, especially if patients are intoxicated, have neurological problems or require general anesthetics (5). Patients should be monitored closely for changes in vital signs as assessed by serial abdominal examinations (6, 7).

X-rays are necessary, but in most cases insufficient to complete the diagnosis (8). Ultrasound has proven to be an ideal recourse in the emergency evaluation of the trauma patient because it rapidly and accurately detects intra-abdominal fluid or blood and is easily repeatable. Ultrasonography provides valuable information that augments the surgeon's diagnostic capability but results in relatively decreased sensitivity for parenchymal intra-abdominal injuries (9, 10). Ultrasound sensitivity in the diagnosis of diaphragmatic rupture is approximately 89% (11). Diagnostic peritoneal lavage is an invasive treatment with a sensitivity of about 95% in detecting intra-abdominal bleeding with the quantitative analysis of the lavage fluid and is indicated in cases requiring quick decision-making (e.g., hemodynamic instability) (2, 3). Diagnostic peritoneal lavage is considered positive when there is 10 ml or more of frank blood or a red cell count over 100,000/mm3 (12).

The CT scan is a safe, fast and non-invasive procedure to accurately assess the two major body cavities but requires hemodynamically stable patients (13, 14). The CT scan is not only necessary for patients who are candidates for conservative treatment, but also for trauma patients with injuries involving the central nervous system. For penetrating injuries, wound exploration under local anesthesia is necessary. This procedure is usually performed in the operating room, but can be performed in the emergency department by some institutions. The wound is extended under local anaesthesia and the track followed through tissue layers (3). This practice solves many diagnostic problems, since it reveals whether there is a rupture of serosa membranes and the diaphragm. Finally, when the diagnosis remains inconclusive after these tests, other modalities such as angiography and intravenous urography are helpful alternatives.

A hemothorax found in association with a diaphragmatic injury in either a penetrating or blunt trauma may actually have its origin from an intra-abdominal source. Blood from injured abdominal organs may traverse a diaphragmatic rupture and enter the thoracic cavity. In cases of hemothorax with diaphragmatic injury, the trauma surgeon should strongly consider the possibility of intra-abdominal injury. The late compli-

cations of hemothorax, including residual clot, infected collections and trapped lung require additional treatment and, most often, surgical intervention (15, 16).

In cases of hemothorax with excessive bleeding that could not be controlled by Bülau placement (>500 ml upon placement and continuous bleeding) a thoracotomy and surgical hemostasis were performed. Concerning injuries of the abdominal organs, splenic injuries were treated via splenectomy (except for a single case), since splenic ruptures are dangerous even in hemodynamically stable patients. For patients with splenic parenchyma contusions conservative treatment was chosen. In 57% of patients with hepatic injuries, surgery was not necessary, and the patients were treated conservatively (as is the latest trend in surgery), although conservative treatment is not free of complications. Criteria for non-operative management of hepatic injuries include hemodynamic stability and lack of an associated injury requiring a celiotomy (16, 17, 18). We applied conservative treatment to most of the renal injuries considered minor in severity, except those patients who were hemodynamically unstable, or those with severe renal parenchyma fractures.

Injuries of the diaphragm are usually accompanied by other injuries, and they indicate that a more severe injury may have occurred, most of which are due to penetrating wounds and are called open thoraco-abdominal injuries. Diagnostic laparoscopy allows for the evaluation of trauma patients lacking clinical indications for a formal celiotomy. The clinical diagnosis of diaphragmatic rupture is difficult and is missed in anywhere from 7-66% of patients (19, 20). Thoracoscopy and laparoscopy are techniques that can accurately establish the diagnosis, but their role is limited to emergencies, whereas major surgical access is often more secured according to current data. Surgical repair is necessary (even for small ruptures) because the defect will not heal spontaneously and thoraco-abdominal pressure gradients will favor the enlargement of the defect with herniation of abdominal content (20).

CONCLUSION

It is evident that thoraco-abdominal injuries are heterogeneous in nature and difficult to categorize. All injuries that involve the chest and abdomen by the same projectile are true thoraco-abdominal injuries (21). Of critical importance is not to define exactly which organs were injured, but if a major surgery is necessary. The mortality rate of thoraco-abdominal injuries is about 5-10% (22, 23). Given this mortality rate, it becomes imperative to surgically explore any doubtful thoraco-abdominal injury, just as one would explore any questionable abdominal penetration. Taken together, unless one is certain that the lesion in question does not involve the abdomen, surgical exploration is mandatory.

THE EVALUATION OF MORTALITY IN ABDOMINAL SURGERY OF PATIENTS AGED OVER 75. A RETROSPECTIVE STUDY ON A SERIES OF 111 CASES (Abstract). Abdominal surgery of patients aged over 75 is a real challenge, regarding the risk-benefit ratio, especially in emergency cases. The aim of the study was to assess the mortality in elderly patients admitted for abdominal surgical conditions. **Material and methods**. A retrospective study was carried out on a series of 111 patients aged over 75 that died during hospitalization for abdominal diseases in the 3rd Surgical Unit during the period 2007-2010. Data from the medical files, operating books and pathology reports were collected and analyzed. **Results**. Of the 61 cases admitted for benign conditions, 11 deceased prior to surgery due to high ASA risk. 50 patients underwent surgery, mainly on emergency basis (42 cases). Most of the patients in this group suffered from intestinal infarction (22), followed by abdominal sepsis (16), intestinal obstruction (12) and digestive bleeding (10). Resection followed by anastomosis was performed in 17 cases; of these, anastomotic fistula with sepsis developed in 7 cases (41 %). Malignant abdominal diseases were diagnosed in 50 patients, most frequently colorectal cancer (25) followed by gastric cancer (14), pancreatic cancer (5), billiary duct carcinoma (3), malignant ampuloma (2) and hepatoma (1). In this group, 46 patients were operated on, mainly in emergency (35). Of the 32 cases where resection was performed, anastomostic fistula with sepsis developed in 21 (65,6 %). **Conclusions**, the main cause of death was abdominal sepsis due to anastomotic fistula following resections, for both benign and malignant condition. **Key words**: MORTALITY, ABDOMINAL SURGERY, ELDERLY.

Patologia chirurgicală abdominală a pacienților peste 75 de ani ridică numeroase probleme de management din cauza prezenței aproape invariabile a comorbidităților de sistem, ce creşte riscul morbidității şi mortalității postoperatorii. Scopul studiului a fost de a evalua cauzele mortalității pacienților peste 75 de ani internați pentru o afecțiune chirurgicală abdominală.

MATERIAL ŞI METODE

Studiul retrospectiv se bazează pe analiza a 111 pacienți cu afecțiuni chirurgicale abdominale, decedați în timpul spitalizării în Clinica a III-a Chirurgie, pe o perioadă de 4 ani (2007-2010). A fost realizată o împărțire a lotului în relație cu tipul afecțiunii în două grupuri - 61 de cazuri cu patologie benignă, respectiv 50 de cazuri cu

afecţiuni maligne digestive.

A fost utilizată baza de date a Centrului de Statistică al Spitalului "Sf. Spiridon" precum şi informaţiile din foile de observaţie, protocoalele operatorii şi registrele de anatomie patologică. S-au exclus din studiu pacienţii decedaţi pentru o altă patologie decât cea abdominală. Factorii analizaţi au fost: vârsta, sexul, diagnosticul principal la internare, tipul de intervenţie chirurgicală, cauza de deces şi durata spitalizării.

REZULTATE

Pe fondul creşterii progresive a numărului internărilor în ultimii 4 ani s-a înregistrat şi o frecvenţă deosebită a pacienţilor vârstnici, cu excepţia ultimului an ce prezintă o uşoară scădere. Rata deceselor bolnavilor spitalizaţi în ultimii 4 ani a avut o medie anuala de 2%, iar cea a pacienţilor cu vârste de peste 75 de ani, din totalul internărilor de 6,9%. Numărul deceselor pacienţilor cu vârste de peste 75 de ani din totalul celor înregistrate în timpul spitalizării a atins un procent mediu anual de 24,6%, ceea ce reprezintă aproximativ 50% din totalul deceselor pacienţilor cu vârste peste 75 de ani internaţi pentru o afecţiune abdominală.

Caracteristicile generale ale lotului studiat

Vârsta pacienţilor a fost de 75-94 de ani, cu o medie de 80,4 ani, fără diferenţă semnificativă între lotul fără neoplazie şi cel cu neoplasm. Dintre cele 61 cazuri fără afecţiuni neoplazice, 37 (60,6%) au fost femei şi 24 (39,3%) bărbaţi. Ischemia mezenterică a fost cea mai frecventă afecţiune (22-36,06%) urmată de patologia septică (16-26,22%), ocluzivă (12-19,67%) şi hemoragică (10-16,39%). Durata medie de spitalizare în cadrul patologiei benigne a fost de 7,9 zile (fig.1).

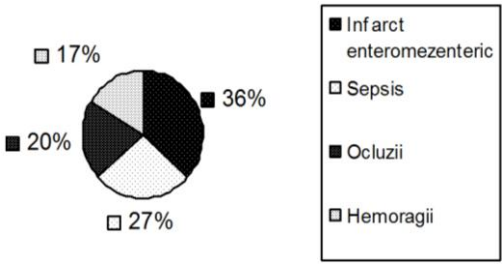

Fig. 1. Distribuţia lotului fără neoplazie pe variate afecţiuni

2. Infarctul entero-mezenteric a fost cauza principală de deces, la 11(50%) s-a efectuat doar laparotomie exploratorie, extensia totală/cvasitotală a infarctului entero-mezenteric fiind deasupra resurselor terapeutice chirurgicale, pacienţii decedând în medie la 48 de ore postoperator. La 8(36,36%) s-a practicat în urgenţă, excizia segmentului intestinal necrozat, însă toţi au evoluat septic, cu apariţia insuficienţei multisistemice de organ (MSOF). Majoritatea pacienţilor erau cunoscuţi cu patologie cardio-vasculară de tipul fibrilaţiei atriale, hipertensiunii arteriale şi insuficienţei cardiace, tratate şi controlate intermitent, fără terapie antitrombozantă. Trei pacienţi au decedat la câteva ore de la internare, iar cauzele infarctului entero-mezenteric au fost embolia arterială (50%), urmată de tromboza arterială mezenterica (30%) şi 20% tromboza venoasă.

3. Patologia septică care a inclus 5 cazuri de icter mecanic litiazic asociat cu angiocolită, 5 de colecistită acută gangrenoasă asociată cu peritonită biliară localizată şi/sau generalizată, 3 de apendicită acută gangrenoasă perforată asociată cu peritonită, un caz de ulcer perforat cu peritonită generalizată, unul cu abces hepatic şi un altul cu diverticulită acută perforată, cu peritonită stercorală. Cu excepţia cazurilor de icter mecanic litiazic, care au fost opera-

te electiv după încercarea eşuată de sfincterotomie endoscopică, în celelalte s-a intervenit de urgență. În trei cazuri de icter mecanic litiazic s-a practicat coledocolitotomia şi anastomoză bilio-digestivă iar în două coledocolitotomie cu drenaj Kehr. Cauza directă de deces a fost reprezentată de şocul septic cu MSOF, în două cazuri fiind evidențiată fistula bilio-digestivă. Cazurile de colecistită acută gangrenoasă asociată cu peritonită biliară, chiar dacă au fost operate în urgență, au evoluat nefavorabil, în ciuda tratamentului adecvat; gravitatea infecției la internare grevată pe un teren biologic tarat a făcut ca rezultatul postoperator să fie infaust. Într-un singur caz s-a documentat septicemia stafilococică, în rest infecțiile au fost cauzate de bacili Gram negativ.

4. Ocluzia intestinală a fost diagnosticată în 12 (19,67%), din care hernia inghinală/crurală ştrangulată în 6; sindrom aderențial, 3; un caz de hernie ombilicală nereductibilă şi un altul de stenoză pilorică. Cauzele directe de deces în aceste situații au fost: 5 fistule digestive cu sepsis agravant intraabdominal; o pneumonie de aspirație; o embolie pulmonară; un accident vascular cerebral (AVC) major şi 3 cazuri de şoc cardiogen. Exceptând stenoza pilorică, toate celelalte cazuri au fost operate în urgență.

5. Hemoragia a fost incriminată drept cauza inițială de deces în 10 cazuri, dintre care 8 cu ulcer peptic hemoragic; un caz de rectocolită ulcero-hemoragică şi altul cu hemoperitoneu prin ruptură de splină. Cauza directă de deces în aceste situații a fost pneumonia de ventilator (2 cazuri), infarct miocardic acut (2), sindrom de aspirație (1), AVC (1), embolie pulmonară (1) şi 3 cazuri de şoc hemoragic. În 2 cazuri de ulcer hemoragic s-a practicat intervenția chirurgicală de hemostază. Un singur caz de pancreatită acută necrotico-hemoragică formă gravă a decedat la câteva ore de la internare prin MSOF.

6. Neoplasmul colo-rectal s-a situat pe primul loc ca diagnostic principal de internare, înregistrând un număr de 25 (50%) din cazurile de neoplasm. Localizarea cea mai frecventă a fost distală: colon sigmoid (8), rect (5), joncțiune recto-sigmoidiană (3), colon descendent (4), colon transvers (3) şi colon drept (2). Numai 4 cazuri din 25(16%) au fost operate electiv, restul cu intervenție de urgență: ocluzie (19), perforație tumorală sau diastatică cu peritonită stercorală (7). Au fost practicate colectomii cu restabilirea continuității (13), operația Hartmann (8), amputație de rect (1), acolostomie laterală (1), ileotransversostomie (1). Un caz de neoplasm de rect hemoragic a decedat în perioada de pregătire preoperatorie secundar unui infarct de miocard acut. Cauzele directe de deces au fost şocul septic (18-36%), şocul cardiogen (3-6%), infarctul miocardic acut (2-4%) şi bronhopneumonia (2-4%). În 10 dintre cele 18 cazuri de şoc septic s-a evidențiat fistula anastomotică ce a contribuit în mare măsură la accentuarea şi agravarea stării septice.

7. Neoplasmul gastric a fost diagnosticat în 14(28%) cazuri. În 11 dintre acestea, s-a practicat gastrectomia totală sau subtotală, în două gastro-enteroanastomoza şi într-un caz jejunostomia de alimentație. Cauzele directe de deces au fost reprezentate de: şocul septic (7-14%), şocul cardiogen (2-4%), pneumonia de aspirație (2-4%), bronho-pneumonia (1), pneumonia stafilococică (1) şi infarctul miocardic acut (1). Şocul septic a avut drept cauză postoperatorie apariția fistulei anastomotice sau de bont duodenal.

8. Neoplasmul pancreatic s-a înregis-

trat în 5(10%) cazuri, toate fiind diagnosticate tardiv, complicate cu icter mecanic asociat cu angiocolită sau în stadiul de carcinomatoză peritoneală. Intervenţiile paliative de *by-pass* biliodigestiv s-au soldat, invariabil, cu fistulă anastomotică, ce a indus şocul septic ca şi cauză de deces.

9. Colangiocarcinomul a fost diagnosticat în 3(6%) cazuri, neoplasm al ampulei Vater în 2(4%) iar hepatom asociat cirozei hepatice într-un caz (2%). Durata medie de spitalizare este mai îndelungată în cazul patologiei maligne, fiind de 15,6 zile (fig. 2).

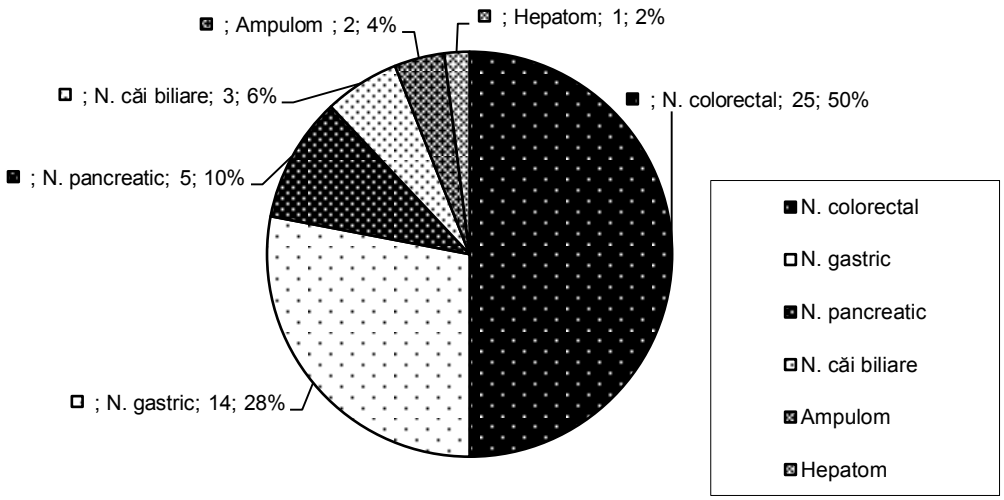

Fig. 2. Distribuţia cazurilor studiate pe categorii de patologie neoplazică

DISCUŢII

În general se admite că pacienţii vârstnici tolerează bine chirurgia abdominală, mai puţin complicaţiile postoperatorii. Rezultatele bune depind de o evaluare preoperatorie atentă, cântărind cu grijă riscurile şi beneficiile tratamentului chirurgical. Vârsta în sine nu este un factor de risc independent pentru morbiditate, mortalitate şi durata spitalizării, ci prezenţa comorbidităţilor majore ce cresc scorul ASA (American Society of Anesthesiology), întârzierea în sancţiunea chirurgicală şi situaţia locală a bolii care nu permite decât o paleaţie (1). O cauză importantă de deces este reprezentată de şocul septic, indiferent de patologia benignă sau malignă, mai ales în situaţiile de apariţie a unei fistule anastomotice. Infecţiile acute de organ reprezintă un diagnostic de internare ce are la vârstnic un potenţial de agravare dacă nu se intervine la timp (1, 10). În general factorii de risc pentru infecţii la un vârstnic includ subnutriţia cronică, reducerea masei musculare, dentiţia deficitară, şi diabetul zaharat. Reflexul de înghiţire deficitar poate conduce la favorizarea aspiraţiei conţinutului digestiv în arborele bronşic, cu apariţia sindromului Mendelson şi dependenţa de respiraţia mecanică. Cancerul este o altă cauză majoră de deces, mai ales pentru cazurile internate în stadii avansate, complicate, la care tratamentul chirurgical este paliativ. Deoarece cancerul colorectal şi cel gastric sunt pe primele două locuri în decesul vârstnicului, metodele de *screening* la

vârstnic sunt dezbătute în literatură în favoarea lor (1, 2, 9). Costa et al. (3) raportează o mortalitate postoperatorie în chirurgia abdominală de urgență la pacienții între 70-79 de ani de 19,7% şi pentru cei peste 80 de 26,2%, concluzionând că mortalitatea este strict dependentă de comorbidități. Tabloul clinic atipic al abdomenului acut la pacienții vârstnici şi tendința de a se prezenta târziu la medic duc la pierderea momentului terapeutic optim. Nu vârsta este un factor de risc ci întârzierea diagnosticului şi prezența comorbidităților severe (4, 5, 6). S-a constatat că există o atitudine de reținere pentru chirurgia radicală cu viză curativă la pacienții neoplazici vârstnici, bazată mai ales pe judecata subiectivă a chirurgului ce decurge din experiența personală (6, 7, 8).

CONCLUZII

Cea mai importantă cauză de deces a fost reprezentată de şocul septic indiferent de caracterul benign sau malign al afecțiunii abdominale. Numai 13% din cazurile cu afecțiuni benigne respectiv 42% din cele maligne s-au internat electiv, predominând în general caracterul de urgență a afecțiunii, ceea ce a contribuit la creşterea morbidității şi mortalității intra-spitaliceşti.

Cazurile la care s-a practicat o anastomoză digestivă s-au complicat cu fistule în proporție de 41% la lotul fără afecțiuni neoplazice şi de 65,6% la cel , fiind cauza princeps de şoc septic şi mortalitate.

INDUSTRIAL SOUND SPECTRUM ENTAILING NOISE-INDUCED OCCUPATIONAL HEARING LOSS IN IASI INDUSTRY (Abstract): In European Union every day millions of employees are exposed to noise at work and the risk this can entail. **Aim:** this study presents the sound spectrum in Iasi heavy industry: metal foundries industry, punching and embossing of metal sheets, cold and hot metal processing. **Material and methods:** it was used a type 2 Sound Level Meter (SLM) and the considered value was the average value over 10 test values in 10 consecutive days for each octave band in common audible frequency range. **Results and discussions:** It is obviously that the large values of sound intensities in the most of frequency octave band exceed maximum admissible and legal values. **Conclusions:** The study reveals the necessity of hardware, medical and managerial measures in order to reduce the occupational noise and to prevent the hearing acuity damage of the workers. **Key words**: INDUSTRIAL NOISE SPECTRUM, NOISE-INDUCED HEARING LOSS (NIHL), TEMPORARY THRESHOLD SHIFT, PERMANENT THRESHOLD SHIFT.

Zgomotul industrial distruge ireversibil celulele ciliate auditive din urechea internă, afectare care, în prezent, este una din cele mai răspândite boli profesionale cu consecinţe devastatoare asupra calităţii vieţii. Directiva europeană 2003/10/EC referitoare la zgomot stabileşte valoarea de 87 dB(A) ca limită maximă admisibilă (1), limită precizată şi de normele româneşti în vigoare (2). Aparatul auditiv nu are un mecanism care să limiteze suprasolicitarea. Expunerea la zgomotul industrial are efecte dăunătoare otice şi sistemice, încât controlul medical are o importanţă majoră şi se efectuează conform legislaţiei actuale (3) .

MATERIAL ŞI METODĂ

Măsurătorile presiunii sonore au fost realizate cu un aparat SLM de tip 2, dotat cu microfon dinamic pentru intensităţi mari, setat pe caracteristica A de referinţă a nivelului pragului minim audibil în câmp liber pentru urechea umană standard, caracteristica indicată la măsuratorile zgomotului industrial. Setarea "Slow" urmăreşte variaţia mediei temporale pe o durată corespunzătoare care este sub valorile instantanee de vîrf ale presiunii acustice; la setarea "Fast", mărimea constantei duratei de integrare este mai mică decît în cazul "Slow", valorile indicate prin medierea

temporală urmărind peak-urile presiunii sonore a zgomotului. Precizia asigurată de instrument este mai bună de ±1 dBA pe toată scala. Instrumentul a fost plasat la o depărtare de 0,5 m faţă de utilaj şi la 1,7 m deasupra nivelului podelei, direcţionat perpendicular pe planul vertical al maşinii, în felul acesta se măsoară cu precădere presiunea sonoră a undei directe, această poziţionare fiind similară celei în care se află uzual receptorul acustic uman în timpul muncii. S-au înregistrat valorile indicate de instrument pentru fiecare din cele nouă octave adiacente ale căror frecvenţe centrale au fost: 31.5, 63, 125, 250, 500, 1000, 2000, 4000 şi 8000 Hz.

Măsurătorile s-au efectuat în 12 zile, la ore diferite, pe parcursul a patru săptămâni, pentru a se diminua influenţa situaţiilor extreme. Pentru fiecare octavă, din cele 12 valori astfel măsurate au fost eliminate valoarea cea mai mică şi valoarea cea mai mare, apoi s-a calculat media celor 10 valori rămase ce au trasat caracteristicile spectrale.

REZULTATE

Spectrul sonor din secţiile de prelucrări la cald rezultă din zgomotele utilajelor din secţiile de forjă care sunt intens folosite. Acestea produc sunete cu nivele de presiune sonoră foarte ridicate şi nocive într-un domeniu foarte larg de frecvenţe.

Dată fiind plaja frecvenţială întinsă, măsurătorile au fost extinse şi pentru octava inferioară a cărei frecvenţă centrală este de 31.5 Hz.

S-au efectuat măsurători în toate cele 9 benzi frecvenţiale de octavă din domeniul audibil, în modul "Peak" şi în modul "Slow" şi s-au calculat mediile aritmetice ale valorilor obţinute (tab. I).

Pe baza valorilor medii s-a obţinut spectrul sonor existent în secţiile de forjă (fig. 1).

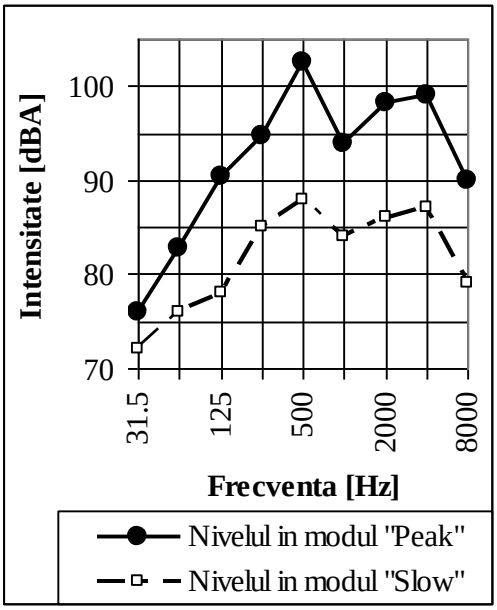

Fig. 1. Spectre sonore ale zgomotului în secţiile de forjă

Prelucrările semifabricatelor metalice la rece constau în cea mai mare parte în operaţii de ştanţare, tăiere şi îndreptare a tablelor groase şi profilelor grele, rezultând zgomote sacadate şi de intensitate deosebit de mare. Măsurătorile s-au efectuat în secţiile de prelucrări la rece cu instrumentul poziţionat în faţa utilajelor precum şi în lateralele acestora (tab. II şi tab. III).

TABELUL II

Intensităţile sonore din secţiile de prelucrări la rece în faţa utilajelor/preselor

Frecvenţa [Hz]	31.5	63	125	250	500	1000	2000	4000	8000
Mod "Slow" [dBA]	0	77	78	82	88	88	92	94	96
Mod "Peak" [dBA]	0	88	91	95	103	105	119	122	122

Spectrul sonor în faţa şi lateral de presă indică valori mari (fig. 2 şi fig 3).

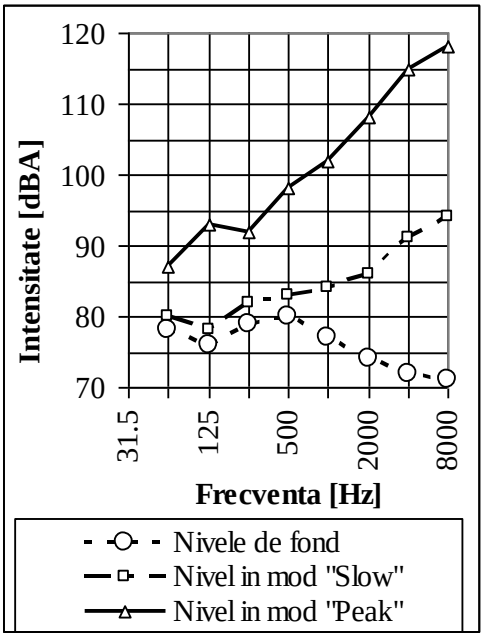

Fig. 2. Spectrul în faţa preselor

Măsurătorile se efectuează atât în faţa preselor, cât şi în lateral, pentru a pune în evidenţă proprietăţile de directivitate ale zgomotelor produse. Pentru că utilajele lucrează ritmat atunci când sunt folosite, s-au făcut măsurători atât în modul "*Peak*", cât şi în modul "*Slow*". Pentru a trasa şi spectrul zgomotului de fond, s-au făcut măsurători când utilajele sunt în aşteptare - "standby", adică sunt pornite, dar nu sunt în sarcină, cu instrumentul setat în modul "*Slow*".

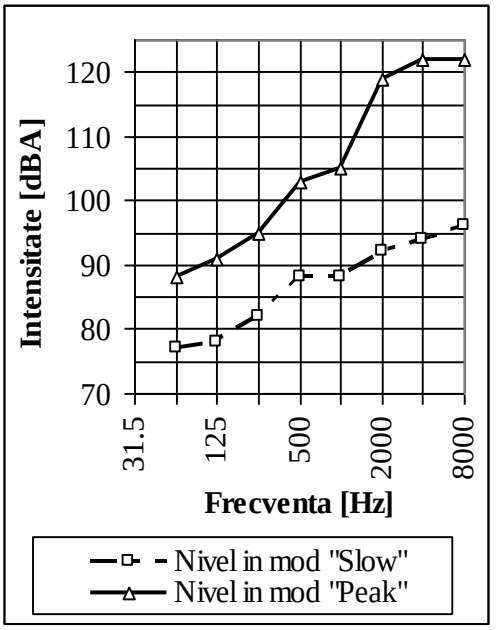

Fig. 3. Spectrul lateral de prese

DISCUŢII

În fiecare caz de reprezentare spectrală s-a calculat valoarea intensităţii globale la care şi-au adus contribuţia nivelele sonore medii ale tuturor celor 9 octave de frecvenţă de la 31,5 pîna la 8000 Hz. Bazându-ne pe însuşi principiul de măsurare care constă în filtrarea în benzi adiacente de frecventă, se poate considera ca fiecare din cele 9 nivele de intensitate sonoră se constitue în câte o sursă independentă de zgomot şi că toate sursele produc zgomot simultan. Având acest temei, pentru calculul valorilor globale ale nivelelor de zgomot, putem aplica algoritmul de compunere a nivelelor

de zgomot provenind de la surse independente (4), toate rezultatele fiind conrelate împreună cu duratele maxime de expunere la zgomot (tab. IV), admise pentru lucrătorii care îşi desfăşoară activitatea la respectivele locuri de muncă (5).

TABELUL IV

Valorile globale ale intensităţilor sonore corespunzătoare tuturor spectrelor sonore din secţiile de prelucrări metalice la cald şi la rece precum şi duratele maxime admise de expunere la zgomot pentru lucrători

	Niveluri sonore globale în modurile "Slow" şi "Peak"						
	În secţiile de prelucrări la cald		In secţiile de prelucrări la rece				
			În faţa presei			În laterala presei	
	"Slow"	"Peak"	Zg. fond *"Slow"*	"Slow"	"Peak"	"Slow"	"Peak"
dBA	99.7	126	85.6	97	121	99.7	126
Durata maximă de expunere	14 min	2 min	8 ore	30 min	7 min	15 min	2 min

Urmărind valorile intensităţilor globale se constată că numai zomotul de fond din secţiile de prelucrare la rece permite prezenţa lucrătorului pe o durată zilnică de 8 ore neîntrerupte, pe cînd, în toate celelalte cazuri, valoarea de 87 dBA menţionată mai sus (2) este considerabil depăşită şi că duratele maxime de expunere permise sunt foarte mici în comparaţie cu norma zilnică a duratei de muncă.

CONCLUZII

Studiul relevă faptul că în astfel de condiţii de zgomot prezentate lucrătorii sunt expuşi unei noxe sonore importante ce poate produce deteriorarea ireversibilă a organului auditiv. Acest fapt justifică implicarea medicului în consilierea managerilor şi lucrătorilor pentru luarea de măsuri tehnico-organizatorice de reducere a acestor noxe profesionale (6). De aceea, rolul medicului constă nu doar în monitorizarea şi tratarea celor afectaţi de această noxă profesională, ci şi în consilierea şi conştientizarea angajatorilor şi angajaţilor pentru prevenirea acestor îmbolnăviri.

DIAGNOSTIC PROBLEMS IN FETAL ECHOCARDIOGRAPHIC EXAMINATION. OBSERVATIONS ON A LOT OF STUDY DURING 2005-2010 (Abstract) : Echocardiography is the key diagnostic method in the diagnostics of structural heart pathologies. **Aim** : To underline some possible situations that may cause errors in ultrasound examination of the fetal heart. **Material and method** : We examined a number of 39370 fetuses along a period of six years. The ultrasound scan was performed according with international standards of basic and extended cardiac scan. **Results** : 442 of them (1,12%) were diagnosed with cardiac malformations. **Conclusion** : Ultrasound examination errors can cause false positive, false negative or incomplete diagnosis. Limitations in fetal echocardiography are related to the examiner experience to do an accurate diagnosis. The difficulty of assessing complex congenital heart lesion is increased. The unsatisfactory study should be repeated and sometimes the exact diagnosis requires sequential procedures. The aim is to define fetal heart anatomy and adise the family, in collaboration with neonatologist. The final results ia an optimal behavior for the fetus and newborn. **Key words :** CARDIAC MALFORMATIONS, ECHOCARDIOGRAPHIC DIAGNOSIS, FALSE POSITIV

În general, malformațiile cardiace sunt bine tolerate intrauterin de către făt datorită particularităților anatomice ale cordului fetal, reprezentate de foramen ovale şi canalul arterial. Practic nu există semne clinice sau paraclinice care să indice sau să sugereze existența unei malformații cardiace fetale. Acestea pot fi diagnosticate doar prin examinare ecografică directă a cordului fetal în cadrul morfologiei fetale.

MATERIAL ŞI METODĂ

În studiu au fost incluse 39370 gravide cu vârste între 19 şi 42 ani, care au născut în spitalul nostru în perioada 1 ianuarie 2005-31 decembrie 2010. Parametrii urmăriți au fost: incidența malformațiilor cardiace raportată la numărul total de naşteri, prevalența acestora din totalul malformațiilor, vârsta gestațională maternă la momentul diagnosticului, sensibilitatea ecografiei ca metodă de diagnostic, atât global cât şi raportată la tipul şi severitatea malformației. Ecografiile au fost efectuate cu un ecograf Voluson ProV (cu sondă convexă de 3,5 MHz şi endovaginală de 7 MHz) de către medici specialişti şi primari cu competență în ecografie. De importanță majoră a fost ecografia de 20-24 săptămâni la care s-a efectuat examenul sistematic cardiac. Acesta a inclus obligatoriu pe lângă imaginea patru camere şi imaginea tra-

iectelor de evacuare ventriculară, secţiunea trei vase, trei vase şi traheea şi imaginile în axul lung al cordului inclusiv secţiunea arcului aortic şi a arcului ductal.

Defectele cardiace au fost împărţite în două grupe: minore şi majore. Au fost considerate majore anomaliile cardiace care au necesitat corecţie chirurgicală. La rândul lor defectele cardiace majore le-am împărţit în următoarele grupe:

– ale inimii stângi (sindrom de inimă stângă hipoplazică, coarctaţie de aotă, stenoză aortică valvulară)

– ale inimii drepte (stenoza sau atrezie pulmonară, atrezie tricuspidiană anomalie Ebstein)

– anomalii conotruncale (transpoziţie de vase mari tetralogie Fallot, ventricul drept cu dublă cale de ieşire)

– alte defecte (defecte complexe de sept atrioventricular, ventricul stâng cu dublă comunicare atrio-ventriculară, displazie tricuspidiană).

Nu au fost incluse în studiu anomalii cardiace minore imposibil de diagnosticat preanatal (defecte septale atriale minore, foramen ovale sau canal arterial persistent).

În cazul sindroamelor malformative, am inclus în statistică cazurile cu afectare cardiacă. Întrucât condicile de morbiditate şi mortalitate au inclus toate malformaţiile, am fost nevoiţi să le clasificăm în malformaţii diagnosticabile şi malformaţii nediagnosticabile ecografic. La cazurile de terminare a sarcinii, avort spontan sau moarte fetală sau neonatal s-a practincat examenul anatomopatologic sistematic al produsului de concepţie. Datele obţinute în urma necropsiei au fost folosite pentru verificarea acurateţii diagnosticului ecografic.

REZULTATE

În perioada 1 ianuarie 2005-31 decembrie 2010 în Spitalul Clinic de Obstetrică Ginecologie Cuza Vodă Iaşi s-au născut 1487 copii cu malformaţii, reprezentând 3,77% din numărul total de naşteri (39370). Din acestea 1174 (79%) au fost malformaţii diagnosticabile ecografic prenatal. Un număr de 800 paciente (53,8%) au provenit din mediul rural şi 687 paciente (46,2%) din mediul urban. Vârsta maternă a fost cuprinsă între 19 şi 42 ani, cu o medie de 31 ani. Prevalenţa pe grupe a defectelor cardiace a fost: 18 defecte ale inimii stângi, 67 defecte ale inimii drepte, 32 cazuri cu anomalii conotruncale, 16 cazuri sindrom Down cu afectare cardiac, 7 cazuri au prezentat alte anomalii genetice şi afectare cardiac. În 52 cazuri afectarea cordului a apărut în cadrul unui sindrom plurimalformativ. La 253 cazuri malformaţia cardiacă a fost complexă. Din 1174 paciente cu malformaţii diagnosticabile ecografic, 812 au efectuat cel puţin o ecografie prenatală (69,17%). Sensibilitatea globală a ecografiei a fost de 55%. Sensibilitatea maximă a fost înregistrată pentru diagnosticul sindroamelor plurimalformative (78%). În cazul malfomaţiilor cardiace complexe a fost dificilă stabilirea ecografică diagnosticului corect.

DISCUŢII

Ecografia prenatală este cea mai bună metodă pentru diagnosticul intrauterin al malformaţiilor fetale. Limitările examenului ecocardiografic ţin de vârsta sarcinii sub 18 săptămâni, rezoluţia echipamentului, caracteristicile programului de investigare şi experienţa ecografistului. Este crescută dificultatea de apreciere a leziunii în malformaţiile cardiace complexe. Cele mai bune imagini cardiace pot fi obţinute între 18 şi 24 săptămâni de amenoree. Condiţii tehnice ce limitează acurateţea imaginilor ecografice: oligoamnios, polihidranios, obezitatea maternă, poziţia fetală nefavorabilă, mişcările fetale excesive, hidrotoraxul, prezenţa herniei diafragmatice. Din experienţa noastră problemele de dia-

gnostic pot apare la cazurile cu:

Defect septal interatrial Foramenul oval (FO) prezintă o variație a dimensiunilor pe parcursul ciclului cardiac. Semne fals pozitive apar în examinările oblice (1). În incidența 4 camere sinusul coronar dilatat poate creea falsa impresie de canal atrioventricular parțial dar în acest caz, tricuspida şi mitrala se inseră la acelaşi nivel al septului interventricular.

Focarele ecogenice marginale Ocazional, un focar ecogen strălucitor este prezent la periferia miocardului ventricular sugerând o mică tumoră sau calcificare. Această imagine apare când planul de secțiune include porțiunea anterioră a unei coaste sau o parte de stern (fig. 2).

Defect septal interventricular Defectele adevărate au margini bine definite (fig.3A) la examinarea cu un fascicul de ultrasunete perpendicular pe septul interventricular. Rezultate fals pozitive apar când fasciculul de ultrasunete este paralel cu septul (fig.3B) şi în cazul examinării Doppler color cu velocitate neadecvată, sau în plan neadecvat (4).

Fig. 1. Imaginea evidențiază prezența unui focar hiperecogen la nivelul ventriculului stâng. În majoritatea cazurilor este uşor de diferențiat de o tumoră intracardiacă.

Fig. 2. Secțiunea longitudinală la nivelul unei coaste poate fi o capcană diagnostică pentru focarele hiperecogene localizate spre apexul cordului.

A

B

Fig. 3. Pseudo defect septal ventricular

A – Pe secțiune apicală 4-camere (când septul este paralel cu fasciculul de ultrasunete) defectul septal ventricular pare să fie prezent; B – Acest artefact poate fi evitat scanând aceeaşi porțiune a septul dintr-o orientarea diferită. În mod ideal fasciculul de ultrasunete trebuie să cadă perpendicular

pe septul interventricular.

Tetralogie Fallot Imaginea patru camere are aspect normal exceptând cazurile cu canal atrioventricular complet, agenezie de valvă pulmonară, dilatație de ventricul drept. În evoluție se observă îngustare infundibulară a ventriculului drept. Marile vase se încrucişează normal (5).

Stenoza valvulară aortică Formele uşoare de stenoză aortică nu pot fi diagnosticate. Îngroşarea valvei aortice şi dilatarea aortei ascendente pot ridica suspiciunea acestui diagnostic. Prin examinare Doppler color se evidențiază flux turbulent la nivelul valvei. Leziunea are un caracter evolutiv prin urmare, examinarea ecografică trebuie repetată.

Coarctație a aortei Apar frecvent rezultate fals pozitive şi negative. Se poate suspecta afecțiunea când există o discrepanță între calibrul arterial şi ventricular. Această discrepanță se evidențiază la 75% din fețiii afectați (6).

CONCLUZII

Limitările în ecocardiografia fetală țin de experiența ecografistului în stabilirea unui diagnostic fidel. Este crescută dificultatea de apreciere a leziunii în malformațiile cardiace complexe (7). Studiul nesatisfăcător trebuie repetat şi uneori, diagnosticul exact nu se poate da fără proceduri secvențiale (6).

Scopul examenului ecocardiografic fetal este definirea anatomiei cordului fetal, conferind obstetricianului în colaborare cu medicul neonatolog capacitatea de a furniza informații şi a sfătui familia în ceea ce priveşte defectul cardiac, anticiparea prognosticului, şi stabilirea conduitei optime privind fătul şi nou născutul. Această abordare multidisciplinară a îngrijirii materno-fetale este necesară pentru optimizarea naşterii (8).

PELLAGRA, A SOCIAL DISEASE IN AN EASTERN EUROPEAN COUNTRY, AT THE END OF THE NINETEENTH CENTURY AND EARLY TWENTIETH CENTURY **(**Abstract): Pellagra appeared in Europe after Christopher Columbus brought maize to the continent, omitting however to bring with him the corn processing method of the Native Americans - which involved treating corn flour with lime water (calcium hydroxide) before thermal processing so as to partially release niacin from cellulose structure, which proved the decisive factor in the occurrence of the disease. It is an extremely rare disease nowadays, but it is the prototype of social disease in the late nineteenth and early twentieth century, affecting especially the rural one due to the poor economic condition of the Romanian peasant and their strong religious beliefs. Pellagra is one of the diseases whose development was directly correlated with socioeconomic status of the population in different regions of Romania, raising major issues of care and active intervention measures in health care. **Keywords**: PUBLIC HEALTH, ROMANIA, PELLAGRA, SOCIAL DISEASE, MAIZE, CORN.

Pellagra is a nutritional disease caused by a deficiency of the vitamin B_3 or niacin. An extremely rare disease in our days, it represents the prototype of the social disease at the end of the 19th and the beginning of the 20th century, its occurrence being linked to the existing economically poor conditions, which caused physical, mental and economic damage (1).

Historical aspects

At the end of the year 1492 Christopher Columbus returned to Spain after the discovery of America. He brought back with him golden beans of a Gramineae that was a cereal species unheard of in Europe. These had the advantage that they did not require more work than wheat and bore a hundred times more fruit. From these beans a sweet and tasty food could be cooked, with little effort and fire expense, and in much less time than bread. Little by little, corn bread replaced wheat bread on the peasant table (2). Moreover, all other foods were more expensive, because, according to Lombroso, the same amount of nutrients cost 3 times more if they were consumed in the form of potatoes or rice. Bread is 2 to 3 times more expensive, milk and meat 7-8 times (3).

Pellagra was first described in 1762 by Don Gaspar Casal, who observed the disease among farmers in the province of Asturias, where they called it “mal de la rosa”. First to describe the disease known as “pellagra”

was Frappoli Francesco from Milan in 1771, a name deriving from "pella-agra" with the meaning of "rough skin" (in Italian) (2).

Trouvenel was the first that signaled accurately the connection between maize and pellagra being considered the promoter of the "maidic" hypothesis.

In 1912 the disease reached an apogee in the U.S., with 25,000 newly diagnosed cases of pellagra in the past 5 years. This endemic development determined various institutions (like United States Public Health Service Investigations and Public Health Service) to engage in the study of pellagra. Joseph Goldberger, chief of the Public Health since 1914, concluded that pellagra was a nutritional disease. He relied on the number of cases of pellagra among patients of mental institutions and on the absence of this disease among nurses and caregivers. The difference between these two groups was in the diet, the latter ones having a more varied and improved diet. Also, Goldberger characterized pellagra as a rural disease associated with poverty. Without discovering the true cause in the diet which determined the occurrence of pellagra, he suggested that increasing the consumption of fresh meat, eggs and milk could act preventively. Seven years since the beginning of his research, Goldberger discovered that the factor which prevented pellagra was a protein, calling it the PP factor (factor that prevents pellagra). In 1926, Goldberger reached the conclusion that this factor was a part of the vitamin B complex, declaring that it was contained in large amounts in dry yeast. Only in 1937 the chemist Conrad Elvehjem found that nicotinic acid is the PP factor (4).

Sociological aspects

The relationship between the introduction of maize in Europe and the prevalence of pellagra can be more easily understood with the help of sociological theories of diffusion and adoption of innovations (5).

Applying this model, it follows that experienced poor agrarian populations in Europe (especially in the plains of SE Europe) easily took over the American maize cultivation practice because: it brought more advantages than cereal crops they were accustomed to, responding to acute needs of populations with poor diet for high-calorie food, the crops were cheap and easy to obtain, being easy to implement, with fast and visible results.

However, these populations did not adopt the practice of treating the corn with calcium hydroxide since they did not have in their culture the habit of undertaking similar actions, they did not realize the need and benefits of such a practice and implicitly they could not realize the ease with which one could apply this procedure. In addition, not knowing the potential dangers of untreated corn, they could not anticipate the immediate results that this process could have. The fact that the cultivation of corn was associated with increased incidence of pellagra predominantly in rural populations with poor nutrition style represents a systemic component of the model of innovation adoption, respectively the existence in the social system of certain norms and patterns of eating behaviors that created the fertile ground for the manifestation of the disease.

It should not be ignored that in certain contexts (such as rural Romania) the option of not cultivating or consuming corn by individuals (and thus avoiding the occurrence of pellagra) was non-existent because at systemic level corn was imposed by the ruling elite, and at community level by landowners. Hunger and poverty also encouraged its introduction in the diet.

Pellagra in Romania

Romania was predominantly an agricultural country. Corn cultivation started at the beginning of the eighteenth century, being introduced around the year 1710 by Nicolae Mavrocordat. The advantages of corn cultivation in parallel with the progressive impoverishment of the people by wars and the excessive taxation of the Phanariot period, was basically to prepare the ground for the emergence of pellagra (6).

The first cases of pellagra were described around 1830 in Moldova region, initially as isolated cases, being described as piles swelling or piles wound. In 1858 Dr. Iuliu Teodori first described the disease by the name of pellagra. Professor Felix described the disease in Walachia, in Muscel County, in 1889. In 1896, in "Gazeta de Transilvania" an article described pellagra as a disease unknown in these regions (2).

The first statistic of the population suffering from pellagra was made in 1882 by Dr. Felix, which counted about 4500 patients with pellagra (2, 6).

During the period 1884-1886, rural military ambulances provided ambulatory consultations, publishing in this matter statistical data regarding the morbidity; thus, 19,797 cases were reported in 1886.

In 1888 Dr. Sergiu, at that time general director of the Health Service, found that 10,626 people were suffering from pellagra in a population of 5,339,650 inhabitants of the Romanian Kingdom, which meant about 2% morbidity due to pellagra. According to their occupation, they were mostly peasant farmers, 7,572 (71.25%), or workers, 2,132 (20%), and only in an insignificant proportion held other jobs (artisan - 19 patients, trader - 28 patients, official - four patients, priest - 15 patients, man servant - 20 patients). It is to be noted the number of children between 1 and 12 years (83 patients). Pellagra affected in this sense the lowest classes (2, 6), dramatically ravaging the rural population (7).

Regarding statistical values about pellagra in Romania between 1888-1935 (6, 8), there are slight differences between the statistical values found in various documents, differences due to imperfect methods of recording. The evolution of these values was as following (fig. 1, 2) (6, 7, 9, 10).

Data reported were considerably smaller than the real number, many patients with a mild form opting not to consult a doctor, the erythema period being evanescent; in consequence those cases were not being considered during social surveys carried out (6).

Noting the differences between the numbers declared in those years, beginning with 1895 a census using nominal lists was established. Out of the 17,912 of patients registered in 1896, 10,173 (56.8%) were female and 7,739 were male (43.2%); almost all lived in rural communes-17,350 (96.8%), 112 lived in small urban communes and 450 in urban communes which were district capitals (11).

In years when we have statistics on gender, it appears that the female gender is predominant constantly sometimes the ratio being over 2:1 (fig. 3). Predominance of the female gender could be explained by organic overworking to which these were exposed, like pregnancy and lactation, while they had in care also the domestic activities, including participating in the agricultural work.

Between the years 1896-1899, looking for the etiology, sensing the connection of this disease with the alimentation, a study was carried out on the 779 pellagrous patients hospitalized in Roman, based on a questionnaire they completed. To ensure the needs of a family, this should have had to possess at least 4-5 hectares of land. Out of the respondents, 78.1 % had insufficient land areas in property to ensure their food needs.

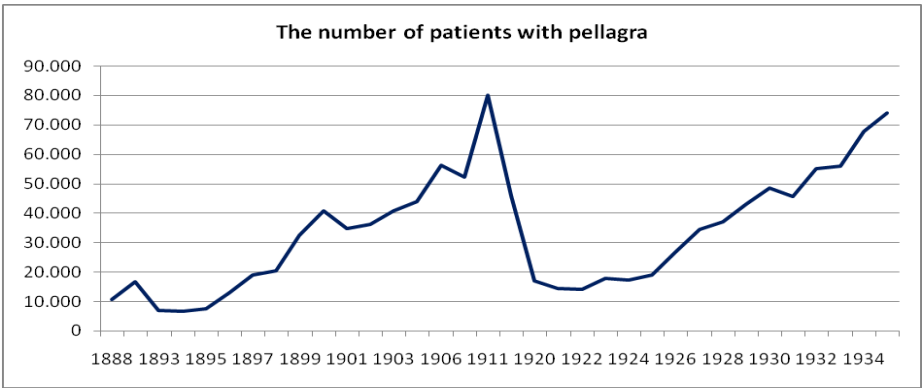

Fig. 1. Number of patients with pellagra in Romania between 1888-1935

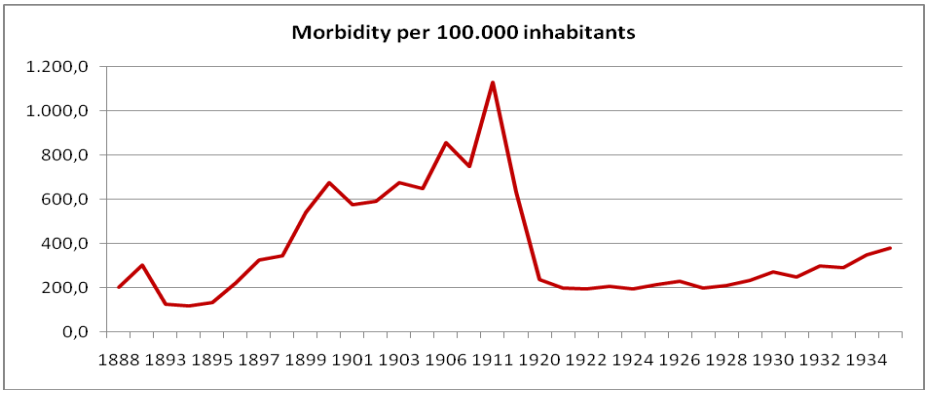

Fig. 2. Morbidity per 100,000 inhabitants at pellagrous patients in Romania between 1888-1935

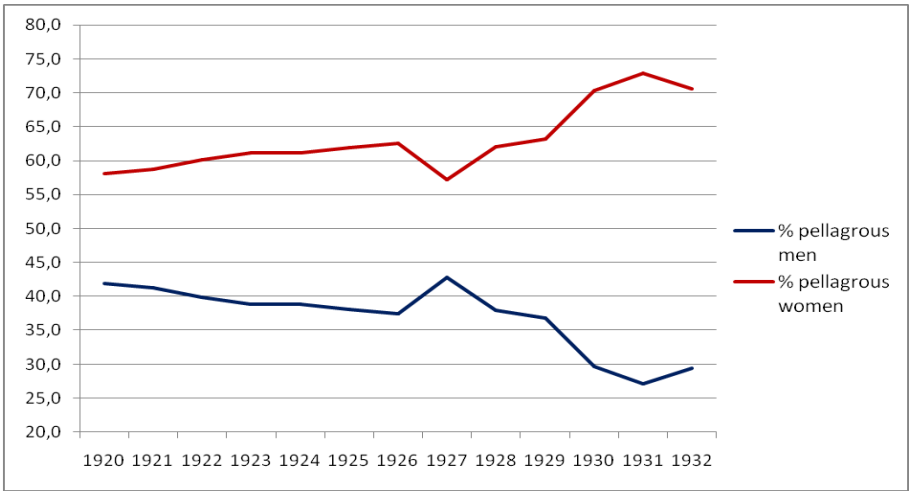

Fig. 3. Statistics by gender (male / female) from 1920-1932

Questioned on the crops grown, 651 of peasants cultivated corn, 164 wheat (which was kept especially for religious charity or to be sold), 112 rye, 493 beans, 67 lentils, 93 peas, 554 potatoes, 483 greengroceries (9). This was because landowners demanded that peasants should cultivate corn, because wheat required more time and they feared that the peasants would not do well their service jobs (12).

Also, of those questioned, only 347 had milk cows and 367 of them owned working cattle (9). The reason why the peasants did not have dairy cows, was because the feeding of a cattle for 10 months on the property of a squire cost 20-25 Lei and a peasant preferred to pay this amount for two plough oxen, with which he ensured the farm work, considering that the fate of the peasant was depending on the squire (13). Dairy cows were unkempt, did not have warm stables, being degenerate, giving very little milk so that the peasant consumed very little milk, cream and butter (7).

Even when the peasants had more substantial foodstuff like eggs, milk and / or poultry, they most of the time, preferred to sell them to other farmers or to townspeople. They were able, by this means, to satisfy their other needs. When these foods were not sold, they could be prohibited because of the fasting, which the peasant observed with the utmost strictness and from which prescriptions he wouldn't deviate, being convinced that violation of fasting caused great misfortunes. One couldn't even stand others to violate it. Peasants tied the occurrence of plagues to the fact that fasting had not been observed properly, accordingly to combat it, a greater sacrifice in observing the fasting period was needed (13). In the name of religion health was thus neglected. It was suggested that it would have been better if Orthodox religion found ways to enforce in believers' hygienic habits, reducing long and heavy fasting, especially during the heavy work. (7).

The years that followed World War I and the annexation of Transylvania to Romania are characterized mainly by a reduction in the number and the percentage of pellagrous patients.

This is explained by the fact that after the war, small property replaced estates, the peasant becoming the owner of the land he cultivated, which influenced his cultural and economic level. Contact with allied and enemy soldiers educated peasants in the sense of improving nutrition, while in the territories occupied by enemy, peasants were forced to sow large quantities of wheat.

Annexation of Transylvania, Bucovina and Basarabia decreased the percentage of the pellagrous in the Romanian population (11), where, apart from Basarabia, where there was widespread pellagra, other areas did not present the disease (6). In Transylvania there were also rare cases of pellagra because at least once a week bread was baked, and at least a stretch equal to the land cultivated with maize, was planted with wheat or rye (7).

Number of pellagra patients dropped probably due to typhus which afflicted the country at the time, but later their number increased again reaching before the war values.

At the same period, countries once afflicted by pellagra had managed, by socio-economic methods and the active involvement of the state, to eradicate this disease, so in the early '30s cases of pellagra were presented as a medical curiosity in the French press (7). Meanwhile, in Romania,

there was nothing happening, health inspectors were doing statistics centralized at the Ministry of Health and that was all. If for other social diseases were ensured funds, were set up committees and societies, for treating pellagra nothing was done, because it affected, in the clear majority, only the poorest strata of the population (14, 15).

The issue of health policy deficiencies addressed to the poor populations is not unique to the Romanian context, having been debated in the international literature for a long time. Profile global organizations have failed to solve these problems even today. It is estimated that only 10% of global health research aims at topics affecting 90% of the world population, specific diseases in poor communities of low-income countries being neglected by the global economic sector of research and development (16,17). In addition, the countries with low and middle income (category which includes Romania) choose to use the few resources they possess for projects that do not always coincide with the basic needs of the population (18). However, in recent decades, progress has also been made. Currently there is a consensus at the level of the scientific community and health activists on the fact that global improvement of the health of the poor (and implicitly diminishing the incidence of poverty and bad nutrition) depends primarily on the ability of public policies to reduce poverty, generating well-being and an improved quality of life (18) and also to educate the young generation for improving their life based by health promotion (19).

CONCLUSIONS

Pellagra, a disease extremely rare nowadays, is the prototype of social disease in the late nineteenth and early twentieth century, affecting in the period studied (1888-1935), the poor population, especially the rural one.

Pellagra appeared in Europe after Christopher Columbus brought maize to the continent, omitting however to bring with him the corn processing method of the Native Americans - which involved treating corn flour with lime water (calcium hydroxide) before thermal processing to partially release niacin from cellulose structure, which proved the decisive factor in the occurrence of the disease.

The emergence of pellagra in Romania predominantly in the rural area was due to the poor economic condition of the Romanian peasant (linked until World War I to the big landlords), but also to his strong religious beliefs. Thus, the Orthodox Church demanded severe fasting, even during the hard work periods, which peasants observed strictly, considering that plagues may thus be kept away.

Predominant presence of the disease in females (sometimes the ratio being more than 2:1) can be explained by organic overwork to which this gender was subjected by pregnancy and lactation. At the same time women in the period studied, also had to do the housework as well as participate in farm work.

The years that followed World War I were characterized mainly by a reduction in the number and the percentage of pellagrous patients, because on one hand big estates were replaced with small peasant properties, and due, on the other hand, to contact with other dietary habits brought by allied or enemy soldiers.

Regarding the Romanian state policy, implicitly of the Ministry of Health, although for other social diseases (alcohol-

ism, syphilis etc.) were assured funds, were set up committees and societies, for treating pellagra virtually nothing was done because this disease affected in the clear majority, only the poorest strata of the population.

FLUIDITATEA MEMBRANARĂ – PARAMETRU BIOFIZIC ÎN RELAŢIE CU PROCESELE DE TRANSPORT MEMBRANARE

Disciplina de Biofizică şi Fizică medicală

MEMBRANE FLUIDITY - BIOPHYSICAL PARAMETER IN RELATION TO MEMBRANE TRANSPORT PROCESSES (Abstract) : Membrane fluidity is a complex parameter, influenced both through some biophysical (temperature, electrical charges, pH) and biochemical factors (protein/phospholipids ratio, phospholipids/cholesterol ratio, degree of fatty acids unsaturation). It is a parameter that reflects the main membrane characteristic organization (gel or liquid crystal structure). Experiments provide consistent data about membrane fluidity relations to various cellular processes, especially membrane processes. Passive transport is influenced directly by membrane lipid composition, and consequently, membrane fluidity, or by channels and carriers molecules interactions with adjacent membrane lipids. Membrane diffusion is related both to the hydrophobic nature of the particles and of the membrane environment. Depending on the mode of interaction with membrane proteins, lipids may be classified as non-annular lipids, annular and "mass" lipids. Different types of fatty acids affect the function of many channels, by stimulating or inhibiting them. These effects might be mediated through direct binding of the lipids to the channel or through indirect hydrophobic interactions. Active transport pumps conformation could be modulated, also, through interactions with adjacent lipids of the bilayer (especially cholesterol) and membrane micro-domains organization. In **conclusion**, membrane fluidity is close related both to passive and active transport. **Key words** : MEMBRANE FLUIDITY, ACTIVE TRANSPORT, PASSIVE TRANSPORT, LIPID BILAYER

Fluiditatea reprezintă o proprietate biofizică globală a membranelor celulare. Ea este consecinţa legăturilor slabe dintre moleculele componente ale membranei ce permit mişcări permanente ale moleculelor. Dinamica moleculară, în parte consecinţa agitaţiei termice cât şi a afinităţilor moleculare de ordin electrostatic (interacţiuni hidrofil-hidrofobe, legături prin punţi de hidrogen, legături van der Waals) determină o distribuţie asimetrică a moleculelor la nivelul membranei (atât transversal, între cele două straturi lipidice membranare, cât şi pe feţele membranare, în interiorul aceluiaşi strat fosfolipidic). Suplimentar, fluiditatea membranară este influenţată de coliziunile domeniilor extramembranare, modul de „adeziune" şi structura citoscheletului**.** Toţi aceştia sunt factori care restricţionează mobilitatea celor mai multe proteine şi lipide, cu alte cuvinte influenţează fluiditatea (1).

Înţelegerea acestui parametru biofizic membranar esenţial, fluiditatea, este în relaţie cu urmărirea evoluţiei modelului „mozaicului fluid" (fig.1.). La asemănarea dintre structura membranei celulare şi organizarea structurală adoptată de lipidele izolate într-o soluţie apoasă se adaugă rolul interacţiunilor hidrofile-hidrofobe în menţinerea statusului energetic inferior al membranei în mediu polar. Proteinele, la rândul lor, prezintă anumite segmente de natură hidrofobă (variabile de

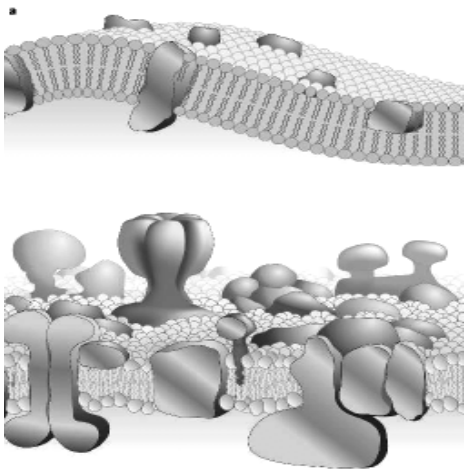

Fig. 1. a) Modelul Singer-Nicholson, b) Evoluţia modelui mozaicului fluid membranar - organizarea în microdomenii membranare (3)

la proteină la proteină) care se „potrivesc" lipidelor adiacente, perpendiculare pe planul membranei. Rigiditatea relativă a proteinelor şi dinamica lipidelor sugerează că, în principal, lipidele sunt cele care îşi modifică stereometria pentru a se „potrivi" proteinelor, deşi este posibil ca şi proteinele să îşi modifice stereometria în anumite cazuri de „nepotrivire" lipid-proteină (2). Modelul mozaicului fluid al membranei poate fi actualizat luând in considerare mai multe aspecte. Dacă lipidele sunt cele care se adaptează proteinelor, atunci raportul transmembranar lipide/proteine va fi unul variabil, ceea ce înseamnă că distribuţia transmembranară este asimetrică iar suprafaţa membranei poate fi „curbă". Aceasta dinamică moleculară membranară considerată, anterior, o consecinţă pasivă a activităţii celulare este privită, în prezent, ca un element activ menit să determine apariţia de domenii membranare (fig.1) implicate, se pare, în traficul celular (3). Tendinţa actuală sugerează un caracter mai mult de „*mozaic*" (de implicare activă în procesele celulare) în detrimentul celui de „*fluid*", în ceea ce priveşte organizarea membranei celulare.

În aceste condiţii fluiditatea membranei devine o proprietate biofizică esenţială a membranei, în relaţie cu numeroase funcţii celulare şi, îndeosebi, cu procesele de transport membranar pasiv şi activ.

FLUIDITATEA MEMBRANARĂ ŞI PROCESELE DE DIFUZIUNE

Transportul pasiv se referă la trecerea moleculelor fără consum de energie prin bistratul lipidic în sensul gradientului electrochimic. Se realizează prin difuziune simplă sau difuziune facilitată. Difuziunea simplă a unui solvit prin membrana celulară este limitată de agitaţia termică specifică moleculei respective şi, deasemenenea, este dependentă de coeficientul de permeabilitate membranară şi de solubilitatea solvitului respectiv.

Studii efectuate pe embrionul de găină au pus în evidenţa faptul că, pe măsură ce embrionul creşte, apar modificări ale fluidităţii membranare. Aceste modificări sunt determinate de schimbarea tipurilor de fosfolipide membranare şi pot fi corelate cu o scădere a permeabilităţii membranare pentru uree şi glucoză (5). Difuziunea ionilor de Na^+ în sensul gradienţilor electrochimici, esenţială pentru menţinerea celulelor în stare funcţională, este dependentă de prezenţa colesterolului în membrană. Apa se organizează în mici bariere hidrofile membranare atât ca urmare a interacţunii inelelor colesterolice între ele cât şi prin împachetarea lipidelor membranare cu partea hidrocarbonată spre centrul bistratului (6). Acestea sunt o argumente care susţin ipoteza conform căreia difuziunea prin membrana celulară depinde de compoziţia lipidică şi de modul de organizare a lipidelor membranare.

FLUIDITATEA MEMBRANARĂ ŞI TRANSPORTUL PRIN CANALE IONICE

Fluiditatea membranară poate influenţa transportul prin canalele ionice în principal prin interacţiunea proteinelor ce au funcţie

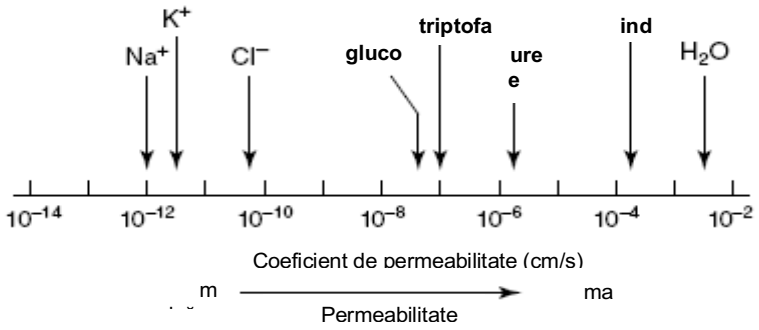

Fig. 2. Reprezentarea grafică a procesului de difuziune membranară în funcţie de coeficientul de permeabilitate pentru diferiţi solviţi (4)

de canal ionic cu fosfolipidele dar şi cu sfingolipidele sau colesterolul. Această interacţiune depinde de localizarea canalului ionic (distanţa dintre lipide şi proteine) dar şi de tipul de lipid (fosfolipid, colesterol, sfingolipid) şi de „disponibilitatea" de interacţiune a proteinei canal cu aceste lipide. In funcţie de modul de interacţiune cu proteinele membranare, lipidele se pot clasifica în lipide non-inelare, lipide inelare şi lipide „de masă". Unele proteine interacţionează specific cu anumite lipide, acestea fiind esenţiale pentru activitatea proteinei şi având rol de co-factor (7). Lipidele cu rol de co-factor se găsesc, de obicei, în interiorul proteinei, între α-helixurile transmembranare sau la interfata proteină-proteină, în cazul unor subunităţi proteice, şi constituie lipidele non-inelare. Lipidele aflate în jurul unor proteine, care sunt într-un status fizic particular şi care au un efect specific asupra acestora au fost numite lipidele inelare. Lipidele membranare care nu sunt în contact cu o proteină sau pentru care efectul proteinelor din jur este limitat sunt numite generic lipide „de masă" ; acestea au aceleaşi proprietăţi cu lipidele dintr-un bistrat lipidic simplu.

În ceea ce priveşte lipidele inelare acestea sunt implicate fie în mod indirect, prin geometria structurii lor specifice, fie în mod direct, prin interacţiunea cu proteina canal.

Cuplarea de tip hidrofob dintre segmentele α-helix intramembranare şi lipidele din jur influenţează conformaţia membranei. Proteinele au o dinamică conformaţională în relaţie cu modificările reversibile locale ale bistratului. Costurile energetice totale ale deformărilor suferite de lipide vor influenţa şi modificările conformaţionale proteice (fig.3).

Canalul MscL, de exemplu, un canal mecanosenzitiv (*mechanosensitive channel of large conductance*), este sub controlul diferenţei de potenţial membranare care depinde de energia liberă asociată moleculelor membranare, aceasta depinzând, la rândul ei, de curbura spontană a membranei şi, deci, de modul de aşezare al lipidelor respectiv al proteinelor în membrană (9).

În cazul canalelor voltaj dependente, modul în care senzorul voltaj-dependent interacţionează cu mediul lipidic membranar nu este cunoscut cu certitudine. Un canal intens studiat a fost canalul de potasiu voltaj dependent, K_v. Structura canalelor potasiu (K_v), deşi cunoscută, nu explică modul în care domeniul S_4 (senzorul cu sarcini pozitive - VS) estet capabil să se rotească în bistratul lipidic. Prin simulare moleculară pe calculator s-a studiat izolarea domeniului VS din structura canalului K_v de la *Archebacterii*, în mediul zwitterionic şi anionic al bistratului lipidic, urmărindu-se interacţiunea VS-lipide. În urma simulării s-a pus în evidenţă pătrun-

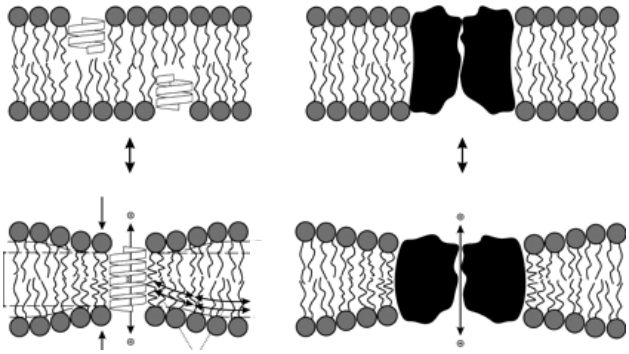

Fig. 3. Cuplarea de tip hidrofob între modificările de conformaţie ale unui canal şi deformările la nivel membranar : a) apariţia unui canal format din doi monomeri implică compresiuni şi modificări de curbură membranară. b) Cuplarea de tip hidrofob dintre membrană şi canal şi modificările de conformaţie ale canalului sunt condiţionate de tipul şi aranjarea lipidelor din bistratul înconjurător (8)

derea moleculelor de apă spre centrul VS şi în bistrat (10). De asemenea, s-a pus în evidenţă o deformare locală semnificativă care apare ca urmare a interacţiunilor dintre gruparea fosfat a fosfolipidelor şi segmentul care conţine reziduurile de arginină (Arg) de la nivelul S4 (fig. 3).

Organizarea membranei celulare depinde, printre alţi factori, şi de conformaţia geometrică a acizilor graşi, conformaţie care este dependentă de gradul de saturare/nesaturare al acestora. Putem spune, în aceste condiţii, că influenţa lipidelor membranare asupra canalului ionic este în relaţie cu gradul de organizare al membranei (ordonată - cristal lichid sau dezordonată - gel), adică şi cu fluiditatea membranei. Unii acizi saturaţi, de exemplu acidul linoleic, au rol în activarea canalelor de K^+ dependente de Ca^{2+} din mioblastele de pui, determinând hiperpolarizarea membranei prin influxul de Ca^{2+} şi fuzionarea celulelor (12). Acidul arahidonic şi oleic scad reversibil conductanţa canalelor de Na^+ voltaj dependente din muşchiul striat şi din miocardul de şobolan, determinând hiperpolarizarea membranei. Alţi acizi graşi saturaţi, de exemplu acidul palmitic, nu au efect asupra canalului (13). Acidul arahidonic inhibă reversibil activitatea canalelor de K^+ dependente de ATP din membrana apicală a celulelor canalului colector renal. Efectul nu se datorează metaboliţilor acidului arahidonic, nici modificării fluidităţii membranei. Mai mult, el apare numai dacă acidul gras se află în stratul lipidic intern al membranei, determinând o interacţiune directă cu canalul ionic (14). Acidul arahidonic şi alţi acizii graşi liberi nesaturaţi cu legături duble *cis* (oleic, linoleic, linolenic, eicosapentaenoic, eicosatetraenoic) activează canalele de Ca^{2+}, dependente de K^+ (canale BK) din celulele GH3, pe când acizii graşi saturaţi (stearic) şi nesaturaţi cu duble legături *trans* (elaidic, linol-enelaidic) nu au efect asupra activităţii acestor canale. Deoarece în acest caz nu s-a detectat o modificare paralelă a fluidităţii membranei, se sugerează de asemenea o interacţiune directă (15).

Nu doar fosfolipidele sunt în relaţie cu fluiditatea membranară ci şi restricţiile impuse de interacţiunea sfingolipidelor cu proteinele membranare. Canalul ionic format de alamethicin în bistraturi lipidice plane de difitanoil-fosfatidilcolină prezintă o activi-

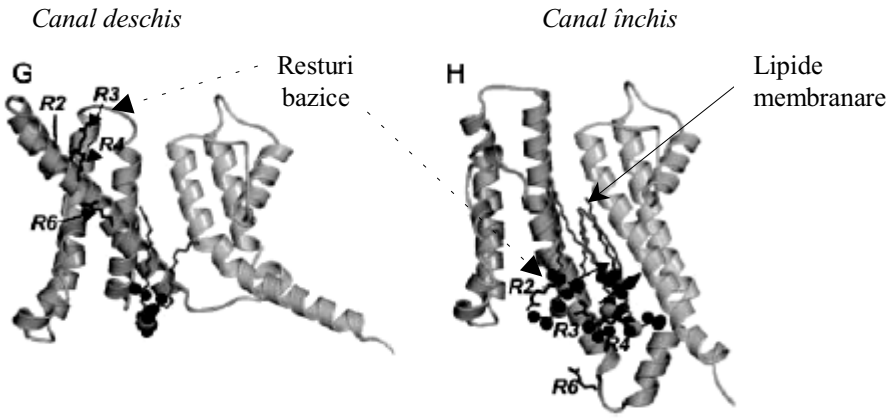

Fig. 4. Senzorul VS (segmentul G şi H) în cazul Kv şi interacţiunea sa cu bistratul lipidic. Segmentul S4 ce conţine resturi bazice (R_2- R_6) interacţionează cu lipidele membranare mult mai evident în conformaţia *închis* (11).

tate maximă dacă se adaugă şi gangliozide (sialoglicosfingolipide : CD1a, un disialoganliozid mai puţin polar, sau GQ1b, un tetrasialogangliozid polar). Autorii nu exclud nici unul din cele două mecanisme : interacţiunea directă sau modificarea microviscozităţii membranei, prin declanşarea unei tranziţii de fază(16).

Canalele ionice cu poartă dependentă de nucleotide ciclice CNG (*cyclic nucleotide--gated*) sunt implicate în semnalizarea fotoreceptorilor, respectiv a neuronilor senzitivi olfactivi. Semnalizarea prin nucleotide ciclice este necesară deoarece asigură o activare rapidă şi eficientă a acestor canale neselective de cationi. *Raft-urile* sunt acele domenii membranare specializate, îmbogăţite în colesterol şi sfingolipide implicate în multe căi de semnalizare cu punct de plecare membranar. S-a raportat că CNGA2, un tip al canalului CNG de tip olfactiv, este asociat în realizarea de *raft-uri* membranre la nivelul epiteliului olfactiv. Acest tip de canal CNGA2 nu este legat de în mod direct de caveolină, iar localizarea membranară se potriveşte doar parţial cu repartizarea caveolinei la nivelul celulelor renale embrionare HEK29. Tratarea celulelor HEK293 cu un agent care reduce colesterolul (metil-ciclodextrină), a dus la inhibarea activităţii canalelor CNGA2 exprimate la nivelul celulelor HEK239. S-a pus în evidenţă de asemenea că depleţia colesterolului duce la scăderea afinităţii CNGA2 pentru AMPc. Ca urmare canalele olfactive CNG îşi pierd activitatea dacă se alterează structura *raft-ului* membranar (17).

În ceea ce priveşte efectul colesterolului asupra canalelor ionice, ne putem referi la modul în care acesta participă la realizarea edificiului membranar, respectiv, prezenţa colesterolului în diferite *raft-uri* membranare, la nivelul cărora se găsesc anumite canale ionice. Efectul colesterolului şi al lipidelor anionice (DOPA-acid dioleil-fosfatidic) în menţinerea conformaţiei receptorului nicotinic (nAChR) a fost studiat prin spectroscopie IR, prin urmărirea modificărilor moleculare ale receptorului în prezenţa, respectiv în absenţa unui agonist al nAChR, reconstituit într-o membrană artificială (PC--din ou (EPC)/DOPA/Col = 3 : 1 : 1). Abilitatea acestor lipide de a modula statusul funcţional al nAChR, sugerează că lipidele prin efectul indirect, sunt esenţiale în funcţionarea şi stabilizarea nAChR. Astfel, putem spune că fluiditatea membranară reglează statusul funcţional sau de repaus al nAChR şi că modificări structurale minore ale fos-

folipidelor anionice sunt esenţiale pentru activitatea maximă a receptorului(18). De asemenea, s-a pus în evidenţă implicarea colesterolului în activitatea canalelor de calciu de la nivelul celulelor musculare netede. Efectul colesterolului asupra activităţii canalelor de Ca^{2+} este în relaţie cu rolul său în organizarea *raft-urilor* membranare. Acest fapt a fost studiat prin administrarea de β-ciclodextrina (un agent depletant de colesterol), în prezenta şi în absenţa colesterolului exogen. Se pare ca β-ciclodextrina afectează vasoconstricţia dependentă de presiune, în timp ce excesul de colesterol atenuează acest efect (19).

În ansamblu, activitatea canalelor ionice este dependentă de compoziţia lipidelor membranare, colesterol, sinfingolipide, fie prin interacţiunea directă cu acestea, fie indirect prin alterarea structurii *raft-urilor* membranare la nivelul cărora se găsesc şi canalele ionice.

FLUIDITATEA MEMBRANARĂ ŞI ACTIVITATEA TRANSPORTORILOR

Rezultatele obţinute cu privire la efectul fluidităţii membranare asupra activităţii transportorilor sunt relativ heterogene. Acestea depind pe de o parte de acţiunea directă a lipidelor membranare şi de modificarea fluidităţii în funcţie de gradul de nesaturare al acizilor graşi precum şi de raportul sfingomielina/colesterol membranar, iar pe de alta parte, indirect, de activarea unor enzime sau prin prezenţa unor metabolitţi sau medicamente.

De exemplu, lanţurile lungi ale acizilor graşi nesaturaţi (LCPUFAs) cresc fluiditatea membranară şi cresc numărul receptorilor de insulină, inhibă TNF-alfa, IL-6 şi MIF (*macrophage migration inhibitor factor*), în timp ce sinteza de leptină creşte numărul de receptori GLUT4 (20).

Sfingomielina este şi ea implicată în semnalizarea insulinică prin intermediul GLUT4, neexistând însă o relaţie bine stabilită între GLUT1 şi transportorul bazal (insulino-independent). S-au verificat efectele asupra GLUT1, prin modificare conţinutului de sfingomielină (prin adăugare de sfingomielină exogenă sau de glutation-inhibitor de sfingomielinază). Captarea bazală de glucoză a fost corelată cu conţinutul de colesterol (CL), sfingomielină (SM) şi raportul SM/CL. Expunerea preadipocitelor la sfingomielinază (SMase) duce la o creştere semnificativă a captării glucozei, fluiditatea membranară şi conţinutul în sfingomielină şi colesterol scăzând la 60 de minute după administrarea de SMase. Nu s-a observat, în acest context, o creştere a numărului de GLUT1 la suprafaţa membranară, fluiditatea membranară, conţinutul în colesterol şi sfingomielina revenind la valorile iniţiale după aproximativ 2 ore. Captarea bazală de glucoză a fost corelată negativ cu conţinutul de colesterol şi pozitiv cu raportul SM/CL (21).

Cotransportorul de Na^+/glucoză, cu expresie crescută la nivelul intestinului subţire, tubului proximal renal (ce are un rol important în absorbţia glucozei şi galactozei din filtratul glomerular) este reglat de cantitatea de AMPc intracelular, respectiv de activitatea PKA care poate creşte rata transportului de glucoză cu 30 % şi PKC care poate scădea rata transportului de glucoză cu până la 60 %. Sinteza de AMPc poate fi influenţată de molecule amfifile precum clorpromazina care poate duce la o creştere a fluidităţii membranare şi, implicit, la creşterea transportului de glucoză (22).

Cotransportul Na^+/glucoză duce şi la un transport al apei, în prezenţa unui gradient osmotic. Astfel factorii care modifică fluiditatea la nivelul interfeţei fosfolipide – apă, duc la alterarea echilibrului de legare al sodiului, prin inducerea unor modificări conformaţionale, prin alterarea afinităţii de legare a glucozei şi prin modificarea translocării glucozei la nivel membranar (23).

Ipotetic, toţi transportorii membranari pot fi afectaţi de interacţiunea cu lipidele (Tabelul I), dar este posibil ca nu în toate

TABELUL I
Efectul fluidităţii membranei asupra transportorilor (23)

Transportorul	Tipul celular utilizat	Factorul utilizat	Fluiditatea membranei	Activitatea transportorului

experimentele a fost atins pragul critic care să afecteze transportul. O altă ipoteză ar fi aceea că numai transportul substanţelor vitale pentru funcţiile vitale celulare este modulat pozitiv de fluiditatea membranei, în timp ce transportul substanţelor care ar trebui să rămână extracelular nu este afectat sau este chiar inhibat (24).

FLUIDITATEA MEMBRANARĂ ŞI ACTIVITATEA POMPELOR IONICE

Modificarea fluidităţii membranare este în relaţie cu modularea unor enzime membranare, cum sunt Na^+/K^+-ATPaza, acetilcolinesteraza şi captarea glutamatului. Administrarea de compuşi de amoniu la şoareci a dus la reducerea sfingomielinei şi a colesterolului de la nivelul membranelor celulelor neuronale, crescând nivelul de fosfatidilserină, în timp ce nivelul de fosfatidilcolină şi fosfatidiletanolamină au rămas nemodificate. Nu s-au pus în evidenţă modificări ale fluidităţii membranare în relaţie cu lipidele „de masă" (evaluare prin metoda de polarizare a fluorescenţei-*DPH*) ci mai degrabă o scădere a fluidităţii membranare în relaţie cu lipidele inelare (evaluare cu ajutorul fluorescenţei cu *pyren*). De asemenea, scăderea tiolilor şi creşterea malondialdehidei indică prezenţa

stresului oxidativ ca posibil factor ce ar modifica fluiditatea membranei, influienţând, secundar, transportul membranar (25). Pentru a putea determina posibila relaţie dintre fluiditatea membranară şi Na^+/K^+-ATPaza în reglarea funcţiilor membranare în hipertensiune, s-au analizat efectele oubainei asupra fluidităţii membranare eritrocitare la şobolani cu hipertensiune esenţială (SHR). Rezultatele au arătat o scădere semnificativă a fluidităţii faţă de lotul martor şobolani Wistar-Kyoto (WKY). De asemenea, s-a constatat că oubaina induce o scădere semnificativ mai mare la SHR faţă de WKY, concluzia fiind că fluiditatea membranei este în strânsă legătură cu activitatea Na^+/ K^+-ATPazei în cazul SHR (26). Recent s-a pus în evidenţă ca activitatea Ca^{2+}-ATPazei membranare plasmatice depinde de gradul de ordine al lipidelor membranare. Astfel, în cazul reticulului sarcoplasmatic, activitatea pompelor de Ca^{2+} (SERCA) este optimă în condiţiile în care mediul lipidic membranar este mai puţin ordonat, în comparaţie cu membrana plasmatică. În schimb activitatea pompei de Ca^{2+} la nivelul membranei plasmatice (PMCA) depinde de caracterul ordonat al bistratului membranar, activitatea PMCA fiind mai crescută cu cât procentul de acizi nesaturaţi este mai mic (27).

Un aspect, cel puţin interesant, care poate pune în relaţie fluiditatea membranei, tratamentul cancerului şi condiţiile în care acesta este administrat, este în cazul pompelor de tip ABC (ATP binding casette). Glicoproteina P joacă un rol esenţial în farmacocinetica rezistenţei la tratament, prin împiedicarea acumulării intracelulare a unor medicamente antineoplazice. Aceasta funcţionează ca o pompă dependentă de ATP, făcând parte din familia transportorilor ABC. Pentru a clarifica efectul terapeutic a hipotermiei moderate asupra distribuţiei medicamentelor via MDR1 (*multi drug resistance protein*, sinonim cu glicoproteina P) s-au urmărit la diferite temperaturi pe culturi de celule. MDR1 se exprimă şi la nivelul barierei hemato-encefalice, limitând efectul blocanţilor de calciu şi al antiaritmicelor (prin efluxul acestora). Digoxinul a fost ales ca marker al transportului via MDR1. Astfel transportul mediat de MDR1 a fost scăzut la temperaturi scăzute, cel mai probabil prin modificări ale fluidităţii membranare. La 32ş C în schimb, nu s-a gasit nici o modificare semnificativă, sugerându-se ca difuzia pasivă nu se modifică în timpul hipotermiei moderate (28).

În ansamblu, factorii care reduc fluiditatea (incorporarea de colesterol în membrane şi creşterea presiunii intramembranare) scad şi activarea ATP-azei, pe când cei care cresc fluiditatea (incorporarea de acizii graşi polinesaturaţi, benzil alcoolul) stimulează activitatea pompei. În unele stări patologice cronice (alcoolism, diabet zaharat, HTA, obezitate) deşi fluiditatea membranei a fost găsită redusă faţă de normal, nu s-a putut stabili o corelaţie clară cu activitatea Na^+/ K^+-ATPazei, aceasta fiind de multe ori neschimbată semnificativ faţă de normal. Acest fapt s-ar putea datora fenomenelor de adaptare ale funcţionării pompei la noile condiţii de fluiditate redusă (fenomen de adaptare homeoviscoasă).

CONCLUZII

Fluiditatea este un parametru membranar complex dependent atât de factori biochimici cât şi de cei biofizici. Factorii biochimici sunt în general reprezentaţi de : raportul lipide membranare/proteine, raportul acizi graşi saturaţi/acizi graşi nesaturaţi, procentul de colesterol membranar şi prezenta unor sfingolipide. Factori biofizici cel mai adesea implicaţi sunt : potenţialul electric membranar şi temperatura.

Se poate pune în relaţie cu funcţia de transport membranar şi fluidiatea membranei. Relaţia este dictată de modul în care sunt implicate componetele membranare în interacţiunea cu structurile de transport. Acestea

pot interacţiona, direct, în funcţie de complemetaritatea electrică-chimică şi sterică, fie indirect, prin modificarea gradului de organizare membranar.

Modul în care fluidiatatea membranei influenţează transportul membranar este în relaţie cu modificarea factorilor biochimici şi biofizici. Fluidiatea membranei poate fi, cel mai probabil, pusă în relaţie şi cu alte funcţii celulare importante.

Pentru a avea o imagine de ansablu asupra influenţei fluidităţii membranei asupra funcţiilor celulare ar trebui realizată o corelaţie şi cu celelate funcţii membranare şi anume de recepţionare şi de transducere a semnalelor.

EMBRYO SELECTION ON MORPHOKINETIC CRITERIA THROUGH TIME-LAPSE TECHNOLOGY ALONG WITH PREIMPLANTATION GENETIC TESTING (PGT) IN A COUPLE WITH RECURRENT PREGNANCY LOSS. CASE REPORT (Abstract): In this paper we present the case of a couple with a history of recurrent pregnancy failure in the first trimester, a balanced Robertsonian translocation (45,XY,der(13;14)(q10;q10)) being identified in the male karyotype. The couple was referred to genetic counseling and underwent an in vitro fertilization (IVF) cycle associated with preimplantation genetic testing. The embryos were cultured in a time-lapse system and the morphokinetic parameters were assessed daily. From the five embryos which were appropriate from embryo biopsy and freezing, only one embryo was genetically suitable for embryo transfer. The frozen embryo transfer resulted in a pregnancy and successful birth of a female baby. In the era of human assisted reproduction, state of the art biotechnologies such as time-lapse embryo monitoring and PGT should be used in synergy in order to complement the overall picture and enhance the process of decision making in the quest of obtaining a healthy offspring. **Keywords:** IVF, PGT, TIME-LAPSE, MORPHO KINETIC PARAMETERS, EMBRYOSELECTION, RECURRENT PREGNANCY LOSS.

Recurrent pregnancy loss (RPL) may be defined by two or more failed clinical pregnancies confirmed by ultrasound or histopathologic examination. This entity affects 2-5% of the couple trying to conceive, genetic abnormalities being among the most common causes of first trimester pregnancy loss, identified in more than 50% of the cases (1;2). In almost 4% of the cases of recurrent pregnancy loss, the chromosomal abnormalities are determined by unbalanced Robertsonian translocation, a chromosomal anomaly involving 2 acrocentric chromosomes (3). One of the most frequent subtype present in clini-

cal practice, strongly associated with male infertility, severe oligoasthenozoospermia and recurrent pregnancy loss is Robertsonian translocation (45,XY,der(13;14)(q10;q10)), and for those couples trying to conceive and have such a genetic disorder, an IVF cycle associated with preimplantational genetic testing (PGT) may be the solution (4).

This case report aimed at presenting the case of a couple dealing with infertility, with an history of recurrent pregnancy loss in the first trimester, most likely due to a meiotic malsegregation of derivative chromosome in a man with a balanced Robertsonian translocation identified in the male karyotype.

CASE PRESENTATION

We present a case of a couple, a 35 years female, respectively 37 years old male patient, with a history of infertility of almost 15 years. The anamnesis revealed that patients had recurrent pregnancy losses in the first trimester, thereby a series of specific investigations, including genetic karyotyping were recommended. A balanced robertsonian translocation (Tr crs 13,22) 45, XY, der (13,22) (q10; q10) was identified in the male karyotype. In light of this information, patients were referred to genetic counseling and were guided to follow an in vitro fertilization procedure associated with preimplantation genetic testing (PGT).

Ovarian stimulation was started on 2nd day of the menstrual cycle, using GnRH antagonist ganirelix (Orgalutran, Organon, Oss), after a previous ultrasound assessment and hormonal blood work. Subsequently, hMG 375 IU per day (Menotropine-Menopur, Ferring Pharmaceuticals) was administered for the following 9 days. Final oocyte maturation was triggered by administration of 0.2 mg triptorelin (Diphereline; Ipsen). Accordingly, the oocyte retrieval was carried out 37 hours after the administration of the trigger and resulted in 20 eggs (17 M II).

The oocytes were evaluated and inseminated using intracytoplasmic morphologically selected sperm injection (IMSI) and the resulting embryos were cultured and monitored until day 5 using a time-lapse system (EmbryoScope, Vitrolife, Denmark).

Further on, daily information regarding the embryos was provided by the Embryoscope software by monitoring the morphokinetic parameters and the images of the embryo's development, without removing the cell from controlled environment. Based on the information provided by the time-lapse system, the following parameters were determined and expressed as hours: tPnf; t2; t3; t4; t5; t8; tEB (tab. I) for the embryos that reached blastocyst stage.

TABLE I

Morpho kinetic parameters of embryos cultured in time lapse system

Embryo	t Pnf	t 2	t 3	t 4	t 5	t 8	t EB
W2	26.80	30.30	41.80	42.56	50.7	63.75	135.75
W4	25.31	29.20	43.22	46.11	57.21	72.74	120.74
W5	27.06	28.81	43.57	47.43	56.94	72.49	121.50
W7	27.32	30.32	43.07	44.32	59.19	63.77	128.51
W10	28.33	30.33	43.59	45.33	60.96	63.61	110.85

*t 2 = time to 2 cells; t 3 = time to 3 cells; t 4 = time to 4 cells;
t 5 = time to 5 cells; t 8= time to 8 cells; t EB= time to expanded blastocyst

Additionally, the length of the third cell cycle (CC3=t5-t3) and the interval t5-t2, were also calculated, based on a model proposed previously by Basile *et al.* (5), according to which these two variables, t5-t2<20.5 hours, respectively 11 hours<CC3 <18 hours may be used to predict the probability of selecting chromosomally normal embryos using morphokinetic parameters.

A number of 16 embryos achieved 2 PN stage, however, only 5 blastocysts had the proper quality to be biopsied and frozen. The embryo biopsy was performed by removing cell from the inner cell mass.

TABLE II

Parameters with defined optimal ranges for ploidy prediction and results from the genetic screening for the biopsied embryos

	Morph kinetic parameters with defined optimal ranges			Aneuploidy Screening
Embryos	t5 (47.2-58.2)	CC3 (11.7-18.2)	t5-t2 (<20.5)	
W2	50.7	12.2	20.39	Arr9p11.2p21.2 (31,127,576-44, 059, 743) x 3
W4	57.21	13.99	28.01	Trisomy 13, trisomy 16, trisomy 21
W5	56.94	13.37	28.12	Trisomy 19, trisomy 22
W7	59.19	16.12	28.87	Trisomy 16
W10	60.96	17.37	30.63	Multiple aneuploidy

The genetic material was amplified with the PicoPLEX® WGA Kit (Rubicon Genomics Rubicon Genomics) as instructed by the manufacturer. Array Comparative Genomic Hybridization (aCGH) was performed on a blade with 8x60,000 (60K) samples covering the whole human genome with a spatial resolution of ~ 5 Mb DNA (G5963A, design ID: 067559, UCSC hg19, GRCh37, February 2009, Agilent). The files obtained from the scan were interpreted with Cyto Genomics software v3.0 from Agilent, using standard cell parameters. The analysis revealed that four of the embryos were abnormal, their transfer being contraindicated. One of the embryos presented a duplication on the region 9p11.2p21.2, as compared to the female reference (tab. II). Since the duplication was small, it was considered to be non-pathogenic.

A hormone replacement therapy was used for frozen embryo transfer, consisting in the administration of oral estradiol valerate (Cyclo-Progynova; Bayer, Germany) 6 mg/ t.i.d, from the first day of menstrual cycle. The first transvaginal ultrasound was performed in day 10 of the treatment when endometrial thickness was 10 mm and from day 11 natural micronized progesterone (Utrogestan; Lab. Besins Int., France) was started at a dose of 600 mg/day. Embryo transfer was performed in day 5 of progesterone administration.

The euploid blastocyst wasted, evaluated and transferred with a soft catheter, under ultrasound guidance. The biochemical pregnancy was confirmed by beta-hCG determination 12 days after the transfer and clinically, by ultrasound, 21 days post transfer. The pregnancy evolved without obstetrical complications and the baby was

delivered at 38 weeks through C-section, with a 9 APGAR score and weighting 3050 grams. The following neonatal assessments did not reveal any development problems.

DISCUSSION

Recurrent pregnancy loss (RPL) is a multifactorial disorder that causes significant physical and psychological distress to patients and challenges medical providers engaged in the management of this reproductive health issue (6,7).

According to the guideline elaborated by ESHRE (8), patients with abnormal karyotype should receive genetic counseling. A study conducted by Ikuma *et al*. (9) showed that miscarriage rates may be lower when preimplantation genetic testing is used along with IVF. The introduction of a new method of embryo selection, called time-lapse monitoring, has been long awaited. Unlike the conventional routine embryo evaluation, the time lapse monitoring of embryos provides a stable microclimate for embryo culture, certain potentially stressful factors such as variation in temperature or pH being avoided because the embryos are cultured continuously, without being removed from the incubator for daily routine evaluation (10, 11).

A study conducted by Rubio *et al.* (12), showed that embryos cultured in the Embryo Scope® system have a higher implantation potential and are associated with lower rates of early pregnancy loss, one of the possible explanations being the more stable culture environment, which ensures a better protection against oxidative stress. Furthermore, a study conducted by Campbell *et al*., (13), Basile *et al*. (5), Chawla *et al*. (14), concluded that the kinetic pattern differs among chromosomally normal and abnormal embryos, euploid embryos having a more defined pattern. Additionally, a study conducted by Del Carmen Nogales *et al*. (15) showed that the subtypes of chromosomal abnormalities such as complex aneuploidy exhibit modified morpho kinetics parameters (t3 and t5).

In our case study, only the morphokinetic parameters registered for the embryo selected for transfer (W2), were in the optimum interval proposed by Basile (5). However, due to the limited number of analyzed embryos, no statistical analysis was performed to reveal any significant statistical differences as compared to the other embryos which were identified as aneuploid with PGT. Nevertheless, there is evidence showing that morphokinetic parameters may reflect the implantation potential of embryos, significant increased pregnancy and live birth rate, as well as reduced early pregnancy loss being observed when embryos classified as low risk were transferred (16-19).

Embryo-selection by morphokinetics criteria-time lapse imaging, may be considered as a complementary method and an option for those couples with multiple implantation failure, especially in those clinics where preimplantation genetic testing is not available, the procedure is forbidden by law or to reduce costs associated with this procedure.

Concluding, in the era of human assisted reproduction, state of the art biotechnologies such as time-lapse embryo monitoring and PGT should be use in synergy in order to complement the overall picture and enhance the process of decision making in the quest of obtaining a healthy offspring.

INFORMED CONSENT

Informed written consent was obtained from the patient for publication of this case

report and accompanying images.

CONFLICT OF INTERESTS

No conflict of interests was declared by the authors.

FINANCIAL DISCLOSURE

The authors declared that this study has received no financial support.

LIST OF ABBREVIATIONS

IVF: in vitro fertilization

IMSI: intra cytoplasmic morphologically selected sperm injection

PGT: preimplantation genetic testing

NEWS

LIQUID BIOPSIES COULD REVOLUTIONISE CANCER MEDICINE

Tumor biopsies are the current standard for cancer diagnosis and the preferred method for molecular testing to guide the selection of precision therapies. Liquid biopsies, mostly those involving cell-free DNA (cfDNA) from plasma, are rapidly emerging as an important and minimally alternative approach. Liquid biopsy is becoming a valuable tool for molecular testing for new insights into tumor heterogeneity, and for cancer detection and monitoring. Although liquid biopsy has most often referred to the analysis of cfDNA from peripheral blood, this term also refers to the isolation and analysis of tumor derived material from blood or other bodily fluid like: cerebrospinal fluid, saliva, pleural fluid, ascites, stool and urine. Although more prospective studies are needed liquid biopsies have the potential to revolutionize cancer medicine (Corcoran RB, Chabner BA. Application of cell-free DNA analysis to cancer treatment. *N Engl J Med* 2018; 379(18): 1754-1765).

PLATELET FUNCTIONS IN ACUTE AND CHRONIC EXPERIMENTALLY INDUCED HEPATOPATHIA (Abstract) : It's well known the coagulation damage in chronic hepatitis and hepatic cirrhosis. The aim of our study was to quantify platelet dysfunction in acute and chronic toxic hepatitis. **Material and method** : We determined adhesivity, aggregability and icosanoids production in rats with acute and chronic hepatopathia induced by CCl_4 administration. **Results** : Our data shows that platelet adhesivity and aggregability are affected in chronic toxic affectation but also in acute intoxication ($p < 0.05$). Icosanoids production (expressed like MDA levels are significantly decreased only in chronic CCl_4 intoxication ($p < 0.001$). Significantly correlation appears between aggregability and adhesivity in control group ($r = 0.66$) and between aggregability and MDA ($r = -0.78$) and adhesivity and MDA ($r = -0.57$) in lot C. **Conclusion** : Primary haemostasis and platelet dysfunction are involved in coagulation dysfunction in hepatic diseases and the modifications of platelet parameters also appeared in acute hepatic affectation. **Key words** : HAEMOSTASIS, PLATELET DYSFUNCTION, HEPATIC DISEASE

Afectarea coagulării în condiţiile cirozei hepatice este binecunoscută. În etiologia acestei hipocoagulopatii este implicat în general deficitul de sinteză hepatică a unor factori plasmatici ai coagulării. Unele studii atestă însă şi deficite ale hemostazei primare asociate mai ales cu un deficit funcţional plachetar. Date preliminare sugerează că afectarea funcţionalităţii plachetare ar exista şi în unele hepatopatii acute. Scopul urmărit a fost evaluarea funcţiei plachetare la şobolani cu afectare hepatică toxică (produsă prin administrarea de tetraclorură de carbon CCl_4) acută sau cronică.

MATERIAL ŞI METODE

Partea experimentală a fost realizată pe şobolani rasa Wistar masculi, de sex masculin, cu greutatea cuprinsă între 216-300 grame. Aceştia au primit hrană şi apă la discreţie şi au fost menţinuţi în condiţii standard de laborator la o temperatură de 20 ± 2^0C cu un ciclu de 12 ore lumină, 12 ore întuneric. S-au asigurat de asemenea condiţiile de ventilaţie ; au fost găzduiţi în cuşti de inox, de dimensiuni potrivite conform normelor în vigoare.

Diagnosticul de afectare acută respectiv cronică a ficatului a fost pus prin evaluarea modificărilor morfologice hepatice comparativ cu lotul de referinţă. Modificările morfologice s-au manifestat atât la nivel celular cât şi tisular, prin alterări în histoarhitectonica hepatică.

Investigarea funcţionalităţii plachetare în condiţiile hepatopatiei indusă experimental s-a realizat prin determinarea agregabilităţii plachetare (1), a adezivităţii plachetare, prin metoda colorimetrică a lui Bellavitte şi colab. (2) şi sintezei de icosanoizi plachetari, prin dozarea MDA (3).

Animalele au fost divizate în trei loturi de studiu, după cum urmează :

- M – lotul martor, format din şase şobolani masculi, rasa Wistar, de crescătorie, cu greutăţi cuprinse între 236 şi 300 de grame ;
- A – lotul cu afectarea acută hepatică, format din şapte şobolani masculi, rasa Wistar, de crescătorie, cu greutăţi cuprinse între 216 şi 274 de grame ; au primit CCl_4, în doză unică, 0,01 ml/kgc în 0,5 ml ulei vegetal administrat intraperitoneal. Animalele au fost sacrificate la 48 de la injectare.
- C – lotul cu afectare cronică hepatică, format din şase şobolani masculi, rasa Wistar, de crescătorie, cu greutăţi cuprinse între 220 şi 258 de grame ; au primit CCl_4, 0,008 ml/kgc în 0,5 ml ulei vegetal, intraperitoneal, de două ori pe săptămâna, timp de 8 săptămâni pentru inducerea hepatopatiei.

Animalele au fost sacrificate la 48 de ore de la ultima injectare după anesteziere cu tiopental, în doză de 1 ml/100 g din soluţia 0,01% tiopental. S-au recoltat fragmente de ficat pentru evaluare anatomo-patologică a hepatopatiei precum şi sânge din cord pentru determinarea parametrilor funcţionali plachetari.

S-a făcut standardizarea tehnicii de lucru, în toate cazurile respectându-se anumite condiţii de recoltare şi prelevare.

În ceea ce privesc probele de anatomie-patologică :

- aceeaşi persoană a efectuat recoltările ;
- s-a utilizat acelaşi instrument de prelevare ;
- aceleaşi zone topografice de prelevare ale fragmentelor ;
- fixarea imediată a fragmentelor tisulare şi evitarea manipulării manuale ;
- aceeaşi persoană a făcut prelucrarea pentru examenul microscopic ;
- acelaşi mod de prelucrare pentru examenul microscopic.

Fragmentele hepatice au fost fixate în formol 10% incluse în parafină, secţionate şi colorate standard, hematoxilină-eozină şi Van Gieson. Tehnica uzuală histologică care s-a folosit pentru toate preparatele a fost completată cu tehnici de prelucrare şi colorare specifice anumitor structuri modificate de procesul patologic studiat.

Recoltarea sângelui. După anestezierea animalului cu tiopental, s-a deschis cutia toracică şi s-a puncţionat cordul cu un sistem de recoltare tip Vacuette®, în vacutainere de 2,5 ml, conţinând ca anticoagulant citrat de sodiu 3,8%. Proporţia finală, sânge/citrat este cea clasică de 9/1. Vacutainerele au fost centrifugate ulterior pentru obţinerea de plasmă bogată în plachete (PRP). Parametrii plachetari determinaţi în acest experiment au fost :

- **Agregabilitatea plachetară**, prin micrometoda pe cititorul TECAN, după Beddnar B (1), modificată de Robert C. Chadderon şi Michael Cappello (4) ;
- **Adezivitatea plachetară**, după metoda descrisă de P. Bellavite et al. (2) ;
- **MDA plachetar**, după metoda lui Enache, 1998, modificată (3).

Datele au fost încărcate şi prelucrate cu ajutorul funcţiilor statistice din *EXCEL* şi *EpiInfo* folosindu-se testul *t-Student* (pragul de semnificaţie unanim acceptat este de 95% adică $p=0,05$) şi testul γ^2. Corelaţia liniară este corelaţia dintre două variabile ale căror valori formează o dreaptă. Intensitatea legăturii dintre variabile se măsoară cu ajutorul coeficientului de corelaţie Pearson (r), care trebuie să ia valori între $-1 \leq r \leq 1$, cu cât este mai apropiat de valoarea 1 cu atât corelaţia este mai puternică, fie directă, fie in-

versă dacă r = -1.

REZULTATE

Examenul anatomopatologic al fragmentelor de ficat recoltate a relevat aspecte normale ale morfologiei hepatice la lotul martor. La lotul cu afectare acută hepatică au fost evidenţiate anomalii morfologice hepatice specifice hepatitelor acute toxice : ficat cu structură histologică păstrată, degenerescenţă hidropică şi steatoza hepatocitară, hepatocitoliză, degenerescenţă hidropică. În cazul lotului C, cu afectare cronică, examenul anatomopatologic efectuat pe fragmentele hepatice recoltate evidenţiază în unele cazuri alterarea arhitectonicii ficatului, cu apariţia de noduli de regenerare (semn de ciroza hepatică-CH), infiltraţii şi fibroză în spaţiul port, mitoze, steatoză macroveziculară si chisturi lipidice (leziuni caracteristice toxice). Rolul examenului anatomopatologic a fost de a confirma apariţia leziunilor hepatice.

Examenului sângelui recoltat pe citrat de sodiu pentru a evalua funcţia plachetară a relevat următoarele valori ale adezivităţii, agregabilităţii şi MDA plachetar.

Agregabilitatea plachetară. Analizând loturile studiate pentru parametrul agregabilitate plachetară se observă diferenţe statistic semnificative între martor şi toate celelalte loturi cu excepţia lotului LA. Vizibilă şi în tabel, diferenţa de agregabilitate plachetară între lotul martor şi cele cu hepatopatie este mare cu un prag de semnificaţie de peste 95%.

Adezivitatea plachetară. Folosind testul *t-Student* pentru comparaţia parametrului adezivitate în loturile de studiu sunt puse în evidenţă diferenţe statistic semnificative faţă de lotul martor.

MDA plachetar. Studiind valorile MDA plachetar se observă că nu există diferenţe semnificative statistic între lotul martor şi cel cu hepatopatie acută (A) dar se remarcă semnificaţii statistice semnificative pentru MDA între lotul martor si cel cu afectare cronică hepatică.

Evidenţierea unor posibile corelaţii între parametrii de investigat. În ceea ce priveşte cei trei parametrii funcţionali plachetari am încercat să observăm eventuale corelaţii în cadrul fiecărui lot în parte şi să evidenţiem dacă există sau nu un paralelism între funcţiile plachetare în condiţii normale şi/sau patologice. Am considerat r > $\pm$0.5 corelat, iar r > $\pm$0.6 semnificativ corelat. Sintetizând, tabelul IV evidenţiază coeficienţii de corelaţie înregistraţi între parametrii investigaţi. Se observă că, în lotul martor singura corelaţie semnificativă, directă există între adezivitate şi agregabilitate, nici un fel de corelaţii nu există între alte două funcţii. Acest tip de corelaţie nu se menţine la loturile cu afectare hepatică acută respectiv cronică probabil datorită prăbuşirii agregabilităţii comparativ cu adezivitatea, parametru care comparativ nu scade într-o manieră atât de importantă. În ce priveşte corelaţia dintre agregabilitate şi MDA aceasta are valori scăzute în lotul martor şi în cel cu afectare acută dar la lotul cu afectare cronică există o corelaţie inversă, importantă (r=-0,78) ceea ce arată

TABELUL I

Semnificaţii statistice pentru agregare între loturile de studiu faţă de martor

Martor	Lot	Media ± DS	*t-Student*	p
22,44 ± 15,43 (n=6)	**C (n=6)**	**1,33 ± 0,61**	**3,35**	**p < 0,01**

TABELUL II

Semnificaţii statistice pentru adezivitate a loturilor de studiu faţă de martor

Martor	Lot	Media ± DS	*t-Student*	p
52,49 ± 1,35 (n=6)	**C (n=6)**	**16,93 ± 6,56**	**13,01**	**p < 0,001**

TABELUL III
Semnificaţii statistice pentru MDA a loturilor de studiu faţă de martor

Martor	Lot	Media ± DS	*t-Student*	p
9,07 ± 2,11	**C (n=6)**	**3,94 ± 1,64**	**4,70**	**p < 0,001**
(n=6)	A (n=7)	7,99 ± 2,09	0,92	NS

TABEL IV
Valori ale coeficientului de corelaţie Pearson „r"

Coeficient de corelaţie Pearson „r"	LOT M	LOT A	LOT C
Agregabilitate-adezivitate	0,66	0,38	0,07
Agregabilitate - MDA	-0,32	-0,06	-0,78
Adezivitate - MDA	-0,02	-0,34	-0,57

că diminuarea agregabilităţii şi a sintezei de icosanoizi plachetari, evidenţiabilă prin valoarea MDA, în condiţiile afectării cronice hepatice. Intre adezivitate şi MDA există o există o corelaţie inversă semnificativă doar în lotul cu afectare cronică hepatică (-0,57).

DISCUŢII

Administrarea de medicamente, radiaţiile ionizante, substanţele poluante din mediu înconjurător cu potenţial pro-oxidant induc formarea de radicali liberi de oxigen (ROS). Peroxidarea lipidică indusă de ROS este considerată a fi nocivă pentru membranele celulare şi stă la baza unor numeroase situaţii patologice. Leziunile hepatice în experimentul nostru s-au realizat folosind CCl_4, un solvent industrial şi un hepatotoxic cunoscut. Este cunoscut faptul că CCl_4 determină afectare hepatică dar şi renală la om dar şi la animalele de experienţă. Prin activarea metabolică, dependentă de citocromul P_{450} a CCl_4 rezultă radicalii liberi CCl_4 respectiv Cl care iniţiază peroxidarea lipidică (5). Vitamina E are efect protector asupra lezării hepatice cu CCl_4 ceea ce confirmă ipoteza stresului oxidativ în acest model (6). La animalele de laborator la care s-a administrat CCl_4 este afectată capacitatea metabolică a mitocondriilor din hepatocit, confirmând ipoteza stresului oxidativ (7). Administrarea pe termen lung de CCl_4 provoacă afectare cronică hepatică, cu necroză, infiltrat inflamator, degenerescenţă hidropică şi fibroză care pot duce în final spre ciroză hepatică, fapt confirmat de numeroase studii (4,8,9). Moartea celulară se produce în final prin necroză şi apoptoză, în proporţii variabile (10).

Numeroase studii au confirmat afectarea toxică a ficatului sub acţiunea CCl_4 administrată intraperitoneal, gavaj sau vapori. Unii autori susţin că după 8-12 săptămâni CCl_4 produce ciroză hepatică (7), alţii indică doar semne de fibroză hepatică (11). Mecanismul prin care apare afectarea funcţiei hepatice şi respectiv fibroza este mult discutat. Acesta este extrem de important pentru studiul nostru, deoarece, aşa cum arătat anterior fibroza hepatică reprezintă un element cheie în funcţionalitatea plachetului (12) şi invers trombocitul, prin factorii de creştere joacă un rol în apariţia şi dezvoltarea fibrozei hepatice. Totuşi afectarea funcţiei plachetare ca urmare a unui deficit funcţional hepatic apare şi în alte tipuri de hepatopatii induse experimental (13, 14). Krahenbuhl et al. (7) realizează un model de ciroză hepatică experimentală la şobolani, prin expunere la CCl_4 şi dovedeşte, prin metode biochimice şi analiza sterologică a ficatului că leziunile hepatice s-ar datora afectării funcţiei mitocondriilor, afectare evidenţiată prin scăderea activităţii unor enzime mitocondriale, prin scăderea formării hipuratului din benzoat şi a metabolizării palmitatului. Acelaşi studiu susţine că, deşi

apar modificări, acestea sunt în special de natură metabolică şi greutatea ficatului nu se modifică (fapt observat şi de noi în studiul efectuat). Deşi studiul lui Krahenbuhl (7) nu abordează direct problema funcţiei plachetare câteva date sunt extrem de interesante şi anume : afectarea metabolismului acizilor graşi cu lanţ lung, afectare care ar putea explica defectele de agregabilitate plachetară obţinute şi de noi.

În determinarea cauzelor scăderii agregabilităţii plachetare la cirotici ipoteza modificării compoziţiei lipidelor membranare, ca urmare a funcţionării defectuoase a ficatului lansată în urmă cu peste 20 de ani este din ce în ce mai incriminată în ultimii ani (15,16,17,18,19). Pe de altă parte tot acest studiu confirmă că defectele mitocondriale evidenţiate pe modelul cu tetraclorură de carbon nu sunt valabile şi pe modelul de ciroză biliară unde din contră, metabolismul benzoatului este crescut ; acest lucru este corelat şi cu funcţia plachetară deoarece şi alte studii arată că, în ciroza biliară există o tendinţă la hiperfuncţionalitate plachetară şi chiar la tromboze (20). Creşterea concentraţiei de acizi graşi mononesaturaţi, ca urmare a unui deficit de metabolizare este evidenţiat de Koike et al. (21) într-un studiu efectuat atât pe subiecţi cu hepatită cronică cu virus hepatitic C cât şi pe şoareci transgenici ; mai mult acesta susţine că, creşterea concentraţiei de acizi graşi mononesaturaţi ar duce la o creştere consecutivă a fluidităţii membranei hepatocitare ceea ce duce la o amplificare a ratei de diviziune celulară şi creştere a riscului de apariţie a cirozei hepatice şi a carcinomul hepatocelular. În acest context, studiul lui Manibusan (22) sugerează că PRP ar putea favoriza carcinogeneza la şobolani la care s-a indus hepatopatie cu CCl_4 ; de altfel şi în studiul nostru am obţinut, la analiza histologică în lotul cu CCl_4 imagini sugestive pentru carcinogeneză. Alţi autori consideră că în hepatopatiile cronice cresc nivelele de acid oleic, palmitic şi stearic şi scad nivelurile de acizi graşi polinesaturaţi (linoleic, arahidonic şi docosahexanoic), precursori de icosanoizi, ceea ce ar putea explica deficitul funcţional plachetar prin alterarea transmiterii mesajului biologic. Studii mai vechi (23) sugerează că defectul plachetar este legat mai mult de factori plasmatici decât de cei intrinseci plachetari (ipoteză negată de Laffi, 24) şi că numai normalizarea funcţiei hepatice este cea care îmbunătăţeşte funcţionalitatea plachetului, ipoteză susţinută şi de noi. Unele experimente au încercat îmbunătăţirea funcţiei plachetare la hepatici prin aport alimentar de acizi graşi (15).

CONCLUZII

Este cunoscut faptul că CCl4 determină o afectare hepatică dar şi renală, atât la om cât şi la animalele de experienţă.

Mecanismele patogenice implicate sunt stresul oxidativ şi modificarea compoziţiei membranare în acizi graşi.

Dintre funcţiile plachetare scăzute semnificativ, în studiul nostru sunt agregabilitatea şi adezivitatea.

Sinteza de icosanoizi plachetari este semnificativ scăzută in lotul cu afectare hepatică cronică dar nu şi la lotul cu la lotul cu hepatopatie acută faţă de lotul martor.

Corelaţiile puternic semnificative apar doar între agregabilitate şi adezivitate la lotul martor şi între agregabilitate şi MDA plachetar la lotul cu afectare cronică hepatică, ceea ce ar putea sugera legătura dintre deficitul de agregabilitate şi compoziţia membranară în acizi graşi.

Studiul nostru confirmă numeroase alte studii care susţin că deficitul hemostazei în hepatopatii are drept cauză şi alterarea funcţiei plachetare.

Trombopatia apare şi în condiţiile unei hepatopatii acute toxice experimentale, nu doar în formele cronice aşa cum descriu cele mai multe studii.

PSYCHOLOGICAL EFFECTS AND ETHICAL IMPLICATIONS OF THE PRENATAL DIAGNOSIS OF SEVERE MALFORMATION IN THE FETUS (Abstract): Considered from the standpoint of the parents' and medical team's rights, the prenatal diagnosis of severe inborn malformations is an ethical and legal must, which carries a twofold meaning: recognition of the women's right to abortion and fetus protection. The purposes of our paper are: to reveal the psychological effect of antenatal diagnosis in case of fetal malformation; to point out a series of ethical implications of elective abortion of fetuses or discontinuation of the treatment of newborns suffering from multiple malformations; and to draw attention on the low antenatal diagnosis rates in our country. **Material and methods:** In Romania, on a 23-year-long study conducted over 115 neonates suffering from gastroschisis and on 105 newborns with omphalocele, the rate of antenatal malformation diagnosis was very low, and implicitly leaded to a high malformation and chromosomal aberration incidence and hence to a high neonatal mortality rate. Also, the birth of these babies set a considerable financial burden on pediatric surgery wards for the somewhat hopeless treatment. **Results:** Most of the times, making abortion decisions, caring for or discontinuing the treatment of newborns suffering from multiple malformations also have a negative impact on the family. Whichever the case, any choice made about an abnormal fetus should be respected and protected by the family, the laws in effect and the country's culture and social structures. **Conclusions**: It is the parents who should decide the future of the pregnancy or, when there was no antenatal diagnosis, of the neonate; the decision must be made after having been well informed by a multidisciplinary medical team. **Keywords**: ABORTION, NEWBORN, MALFORMATIONS, CHROMOSOMAL ABERRATIONS, ANTENATAL DIAGNOSIS.

An increasingly higher number of newborns with anterior abdominal wall malformations have benefitted from antenatal diagnosis. Therefore, whenever the obstetrician detects any type of fetus abnormality by ultrasound scanning, the parents ought to be prenatally advised by a multidisciplinary medical team (1). Despite the fact that isolated omphalocele and gastroschisis have better prognosis than other inborn malformations detected prenatally, such a diagnosis may have an unfavorable

psychological impact on parents and even an unfortunate influence on their future reproduction decisions (2). Should other associated abnormalities be detected, or should the malformation be classified as part of a particular genetic syndrome, the fetal prognosis may be poor, and the parents may consider an elective termination of pregnancy (3). The debate may be extended to include the case of newborns suffering from multiple malformations, for which "postnatal abortion" may be considered (4, 5). Considering that abortion (therapeutic or elective) is both moral and legally accepted in most of the countries, does this implicitly mean that these neonates may be condemned to non-treatment (namely "postnatal abortion")? The purposes of our paper are: to reveal the psychological effect of antenatal diagnosis in case of fetal malformation requiring surgical therapy; to point out a series of ethical implications of elective abortion of fetuses or discontinuation of the treatment of newborns suffering from multiple malformations and chromosomal aberrations; and to draw attention on the low antenatal diagnosis rates in our country.

MATERIAL AND METHODS

Unfortunately, in Romania, the prenatal malformation diagnosis rate is very low, which implicitly leads to a high malformation and chromosomal aberration incidence in newborns, and hence to high neonatal mortality rates (6, 7). Therefore, a 23-year-long study (1990-2012) conducted over 115 neonates suffering from gastroschisis and on 105 newborns with omphalocele, who were hospitalized in the Pediatric Surgery Department of the "Sfânta Maria" Clinical Emergency Children's Hospital of Iaşi, revealed prenatal diagnosis rates of only 11.4% for gastroschisis and 13.3% for omphalocele, whereas in most European countries these rates exceed 70-80% (8, 9). The studies that considered the socio-economic factors showed that the omphalocele and gastroschisis risks were higher among underprivileged mothers, which may probably be accounted for by the tender age of the mothers, by the mothers' drug and tobacco abuse, by the absence of any family planning within this population, by their single status or their low education level (10, 11). According to our findings, 40% of the mothers whose babies were diagnosed with gastroschisis and 22% of those whose newborns were diagnosed with omphalocele were single, whereas 15% of the parents with babies suffering from gastroschisis and 32% of those whose neonates had omphalocele were alcohol and tobacco abusers. The mothers' education level was slightly higher for omphalocele (27% illiteracy or only primary education versus 40%). On the other hand, they were also older (27.0 years on the average versus 20.6 years). As concerns the gastroschisis newborns, we should also point out that almost half (41.2%) of the mothers were very young, i.e. 20 years or younger, and 65.7% of them were primigravida, primipara. The babies diagnosed with gastroschisis and omphalocele came mostly from the rural areas (68.5% and 62% of the cases, respectively). Urban newborns enjoy prenatal diagnosis rates that are two times higher as compared to rural neonates, which is statistically significant. All these socio-economic factors had a negative influence on the number of mothers with anterior abdominal wall defect babies who came to be seen by a doctor and also on the antenatal diagnosis rate, respectively. In its turn, this also had negative repercussions

on the future course of the disease. Therefore, the mortality rates were extremely high in our study, i.e. 70.2% for gastroschisis and 54.3% for omphalocele, as compared to 0-10% rates in developed countries (9, 12). In our country, high antenatal diagnosis rates of severe chromosomal aberrations or inborn malformations associated with anterior abdominal wall defects (27.6% of the omphalocele cases also suffer from chromosomal aberrations) may result into a therapeutic abortion decision meant to protect the families involved against the unwanted psychological effects of giving birth to a baby suffering from multiple malformations, which would put a considerable financial burden on pediatric surgery wards for the somewhat hopeless treatment of these babies. This would remove these patients with guarded prognosis from future studies and thus improve survival rates (abortion being presented as treatment) (6). In our study, due to the small number of cases diagnosed prenatally (13 cases of gastroschisis and 14 cases of omphalocele) and also due to the retrospective nature of the study, as the mothers came to our clinic one or two days after baby delivery, we were unable to quantify the full extent of the psychological impact of the prenatal diagnosis of abdominal wall defect, although, according to their statements, it had been a strongly negative one.

RESULTS AND DISCUSSION

The purpose of any antenatal examination in case of inborn abnormality or malformation detection is to provide information on the fetus' evolution and quality of life, on any possible ante or postnatal procedures, on adequate management and type of delivery, and on the baby's long-term prognosis. Several meetings between the parents to be and the multidisciplinary medical team monitoring the malformed fetus will most probably be necessary in order to tackle all these issues (1). The team should include an obstetrician, an ultrasound scanning specialist, a neonatologist, an anesthesiologist, a pediatric surgeon, a geneticist and a psychologist. The influence of a prenatal surgical examination on the mortality rates and on the perinatal management of anterior abdominal wall defects, as well as the psychological effects of antenatal parent counseling have been thoroughly described in literature (13), but the number of counseling sessions required to decrease the parents' anxiety has not been determined yet (14). Should other associated abnormalities be detected, or should the malformation be classified as part of a particular genetic syndrome, the fetal prognosis may be poor, and the parents may consider an elective termination of pregnancy (3). This decision varies greatly depending on the antenatal diagnosis team, on the parents' attitude, on the fetus' state and also on the laws regulating therapeutic abortions in effect at that time. Therapeutic abortion is the abortion induced legally by a qualified physician because the fetus is severely malformed or to safeguard the health of the mother. In some cases, the parents' religious beliefs or their socio-economic and educational status may have considerable influence on their making a therapeutic abortion decision. Especially these parents should be given the possibility to talk about their fetus' prognosis with the members of the neonatal team and with a specialized psychologist, in order to get full grasp of the actual situation and to make the last feelings of fear or guilt disappear before making their final decision. Given all these factors, a homo-

geneous set of therapeutic abortion assessment criteria is hard to define and to harmonize worldwide, which also accounts for the very diverse and somewhat contradictory data provided by literature.

A European study conducted in 2001 reveals a therapeutic abortion rate amounting to 37% for omphalocele associated with other malformations or chromosomal aberrations, and to 29% for gastroschisis (8). Although most researches acknowledge a positive prognosis of these cases after their surgical repair, the high rate (16-17%) of abortions performed in Europe in cases of planned pregnancies with isolated anterior abdominal wall defects, with no other associated diseases, proves that parents still do not trust the specialists' ability to rule out any malformations and abnormalities associated with omphalocele and gastroschisis prenatally, which leads too easily to the parents' making a decision of termination of pregnancy (8). Similar conclusions were noted in a recent study, which pointed out that one in three mothers chose abortion when their fetus was diagnosed with isolated omphalocele (15). That is why sometimes, if the parents' decision is clearly against the best interest of the child, it is ethically permissible and legally required to disqualify them.

There are currently many papers assessing the psychological impact of antenatal diagnosis on the expectant parents (1, 2, 13-16). Both family planning and pregnancy are normally considered happy times for the family, but when a fetal condition is detected prenatally, the time left until the baby's delivery is one of stress and uncertainty for the couple. The parents' anxiety is not connected to their age or social status, and their apprehension is significantly reduced after surgical examination and adequate antenatal counseling. Moreover, there has been noted no statistically significant difference between the extent of the parents' anxiety about the various groups of inborn malformations (13). In other words, the level of anxiety, both when the diagnosis was initially set and when the baby was born, was independent of the severity of the abnormality detected. Just like Drotar pointed out, this finding may reflect the state of shock suffered by the parents when given the inborn malformation news, which news will cause a "crisis" situation in the lives of the expectant parents (17). Marteau suggests that immediate and long-term suffering caused by the occurrence of a fetal malformation may be reduced by the parents' adequate preparation before the test, and especially by support, by post-test counseling and the provision of information as complete as possible (18). Although anterior abdominal wall anomalies have better prognosis than other inborn malformations detected prenatally, such a diagnosis may have an unfortunate influence on their future reproduction decisions. In a research conducted on 18 parents with omphalocele and gastroschisis babies, 9 of the 14 mothers that initially wanted to keep having children before the delivery of the malformation baby decided to stop trying to have children, whereas the others deferred making any such decision. Nevertheless, 6 of the 7 mothers of babies with omphalocele and 10 in 11 mothers of babies with gastroschisis retrospectively admitted that the antenatal diagnosis was useful, as it provided them with the time required for the parents' psychological preparation for making the best possible decisions related to birth planning (2). Prenatal diagnosis influenced the clinical prevalence of anterior abdominal wall ab-

normalities both by the therapeutic termination of problematic pregnancies and by better delivery and pre and postnatal conduct planning. Therefore, Forrester shows that 87% of the prenatally diagnosed omphalocele cases and 37% of the gastroschisis cases underwent at least one procedure during pregnancy, namely a fetal karyotype test (41%) or therapeutic abortion (59%) for omphalocele and successive ultrasound scans (59%) of *"in utero"* transportation to a specialized center (63%) for gastroschisis (19). Invasive antenatal diagnosis procedures are carried out in pregnancies with high risks of chromosomal aberrations detected by screening, as well as if the couples wish an absolute guarantee of a normal fetal karyotype, regardless of the aneuploidy risk calculated by screening.

Considered from the viewpoint of the rights of the parties involved, prenatal diagnosis is a legal must, caring a twofold meaning: recognition of the women's right to abortion and, on the other hand, recognition of the fetus' right to life and protection. The extraordinary development of medical techniques and devices that we have witnessed these last decades should serve the patient's best interests; more precisely, it should support the improvement of the patient's health and even save his/her life. As far as ultrasound scanning of a pregnant uterus is concerned, when severe fetal malformations are diagnosed, to the healthcare system the fetus becomes a new patient. This new patient will be subjected to repeated ultrasound scanning examinations, biochemical tests will be carried out on him/her (amniotic puncture, umbilical cord puncture) and he/she may even undergo surgical procedures (vesical-amniotic shunt for posterior urethra valve, ventriculo-amniotic shunt for hydrocephaly, trachea obstruction for congenital diaphragmatic hernia, silo-bag insertion for gastroschisis). However, when the malformations detected are varied and severe (unfortunately, though, sometimes even for isolated surgically rectifiable abnormalities (8)), their antenatal diagnosis could lead to abortion, i.e. virtually to killing the patient, in which case the breakthroughs of medical science and technology are a disservice to the patient.

Abortion for genetic reasons has been considered a discriminative action against disabled people for a long time, as numerous cultural and social factors are involved in the decision of termination of an abnormal pregnancy (20). Thus, during its General Conference of 1997, UNESCO forbade any form of discrimination based on genetic characteristics, whereas the Catholic and Orthodox Churches recommend that human life be respected and protected in an absolute manner since the very conception of the baby, and the products of conception diagnosed with various genetic abnormalities should be entitled to a social environment adapted to their human development (21). In any event, the choice made by the family about a pregnancy with impaired fetus should be respected and protected by the family, the laws in effect and the country's culture and social structures. The couple and not the doctors should decide the future of a pregnancy (autonomy principle) (20). Nevertheless, since the prenatal diagnosis is set and the associated conditions are revealed at increasingly lower gestational ages, which are even considered "legal" for elective termination of pregnancy, matters related to the definition of normal/abnormal fetuses or to the possibility of selection of the "ideal baby" have been tackled in literature lately. Therefore,

Gauderer, in a research conducted on 139 fetuses with congenital malformations (18 of whom had anterior abdominal wall defects or other gastro-intestinal anomalies), pointed out a fact which is difficult to reveal by statistical analysis and hard to accept from an ethical point of view, namely that too few couples decide to go on with a pregnancy with an "imperfect" fetus, as two pregnancies with surgically rectifiable anterior abdominal wall anomalies and with no other associated malformations were electively terminated, despite proper antenatal counseling (22). On the other hand, the pregnant woman's 'altruistic' position in relation to the health and wellbeing of the fetus is more often a problem in the obstetric practice (23). Almost every woman would go through a great deal and put up with discomfort, pain and even risks to their own health in order to protect the fetus, and that is why sometimes they would say no to therapeutic abortion even in the worst-case scenario (plurimalformative syndrome, chromosomal aberrations). Moreover, killing a human being who is not an aggressor is a terrible deed, which is legally and morally inacceptable in any community, regardless of its religion or social development status (24). The question is at what point during their human development from egg, embryo, fetus or newborn, be they malformed, human beings earn their right to live (divergent views were apparent in relation to if, or when the fetus might be regarded as a person, starting with the view that the fetus became a person from conception; some perceived the point of viability as crucial, or when the nervous system is ready to function). And does anyone have the right to suppress the future of a human being, who is either "perfect" or "imperfect", regardless of his/her embryo, fetus or malformed newborn status?

On the other hand, there is the principle of "respect for persons", which presumes recognizing the women's autonomy and capacity for decision-making and as full participants in the medical decisions of abortion. The principle of respect for autonomy requires that the views of those who are capable of deliberation about their personal goals be sought and respected. As the foetus lacks such capabilities, the question of foetal autonomy does not arise. Another leading concern of bioethics is justice, which requires a fair distribution of family planning methods, including access to safe abortion in cases of contraceptive failure (25, 26). Unfortunately, these problems do not have a certain answer and, although many countries have legalized abortion, the issue of active or passive neonatal euthanasia is still open to debate, as is the case for neonates with inborn anterior abdominal wall defects associated with chromosomal aberrations or other inborn malformations.

The debate may be extended to include the case of newborns suffering from multiple malformations, for which "postnatal abortion" may be considered (4, 5). If abortion (therapeutic or elective) is morally and legally accepted, does this implicitly mean that these newborns may be condemned? In Netherlands, according to the Groningen Protocol, active neonatal euthanasia would be morally acceptable in particular circumstances (27), but in other European countries it is illegal, yet sometimes tacitly accepted and practiced (28), and the exclusive assurance of life support and physical comfort to terminal patients or to very premature infants (below 22 weeks of gestation) is widely practiced (29, 30). Although the principle of nonmaleficence or "primum non nocere"

requires physicians to avoid harm, and withholding a beneficial treatment is likely to have the consequence of producing harm (passive euthanasia), no clear-cut legal support exists in all these cases. Nevertheless, from a moral point of view the feeling of compassion and the intent to put an end to the suffering of a newborn without real chances to a happy future are expected. This is requested either by the parents or by the attending physician, with or without a prior talk with the parents.

If no abnormalities and malformations are associated, over 90% of the babies with anterior abdominal wall defects will enjoy normal physical, mental and intellectual development, and will be perfectly integrated in society as adult, so they may be declared "cured and healed". Healing was associated with themes of wholeness, narrative, and spirituality and was defined in terms of developing a sense of personal wholeness that involves physical, mental, emotional, social and spiritual aspects of human experience. "If you become whole again," Kubler-Ross observed, "you're healed" (31). But if the neonate is plurimalformated, could anyone know and measure his suffering, how could anyone be certain that the case is truly terminal or that there may be a little hope of recovery and what would a happy future mean to a newborn suffering from multiple malformations? The principle of beneficence obligates people to try to bring about more beneficial consequences than harmful ones. Both the medical team and the parents have the obligation to consider and protect "the child's best interest", which involves all those actions that need to be taken for a better life: physical and emotional integrity, family, access to education and healthcare, social integrity. Philosophically and ethically speaking, promoting "the child's best interest" means doing one's best, using the resources available at a given moment, in order for the child "to feel good", to have a "good life" (32). In children, however, this calls for delicate action both from the medical team and from the parents, who ought to take into consideration the patient's state and life quality. From a strictly surgical viewpoint, we reckon that the life quality of a child suffering from multiple congenital malformations and chromosomal aberrations, who needs many surgical procedures and whose life expectancy is several years at the most (this is the case with children with trisomy 13 or 18 who, in addition to their anterior abdominal wall defects, may also suffer from porencephaly, hydrocephalus, myelomeningocele with double incontinence, cardiac malformations, limb anomalies, cleft lip and palate, internal organs malformations) is extremely poor. According to the definition of World Health Organization (WHO), health refers to physical, mental and social integrity and well-being, as well as the patients' ability to fulfill their regular tasks in their everyday life. Life quality is a subjective concept, as each patient experiences his or her own feelings; what is unconceivable for some may be acceptable to others, and the parent-child relationship is even more difficult to handle as it involves feelings of love, pity, responsibility, protection. More often than not, making medical decisions related to the care or treatment discontinuation of such children has an important psychological impact on the family members. Who is in a position to make the final decision, the parents or the medical team, considering that abuse and conflicts may arise from both sides? Both the parents' autonomy as regards the discontinuation of their child's medical treatment, and the responsibility of

the medical team when non-treatment is the only alternative to preserve the pediatric patient's best interest are matters that are insufficiently dwelt on and poorly regulated in our country's laws. As there is no clearly defined legislative framework regulating fetuses in our country, newborns suffering from multiple malformations and pediatric patients, the whole responsibility and ensuing emotion are transferred to their families, tutors and members of the medical team. The ethical principles, which the medical decision-making process relies on, more precisely the principle of patient autonomy respect, the doctor's duty not to act to the detriment of the patient and to promote the latter's best interest, a fair assignment of resources and non-discrimination, require adaptations and specification in pediatric medical practice (25, 26).

CONCLUSIONS

When parents have to face an antenatal diagnosis of congenital malformation, a multidisciplinary team should provide adequate counseling, considering both fetus evolution and prognosis, and the psychological effects of parents. The counseling should be done with honesty, compassion and integrity, with the observance of ethical principles such as autonomy, freedom of reproduction, beneficence and justice principle. Unfortunately, there are still many instances where principles, guidelines, rules or laws applied for the benefit of one part may restrain autonomy, beneficence and justice done to another. The latest developments in medical sciences and the implementation of the most advanced techniques of resuscitation and intensive care make it possible for newborns with severe congenital malformations to survive. Nevertheless, the use of this technology sometimes makes one wonder whether this is in the child's best interest, considering the poor life quality it provides.

NOVEL THERAPEUTIC OPTIONS FOR OLD DRUGS (Abstract): Introducing a new drug on the market requires a long time and costs. That is why discovery of new uses for existing drugs offers the advantage of delivering drugs already tested over time, this being for the benefit of the patients. This article aims to review some of the drugs whose initial use was different from the current one, analyzing their therapeutic course, from the discovery to the present. **Keywords**: OLD DRUGS, POTENTIAL USES, BENEFIT OF THE PATIENTS.

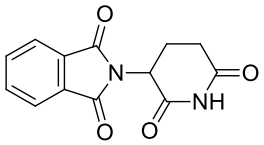
Since decades, the rational discovery of new medicines has depended on the modification of molecular structures. In recent years, there have been major changes in the identification and development of new drugs at the industrial level; it has been estimated that it takes about 15 years to bring a drug to the market and the pharmaceutical industry is investing tens of billions of dollars annually (1).

From the statistical data provided by pharmaceutical companies and research laboratories, it was found that from about 5,000 preclinical candidates, only five are clinically tested and only one will receive marketing approval. So, discovery of new uses of already existing drugs on the market, whose tests and side effects are well known, can be beneficial in the treatment of some of the diseases of the present century. Many examples can be quoted to prove its benefits. For example, aspirin, approved by the *Food and Drug Administration* (FDA) as a pain killer, was used to reduce the mortality rate among heart attack victims; the drug mitomycin, approved for the treatment of gastric and pancreatic cancers, has been found to be useful in the treatment of lung, bladder, breast and cervical cancers, as well as in certain forms of leukemia; trimethoprim, a drug approved to treat pneumonia, has been proved useful as an AIDS management (2).

The new uses of the old drugs therefore may provide cost-effective treatment, especially in developing countries with limited resources. In the present review, we are presenting the novel potential uses of drugs that are approved by FDA for important clinical conditions.

Thalidomide

Thalidomide is a glutamic acid derivative originally developed as a hypnotic in the 1950s and taken off the market because of its teratogenic effects (3).



2-(2,6-dioxopiperidin-3-yl)isoindoline-1,3-dione

Fig. 1. Thalidomide

Because thalidomide causes drowsiness, it has also been used as a sedative, being considered a safe and effective medicine that causes a deep sleep. It has begun to be quickly manufactured and sold around the world under various trade names; because of its effectiveness in improving morning sickness, it has become extremely consumed among pregnant women. Between 1957 and 1960 there was an unusually high increase in babies born in Germany, Australia and the UK with severe deformities of limbs and internal organs, an increase that initially produced confusion and anxiety among doctors and researchers. In 1961 a German doctor, Widukind Lenz, and an independent doctor in Australia, William McBride, expressed suspicion that the terrible malformations were related to the ingestion of thalidomide by mothers during pregnancy. Thus, at the end of 1961, Lenz suggested a possible connection between the occurrence of these congenital anomalies and the use of thalidomide during pregnancy (4). The substance not only caused limb deformities but also affected other organs such as ears, eyes, heart, kidneys, nerves, genital organs and other internal organs.

Because of these observations thalidomide was quickly retired from the market in Germany and England, and later in several other countries. Until August 1962, a significant decrease in the births of children with limb malformations was reported, but at least 10,000 affected children were already born worldwide (5).

New therapeutic uses of thalidomide

Thalidomide and its derivatives are known as immunomodulating agents, known for their sedative, teratogenic, antiangiogenic and anti-inflammatory properties (6). They are commonly used in the treatment of various types of cancer, such as multiple myeloma or myelodysplastic syndrome (MDS), but also in the treatment of inflammatory skin pathologies associated with leprosy or Hansen's disease (7).

The anti-inflammatory and immunomodulatory effect of thalidomide

Thalidomide has been reintroduced in therapy as an anti-inflammatory agent, with remarkable efficacy in the treatment of erythema nodosum leprosum (ENL) and subsequently in the treatment of multiple myeloma (7). ENL is an inflammatory and debilitating complication of leprous, infectious disease caused by *Mycobacterium leprae*. The anti-inflammatory action of thalidomide is explained by the mechanism discovered by Sampaio *et al.* (8) and by Moreira *et al.* (9). They argue that by inhibiting TNF-α production in monocytes and macrophages, the inflammatory response is regulated by inducing the production of a wide range of cytokines, such as interleukins and interferon-d, in response to injuries.

As for the immunomodulatory effect thalidomide revealed some of its effects on the immune system. In 1984, Barnhill *et al.* (10) showed that thalidomide is an inhibitor of phagocytosis in polymorphonuclear leukocyte cultures and a chemotaxis inhibitor in cultured monocytes. They suggested that these results help explain the anti-inflammatory properties of thalidomide.

Anti-proliferative effects of thalidomide

Both thalidomide and its structural derivatives can reduce the proliferation of cancer cells that have developed resistance to standard chemotherapy, being successfully used in both the United States and Europe for the treatment of multiple myeloma and other cancers; their use are prolonging patients' lives. Anti-tumoral effects of thalidomide have been attributed to the increased degradation of mRNA for both FGF and VEGF and a decrease of adhesion receptors (11). Myeloma cells are affected both by its

antiangiogenic action and by the ability of thalidomide to enhance the immunomodulatory response.

Antiangiogenic action of thalidomide

In 1994, D'Amaro *et al.* (12) has been discovered another property of thalidomide: it has been found to be a potent inhibitor of angiogenesis (formation of new blood vessels) on a rabbit cornea model. They have suggested its use in diseases where this effect may be desirable, diseases such as diabetic neuropathy, macular degeneration, or in solid tumors. Other researchers have suggested the use of thalidomide in serious cases of infantile hemangiomas (13).

Uses of thalidomide in dermatology

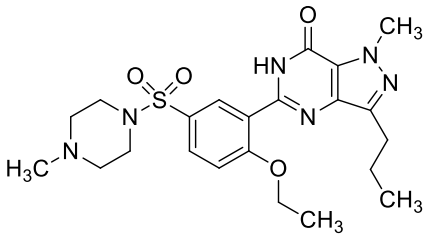
Thalidomide is an effective second-line treatment against foot-and-mouth stomatitis and is the only one that has shown a certain consistency in efficiency (despite the more suppressive than curative effect.) However, the use of thalidomide is limited by adverse effects, which are often dose dependent. Although the efficacy of thalidomide on recurrent stomatitis is recognized, the literature has less or no information on the efficacy, tolerance, safety and long-term use posology in current practice. Many patients achieve complete long-term remission with a low maintenance dose and high tolerance (14).

Similar results were also obtained when thalidomide was used in Behcet's treatment. Behcet's syndrome is an inflammatory autoimmune disease characterized by a systemic vasculitis whose main symptoms are oral and genital ulceration and eye, joint, blood vessel and central nervous system injuries.

Another use of thalidomide is in the treatment of prurigo nodularis, a disorder characterized by extremely pruritic nodules, mainly located at the extremities of the body (13). Most of the therapies were unsatisfactory, but thalidomide administration in doses ranging from 100-300 mg/day was found to be quite useful in these patients.

Sildenafil

Sildenafil was introduced into the pharmaceutical market in 1998 as sildenafil citrate in the VIAGRA™ pharmaceutical product. This is a highly selective inhibitor of the phosphodiesterase (PDE5) enzyme, widely used as a treatment for erectile dysfunction (15).



5-(2-ethoxy-5-((4-methylpiperazin-1-yl)sulfonyl)phenyl)-1-methyl-3-propyl-1*H*-pyrazolo[4,3-*d*]pyrimidin-7(6*H*)-one

Fig. 2. Sildenafil

Although initially sildenafil was used in the treatment of angina pectoris and more erectile dysfunction, today the compound appears to have therapeutic effect in disorders of the respiratory system and central nervous system. On the central nervous system, it can have neuroprotective effects in multiple sclerosis as well as significant

memory enhancement effects (16).

Sildenafil and pulmonary arterial hypertension

Pulmonary arterial hypertension is defined as a group of diseases characterized by a progressive increase in pulmonary vascular resistance, leading to right ventricular failure and premature death (17). Pathobiological mechanism of the disease includes pulmonary endothelial dysfunction, which leads to impaired production of vasodilators, such as nitric oxide and prostacyclin, and overexpression of vasoconstrictors, such as endothelin-1 (18).

Alkhayat *et al.* (19) investigated in a study the efficacy and tolerability of sildenafil 20 mg given orally three times daily in patients with secondary pulmonary arterial hypertension. In this placebo-controlled trial, sildenafil significantly improved exercise capacity, as assessed according to the six-minute walking test, in patients with pulmonary arterial hypertension. Their findings show that there is a symptomatic benefit associated with the inhibition of phosphodiesterase type 5 in patients with pulmonary arterial hypertension improvement in exercise capacity with sildenafil treatment, regardless of demographic or disease characteristics or other baseline variables. Sildenafil also significantly improved cardiopulmonary hemodynamics. In conclusion, this study demonstrates the efficacy and safety of sildenafil in the treatment of patients with symptomatic pulmonary arterial hypertension secondary to COPD (19).

The use of sildenafil in systemic sclerosis

Systemic sclerosis (SSc) is a connective tissue disease that is characterized by inflammation, vasculopathy and fibrosis (20). Tissue fibrosis directly contributes to increased mortality and decreased quality of life (21). However, an effective therapy for tissue fibrosis has not been established.

Higuchi *et al.* demonstrated the antifibrotic effects of sildenafil on cultured SSc fibroblasts. Sildenafil is a PDE5 inhibitor and a standard therapeutic agent for pulmonary arterial hypertension due to its strong vasodilatation effects (22).

Recently, it has been demonstrated that an increase in intracellular GMPc level can improve fibrosis levels in various diseases. Thus, in a recent study, the phosphodiesterase inhibitor, sildenafil increased the intracellular GMPc level in cutaneous fibroblasts in a dose-dependent manner and also significantly decreased the expression of profibrotic factors such as TGF-β1, whose level shown to be increased in skin fibroblasts of systemic sclerosis (22).

Therefore, various PDE5 inhibitors such as sildenafil and tadalafil have been investigated and developed, demonstrating excellent results in the treatment of systemic sclerosis and digital ulcers (22). These results suggest that PDE5 inhibitors may have notable effects on vasculopathy and systemic sclerosis associated fibrosis, and sildenafil may be considered a promising treatment for fibrotic disorders such as systemic sclerosis.

Sildenafil in the prevention of fetal cardiovascular dysfunctions

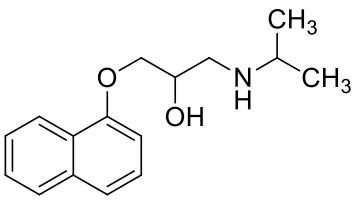
Frequent complications occurring during pregnancy, complications such as fetal hypoxia, may trigger various cardiovascular dysfunctions during uterine life, and may also lead to the appearance of extrauterine cardiovascular disease. Using the chicken embryo model, Itani *et al.* (23) demonstrated in 2017 that sildenafil treatment directly protects the fetal cardiovascular system during hypoxia, its protective mechanisms including reducing oxidative stress and increasing the availability of nitric oxide.

The effects of sildenafil have been ana-

lyzed on the fetal cardiovascular system of chicken embryos, as this is the only established animal model on which direct effects on the heart and fetal circulation can be studied, independently of the effects on the mother and / or placenta (23). Therefore, the data obtained from this study demonstrated that sildenafil can have direct benefits on the fetal cardiovascular system in case of hypoxia during intrauterine life, thus proving to be a good antioxidant that can prevent cardiovascular dysfunction of fetal origin.

Propranolol

Propranolol is a non-selective beta-adrenergic antagonist used in the treatment of hypertension, angina pectoris, anxiety, cardiac arrhythmia, essential tremor and also prophylactic against migraine, varicose vein and myocardial infarction (24).



1-(isopropylamino)-3-(naphthalen-1-yloxy)propan-2-ol

Fig. 3. Propranolol

In addition, data from clinical trials suggesting the use of propranolol in several diseases such as hemorrhages, septicemia, hypermetabolic syndrome associated with severe burns (25), Alzheimer's disease-associated acne or psychosis (26) and aggression associated with lesions or cerebral diseases (27).

The antimigraine action of propranolol

Propranolol has been prescribed for migraine prophylaxis since 1966, when Rabkin *et al.* (23) have occasionally discovered their effectiveness in migraine headache in patients who were treated for angina pectoris. There are several research reports illustrating the effect of propranolol as a β-adrenergic blocker on the expansion of cortical depression, demonstrating that treatment with it blocked CSD in rats suffering from ischemic stroke without altering regional brain flow. Ayata *et al.* in 2006 demonstrated that chronic administration of several drugs, including propranolol, inhibited the generation of CSD (cortical depression) (28).

The antitumor effects of propranolol

The use of β-blockers in the cancerous process has been extensively studied in breast cancer, prostate, ovarian, melanoma, and colon cancer. Beta-blockers have been shown to reduce metastatic recurrence and reduce mortality in most studies, although there were, of course, studies in which the results were irrelevant (29).

Propranolol is a non-specific β-adrenergic antagonist, well-known and widely used, with a range of actions of interest in the oncology context. Propranolol has shown effects on cell proliferation and invasion, on the immune system, on the angiogenic cascade, and on the sensitivity of tumor cells to existing treatments. Furthermore, there is evidence that it acts at several points in the metastatic cascade, especially

in the context of the postoperative wound response (30).

Use of propranolol in the treatment of burns

Burns are traumatic tissue injuries, accompanied by systemic nervous, vascular, metabolic and humoral reactions, heat, chemical or microbial lesions. Burns are among the worst forms of injuries, ranked fourth among the causes of injuries after car accidents, falls and violence, with about 90% of cases occurring in middle-income countries (31).

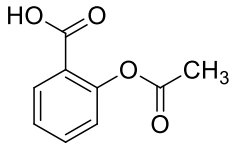
Recent studies have reported that the administration of propranolol to children with severe lesions for one year significantly improved energy consumption at rest as well as cardiac function. Attenuation of cardiac sequelae occurred at dose level, with the most favorable results being observed at a dose of 4 mg/kg body weight/day. Peripherally, propranolol has been shown to decrease the blood flow of the lower limbs by increasing vascular resistance in adults with severe burns. The induction of peripheral vasoconstriction by propranolol has led to the successful implementation of β-blocker in the management of infantile hemangiomas, varicose bleeding and recurrent epistaxis (31).

Propranolol administration at a dose that reduces heart rate by an average of 20% in adult patients with burns to a body surface area of ≥ 30% of the total area has been shown to diminish blood loss during skin grafting procedures and improved the lesion healing rate on average by one week. This is a tremendous therapeutic benefit, as patients with burns require many special surgical interventions, where limitation of blood loss is more than necessary (32).

Recent studies have shown the efficacy of propranolol in *hyperthyroidism*. The level of thyroid hormones in the circulation is increased in hyperthyroidism and this can lead to tachycardia, palpitations, tremors, and anxiety. So, propranolol has been widely used to treat these beta-adrenoreceptor effects (33).

Acetylsalicylic acid

Acetylsalicylic acid, which has been used for over a century as an analgesic, is used in the last several years for its antiplatelet activity in cardiovascular disease (34).



2-acetoxybenzoic acid

Fig. 4. Acetylsalicylic acid

In 1853, salicylic acid was synthesized in its pure form by a French pharmacist Henri Leroux and an Italian chemist Raffaele Piria, and it was observed that this substance produced gastrointestinal irritation; these problems were solved by replacing a hydroxyl group of salicylic acid with an acetyl group (35).

In 1897, a German chemist Felix Hoffman developed and patented an acetylsalicylic acid synthesis process, patented under the name Aspirin™ on February 27, 1900, which is also the time when the name "aspirin" was born (35).

Currently, aspirin or acetylsalicylic acid is one of the most commonly used drugs worldwide, producing around 40,000 tonnes per year. In addition to the well-known analgesic, antipyretic and anti-inflammatory effects, aspirin are used in the secondary prevention of cardiovascular events, where benefits are clearly demonstrated, but also in primary prevention, where studies continue to evaluate benefit-risk ratio (36).

Aspirin in the primary prevention of cardiovascular events

Cardiovascular diseases represented by ischemic heart disease and stroke (AVC) are the leading causes of mortality in the world, according to the World Health Organization (37). Acetylsalicylic acid at a low dose of 75-100 mg inhibits irreversibly acetylation, cyclooxygenase (COX), thus blocking the production of thromboxane (TXA2) and inhibiting platelet aggregation. Thus, aspirin is the most widely used drug in the prevention of cardiovascular disease, proving its effectiveness in the secondary prevention of vascular atherothrombotic disorders (non-fatal myocardial infarction, non-fatal stroke) in patients with known cardiovascular disease (38).

The role of aspirin in the prevention of preeclampsia

Preeclampsia is defined as the presence of excess hypertension and protein in the urine after the 20th week of pregnancy in a woman who previously had a normal blood pressure. Untreated, the disease can lead to serious complications for the mother and the fetus, sometimes even to death (39).

Meta-analyzes of different randomized clinical trials have suggested that lower-dose aspirin before or at 16th week of pregnancy is associated with a significant reduction in the risk of preeclampsia.

Based on the studies studied, early administration of aspirin (≤ 16 weeks) was associated with significant reductions in preeclampsia, while its administration at 16 weeks later had no significant effect on preeclampsia or fetal growth restriction (39). In conclusion, low doses of aspirin (50-150 mg/day) may be a promising prophylactic treatment for pregnant women at high risk of preeclampsia or other placental disorders when given early.

The role of aspirin in chemoprevention

One of the most extraordinary new perspectives for the use of aspirin in therapy is in preventing cancer. In 1971 was made the first study showing the existence of a relationship between aspirin and chemoprevention, but over the last two decades many publications have suggested that aspirin can substantially reduce the risk of a person to develop cancer and in the same time can have a beneficial effect on its survival (40).

Rothwell *et al.* published in 2010 a 20-year follow-up of a study supporting the role of a low dose of aspirin in reducing the incidence and mortality of colorectal cancer, with the greatest benefit being shown in the case of proximal cancers. Thus, administration of aspirin to the subjects for 5 years or longer has reduced the risk of colorectal cancer on the right side by 70% and also the associated risk of rectal cancer. According to the published information, there was no benefit increase for doses greater than 75 mg per day (41).

In 2015, Cuzick *et al.* (40) indicated that the effects of aspirin on the prevention of colorectal cancer are beginning to be observed about 3 years after the start of use, and the low doses between 75 and 325 mg/day appear to be most effective, the toxicity increasing with the increasing of the dose. Therefore, the use of aspirin is still associated with hemorrhagic events, both cardiovascular and gastrointestinal, when increasing doses are administered over a prolonged period (42).

Therefore, aspirin, one of the most long-acting therapeutic agents, manages to remain constantly in the news by the variety of actions and benefits it demonstrates. The use of cardiovascular events in secondary prevention is well established, and its effectiveness in the medium-risk population will continue to be investigated, also considering the increased risks of gastrointestinal and hemorrhagic side effects. At the same time, there is increasing evidence for the benefits of using low-dose aspirin in reducing the risk of can-

cer, especially colorectal cancer, benefits highlighted in many studies about 5 years after administration (43).

CONCLUSIONS

Both for the substances presented in the present paper and for many other drugs whose therapeutically value can be revalued, time is the most important factor that will prove their evolution in therapy.

The rediscovery of an old drug is a challenge the old therapeutic agents can become valuable targets in research and development of new drug therapies.

THE REASONS FOR CHOOSING THE PROFESSION OF DENTIST AMONG THE STUDENTS OF THE FACULTY OF DENTAL MEDICINE-IASI, ROMANIA (Abstract): The profession of dentist, as any other medical profession, is a challenging one. **Aim**: To determine the reasons and factors that are influencing the choice of Dental Medicine as profession among the students of the Faculty of Dental Medicine from "Grigore T. Popa" University of Medicine and Pharmacy Iasi, Romania. **Materials and methods:** The data were collected through redesigned questionnaire containing 33 questions. Career aspirations questionnaire were distributed among dental students of the 2nd year and 3rd year, Faculty of Dental Medicine Iasi. The collected data were analyzed using the *SPSS 20.0* software. For the age variable, were determined the average, median, and standard deviation. The Pearson chi-square correlation test was used in order to evaluate the correlations of the results. The confidentiality threshold was set at 5%. **Results:** Most of the participants consider that dental careers offer a stable job (82.5%), this profession is better paid (80%) and offers a better status (85%). Rural subjects are more insecure as regards their future career in dentistry than those from the urban areas (35.7%). Male subjects are more uncertain about their future in the field of dental medicine in comparison with female. The influence of the environment, especially of the entourage, represented an important factor in choosing a profession, along with the family (the parents). **Conclusions:** The reasons for choosing the profession of dentist differ from one person to another and are influenced by the educational background, socio-economic status and cultural history. **Keywords**: DENTAL STUDENTS, DENTAL SCHOOL, CAREER CHOICE.

Investigating the point of views and perspectives of medical students contributes to a better understanding of the way in which academic studies are coordinated, how they plan their career, how they shape interpersonal relationships, and how they shape their role in society. In a broader sense, such investigations can be useful for planning and evaluating the educational process by influencing curricula, the learning process and the profile of future professionals.

Students' motivation in choosing careers in the medical field is of particular importance to professors and admissions committees (1). Studies conducted so far in many countries have "examined" the reasons for why the people are choosing the profession of dentist (2-4). At some point,

dentistry was a predominantly a male occupation, but women gained ground over time (5). External social factors determine students to shape their future dentist career based on models to which they can identify and confirm professionally (3).

The profession of dentist, as any other medical profession, is a challenging one, is a profession which requires the pursuit of the principles of bioethics. Therefore, the dental treatment in its complexity (orthodontic, pedodontics, prosthetic, endodontic, etc.) must follow the ethical and bioethical principles, as "*Bioethics brings hope of respect and permanent revival of human values, of spiritual revival of man as a unique being*" (6).

The reasons for choosing the dental profession, as well as the requirements and selection processes, vary from one country to another or even within the same country (2-4). Several studies have been conducted on the socio-economic profile, career choices and professional profiles of dental students. In general, the results indicate that career choice is motivated by vocation and status, most students focusing on technical issues and professional status rather than on their role in society (7, 8).

Understanding the reasons for choosing this profession is important because this decision involves setting future goals that may affect career choices. While some individuals choose knowledgeable professions with realistic goals, others can choose a profession not knowing in which direction they are heading. Some make career choices by choosing the most convenient path, such as choosing the profession that one or both parents practice. The aim of the study was to determine the reasons and factors that are influencing the choice of Dental Medicine as profession among the 2nd and 3rd year students of the Faculty of Dental Medicine from "Grigore T. Popa" University of Medicine and Pharmacy Iasi, Romania.

MATERIALS AND METHODS

The data were collected through redesigned questionnaire containing 33 questions related to subjects' age, sex, background and reasons for choosing the profession of dentist, what influenced the choice of this profession, and questions about the expectations in the relation with the future profession.

Career aspirations questionnaire were distributed among dental students of the 2nd year and 3rd year, Faculty of Dental Medicine, "Grigore T. Popa" University of Medicine and Pharmacy Iasi, Romania. Approval of the questionnaire and research methodology was received from the college ethics board. A pilot survey was conducted (n=20) where the validity and reliability of the questionnaire was ascertained.

The collected data was analyzed using the *SPSS version 20.0* software. For analyzing the data collected, distributions and percentages were determined. Average, median, and standard deviation were determined for the age variable. In order to evaluate the correlations of the results was applied the *Pearson X-square* correlation test. The test was considered to have a statistical significance for a p value < 0.05. The confidentiality threshold was set at 5%.

RESULTS

The study group consisted of 394 students (167 female and 127 male) (tab. I), 214 students being enrolled in the second year of studies and 180 students in the third year at the Faculty of Dental Medicine,

"Grigore T. Popa" University of Medicine and Pharmacy. The distribution of subjects by the residence was as follows: 89% of the subjects were from urban area and 11% of the subjects from rural area (tab. I).

The average age in the study sample was 22.32 years (minimum 20 years, maximum 42 years) (fig. 1).

TABLE I.

Demographic characteristics in the study sample

Characteristics	2nd year		3rd year	
	N	%	N	%
Students	214	54%	180	46%
Sex				
• Female	124	57.9%	115	63.9%
• Male	90	42.1%	65	36.1%
Residence				
• Urban	194	90.7%	158	87.8%
• Rural	20	9.3%	22	12.2%
Family socio-economic status				
• High level	159	74.3%	136	75.6%
• Medium level	49	22.9%	42	23.3%
• Low level	6	2.8%	2	1.1%

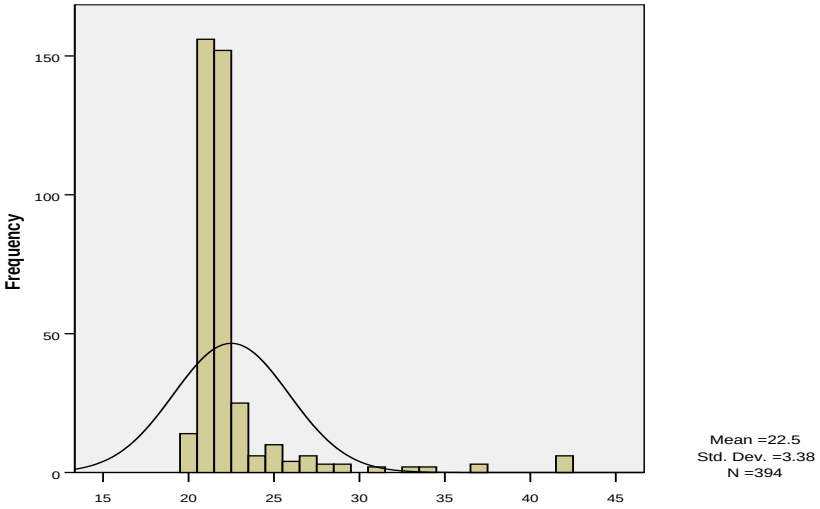

Fig. 1. Participants average age.

To the question "*Is it easy for a dentist to find a job*?" 38% of the students responded negatively, 37% positively and 25% "*do not know*". The distribution of answers to this question according to the residence had a higher value for the urban subjects who responded positively in a proportion of 38.4%. Rural subjects are more insecure as regards their future career in dentistry than those in urban areas (35.7%). Male subjects are more uncertain about their future in this area, as 32.3% of them responded "*do not know*" and 46.4% of female subjects' responded negatively (tab. II).

TABLE II

Repartition of the answers to the questionnaire

		Sex			*Residence*		
		Male	*Female*	*p*	*Urban*	*Rural*	*p*
It is easy for a dentist to find a job ?	Yes	43.9%	34.3%	.000	38.4%	35.7%	.168
	No	23.9%	46.4%		38.6%	28.6%	
	Don't know	32.3%	19.2%		23.0%	35.7%	
I would like to make more money	Yes	74.2%	81.6%	.213	80.1%	66.7%	.006
	No	17.4%	12.1%		14.2%	14.3%	
	Don't know	8.4%	6.3%		5.7%	19.0%	
Careers in dentistry offers a stable job	Yes	85.8%	87.9%	.652	86.6%	90.5%	.699
	No	4.5%	5.0%		4.8%	4.8%	
	Don't know	9.7%	7.1%		8.5%	4.8%	
Dentistry is better paid than other professions	Yes	85.2%	83.3%	.675	83.2%	90.5%	.101
	No	7.7%	7.1%		7.1%	9.5%	
	Don't know	7.1%	9.6%		9.7%	0.0%	
Dentistry provides a high professional status	Yes	85.2%	89.1%	.087	87.2%	90.5%	.827
	No	9.0%	3.8%		6.0%	4.8%	
	Don't know	5.8%	7.1%		6.8%	4.8%	
I can work in several specializations of dentistry without having that specialization	Yes	36.8%	40.2%	.041	39.2%	35.7%	.574
	No	43.9%	32.2%		37.2%	33.3%	
	Don't know	19.4%	27.6%		23.6%	31.0%	
I can make my own schedule	Yes	87.7%	79.5%	.047	82.4%	85.7%	.109
	No	10.3%	13.8%		13.4%	4.8%	
	Don't know	1.9%	6.7%		4.3%	9.5%	
I like the idea of being my own employer	Yes	87.7%	91.6%	.449	89.5%	95.2%	.434
	No	9.7%	6.7%		8.2%	4.8%	
	Don't know	2.6%	1.7%		0.3%	0.0%	
Dentistry is an exciting and challenging career	Yes	89.0%	94.1%	.008	93.2%	83.3%	.052
	No	7.1%	5.9%		5.7%	11.9%	
	Don't know	3.9%	0.0%		1.1%	4.8%	
I like to interact with other people	Yes	96.8%	97.5%	.199	97.4%	95.2%	.000
	No	1.3%	0.0%		0.0%	4.8%	
	Don't know	1.9%	2.5%		2.6%	0.0%	
I like helping people	Yes	96.8%	97.9%	.211	97.2%	100.0%	.542
	No	1.3%	0.0%		0.6%	0.0%	
	Don't know	1.9%	2.1%		2.3%	0.0%	
I like to work manually	Yes	91.0%	91.0%	.022	87.8%	85.7%	.319
	No	7.7%	7.7%		7.7%	4.8%	
	Don't know	1.3%	1.3%		4.5%	9.5%	

Statistical analysis revealed that female subjects chose this professional career to earn money in a bigger proportion (81.6%) than the male subjects (74.2%), those from the urban area being more motivated by this statement than those from rural ones (80.1% *vs.* 66.7%). The majority of the participants considered that the dental careers offer a stable job, this profession being better paid and offering a better social status.

Since the residency exam is not an obligation in Romania, we can consider this statement as one of the reasons for choosing Dentistry at the expense of General Medicine. The difference between positive and negative responses at the question concerning the fact that dentists can work in several specializations of Dental Medicine without having a specific specialization was small (39.2% and 35.7% respectively), urban subjects responding positively in a bigger proportion than those from the rural areas, with more female subjects (tab. II).

Other reasons underlying the choosing of this profession among the dental school students was the possibility "*to make their own schedule*" (84%) (male subjects (87.7%) and the one from rural area (85.7%) responded predominantly positive at this question) and "*to be their own employer*" (88%) (predominantly female subjects (91.6%)). From all the questioned subjects, 90% considered that being a dentist represents as an exciting and challenging career. Other reasons that may influence the choice of the dentist profession were represented by the desire to work with people (to interact with other people) (96%), to help people (97.5%) and to work manually (86.0%) (tab. II).

The influence of the environment, especially of the entourage, represented an important factor in choosing a profession. To this assertion, about 40% of the study sample subjects responded affirmatively, more being male subjects (39.37%) and from the urban area (38.06%). Over 55% of respondents answered this question negatively.

Another important factor in choosing the profession was represented by the family and especially by the influence of the parents. At the question concerning the family and friends encouragement to be a dentist, the subjects responded 69.7% affirmatively, mostly being male subjects (74.8%) from the rural area (74.1%). To a lesser extent, subjects were influenced by their own dentist (32.73%), these categories of students being in majority male subjects (44.5%) and from rural areas (40.5%) (tab. III).

The affirmation *"I have been studying / working in the past in a field related to dentistry*" is suited more to the older subjects who attend dental medicine as a second faculty, previously working as dental assistants or dental technicians. Thus, 30.3% of respondents to this assertion were males from the urban area (22.7%).

The analysis of the results showed a reduced influence from the parents, the mother being more influential than the father (18.3% and 16% respectively), the relatives (11.4%) or other persons from the entourage (the school professors 4.8%, the dentist 9.1%, the family dentist 9.4%). 66.8% of the subjects responded that they have chosen this profession for their own reasons (fig. 2).

"*What influenced the choice of this profession*?". Figure 3 highlights the future career options: 54.35% of the participants want to become specialists after finishing the faculty while 30.9% are satisfied with the status of dentist.

TABLE III

Factors that have influenced the choice of the dental profession

		Sex			*Residence*		
		Male	*Female*	*p*	*Urban*	*Rural*	*p*
I've heard about dentistry in high school	Yes	43.9%	41.8%	.002	44.6%	26.2%	.073
	No	49.0%	57.3%		52.3%	69.0%	
	Don't know	7.10%	0.80%		3.10%	4.80%	
Family and friends encouraged me to be a dentist	Yes	74.8%	69.5%	.084	74.1%	50.0%	.003
	No	23.9%	30.5%		25.3%	50.0%	
	Don't know	1.30%	0.00%		0.60%	0.00%	
The family dentist encouraged me to choose this career	Yes	44.5%	27.6%	.002	33.5%	40.5%	.470
	No	54.2%	70.3%		64.5%	59.5%	
	Don't know	1.30%	2.10%		2.00%	0.0%	
I have been studying / working in the past in a field related to dentistry	Yes	30.3%	17.6%	.011	22.7%	21.4%	.821
	No	67.1%	81.2%		75.3%	78.6%	
	Don't know	1.90%	1.30%		1.70%	0.00%	

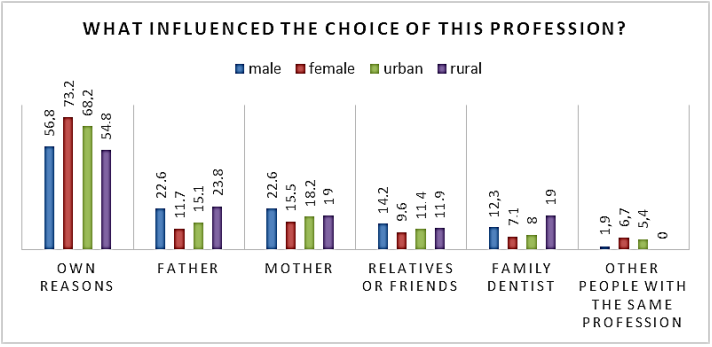

Fig. 2. Distribution of responses to the statement

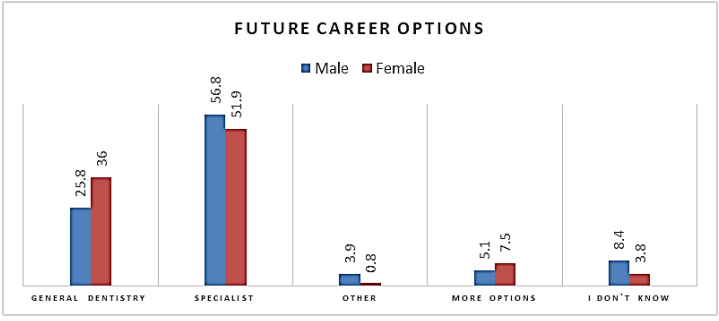

Fig. 3. Distribution of responses to the statement *"Future career options".*

Given the fact that students are at the begging of their studies in the area of dentistry being in the first years of college, it is expected that most of them to be undecided (39.3%) with regard to the specializations they will choose. However,

among the chosen answers, we can see that the options are directed towards orthodontics (21.8%), oral surgery (20.1%) and even specialist/researcher, with most of the responses in female subjects from the urban area (fig. 4).

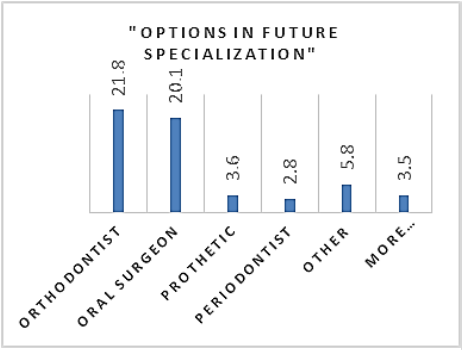

Fig. 4. Distribution of the responses to the question "*Options in future specialization"*

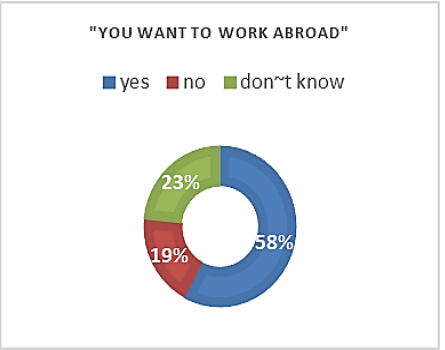

Fig. 5. Distribution of responses to the question "*You want to work abroad ?"*

Regarding the option to work abroad, in other country than Romania, more than half of the subjects (58%) responded affirmatively, followed by those who are undecided (23%). The main reason the participants want to leave the country is the financial one and the uncertainty of finding a job for young graduates (fig. 5). The highest frequency of affirmative responses was recorded in female subjects (65.91%) from the urban area (61.07%).

DISCUSSION

Career choice is a critical decision that can affect the progress of the young, so it is important to understand what motivates young people to pursue their careers, but also what they want to do after completing medical studies (9, 10).

Dentistry, among other professions, remains one of the most sought-after professions among young graduates, with dentists having an important position in society as health insurers. Nowadays, health promotion represents a global problem that requires as a must, much attention from both the health professionals and the public. Over centuries, health promotion has been regarded as an effective strategy to improve the nation's health and to attain a high level of well-being for the individuals (11). Therefore, the young people choose dentistry as their future career having in their mind that the oral health promotion will decrease the disease, and in the same time will enhance the well-being of a person/community.

The factors that can influence the choice of this profession may vary from socio-economic to emotional factors (being motivated by own dental experiences) (12, 13). The choice and the way the individual engages in the profession are influenced by economic and social factors. Various studies among students showed that financial stability and social status are the most relevant factors influencing the choice of this profession (14-16). The results of this

study indicate that choosing the profession of dental practitioner is mainly influenced by the socio-economic factor by having a stable job and a consistent financial gain. These results are supported by studies conducted so far, where job stability was the main factor influencing choice, followed by the "regular working hours", the fact that this profession is recognized as important and also because "they like to work with people"(17). In female subjects, the percentage was higher in the perception that "they can run a business" compared to male subjects, the same ratio being kept when referring to "the desire to work with people".

In our study, thee desire to work with people was the second motivating factor in choosing this profession. This situation was also found in other studies as a primary or secondary factor in choosing the profession of dentist (17, 18). Our findings on the reasons for choosing a physician profession are supported by the results of studies in other countries (19). Students generally choose this career because they perceive dentistry as a challenging profession.

Unlike other studies in America and Sweden showing parental influence in choosing the profession, in our study the subjects chose this path for "own reasons", with parental influence being reduced (about 14%). Increased influence is found in families where one or both parents are dentists (1, 19).

Other important elements in the future professional evolution of dental students are represented by the desire to pursue postgraduate studies after completion of house job and the possibility to work abroad. The results of the present study shows that 53.5% of the graduates wanted to pursue postgraduate studies following medical studies. The results are much lower compared to other studies conducted therefore it is important to increase the effort needs to be made to encourage graduates to pursue this field (20, 21).

CONCLUSIONS

The reasons for choosing this profession differ from one person to another and are influenced by the background, socio-economic and cultural history. The financial factor is one influencing the choice of this profession. It is important to increase the efforts needs to be made to encourage graduates to pursue postgraduate studies.

NEW ORIGINAL *IN VITRO* METHOD TO ASSESS CHOLINESTERASE REACTIVITY IN ORGANOPHOSPHATE POISONING (Abstract) : Assessment of organophosphate poisoning could benefit from a safe, non-expensive, easy to perform, quick (< 1 hour) test, which evaluates the level of cholinesterase activity "in vitro" regarding to the capability of oximes to reactivate OF-blocked cholinesterase. In the proposed protocol, 0.5 mL of sample serum is incubated, prior to the evaluation of level of cholinesterase activity, with 5 μL of a Toxogonin® dilution (0.125 mg) for 30 minutes at 37°C. For the standardization of the newly proposed protocol, several important issues were documented in the present article. The new original method of assessing cholinesterase reactivability will consist in an advantage for the diagnosis, prognostic evaluation and therapeutic orientation in OF intoxication. **Key words** : ORGANOPHOSPHATE, CHOLINESTERASE, TOXOGONIN

Organophosphate (OF) poisoning continues to represent an important medical issue through its high prevalence and severity among toxic pathology. Despite the existence of efficient antidotes, the prognosis of this intoxication remains reserved.

Diagnosis in OF poisoning is based on the assessment of plasma cholinesterase (ChEs) activity, this being the most constantly affected enzyme in OF poisoning (1,2). A method limitation results from a very wide interval of normal values for ChEs activity. Due to this, in medical practice, a relatively low value may represent the normal, while a so-called normal value may be detected when inhibition of ChEs activity is present (3,4,5,6).

Reversibility of cholinesterase inhibition after Toxogonin® (Tox) administration characterizes, with few exceptions, OF poisoning. The reactivation through Tox consist in the release of ChEs from the complex with OF, with the consequent regain of its enzymatic capabilities on choline compounds, expressed by an increase in the ChEs level of activity towards normal values. Thus, in case of suspected OF poisoning, evaluation of reactivability of ChEs activity levels will add important new perspectives for the diagnosis, compared with only the simple detection of the plasma ChEs activity.

In a specific "in vitro" protocol of testing, adding Tox to the serum sample will generate a recovery of the ChEs activity only in circumstances of acute OF poisoning. ChEs activity will not be significantly influenced if there is no previous blockage

of ChEs by OF. Tox-sensibilization method is based on the reactivatory effect of Tox, which increases the level of ChEs activity when the enzyme is blocked by OF. This effect is possible only in the initial period after intoxication (generally the first 48-72 hours). Then, the enzyme becomes irreversibly blocked by OF, called "ageing process" (a dezalkylation of the complex ChEs–OF). During this interval, obidoximes are efficient in recovering ChEs from their complexes with OF. This period can be longer, if the absorption still continues (i.e. additional ignored sites where absorption of poison persist, such as head hear, fat tissue, enteroenteric circuits etc.), or shorter (depending on the type of OF involved, different ways the poisoning was produced etc.) (7,8,9).

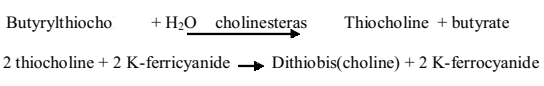
Another advantage of this test is the possibility to assess if the enzyme is still responsive to Tox, and sustains the continuation of Tox treatment, an expensive and even harmful treatment if the ChEs complex is „aged" (instead of unbinding the OF from the enzyme by linking with it, Tox will bind the enzyme, decreasing even more its level of activity) (10).

The aim of this study is to propose and standardize an original laboratory test, helpful for diagnosis with high sensitivity the OF poisoning, allowing a more orientated therapeutic approach.

MATERIAL AND METHOD

Serum samples from 23 consecutive patients, admitted in "Sf.Ioan" Emergency Clinic Hospital of Iasi, during 2009-2010, were used in the study. Inclusion criterion was the diagnosis of acute OF poisoning. Exclusion criteria were: age less than 18 years, mixed poisonings, refuse of patient or patient's family to sign the informed consent, associated chronic therapies with either: ibuprofen, procainamide, phenazopyridine, L-Dopa (which are known to interfere with the spectrophotometric method for detection ChEs levels of activity used in the study). Reference serum samples were analyzed from patients free from pesticide exposure, as follows: 23 patients with severe liver disease, and 23 patients without hepatic disorders.

The method used to determine the level of ChEs activity is a colorimetric technique, and relay on a Vitros System Chemistry 5,1/FS in which 11 ěL drop of sample is deposited on a dry, multilayered, analytical element coated on a polyester support type of slide and evenly distributed by the spreading layer to the underlying layers. ChEs brought in the reaction from the sample will hydrolyze butyrylcholine to thiocholine. The liberated thiocholine will reduce potassium hexacyanoferrate II, as it is shown below:



The rate of color loss is monitored by reflectance spectrophotometry and is proportional to the amount of ChEs activity present in the sample. Reference interval is: 4.65 – 10.44 U/mL (females), and 5.90 – 12.22 U/mL (males).

The idea of the research was to determine the level of ChEs activity using two samples of 0.5 ml serum obtained from the same specimen of blood, one analyzed without any preparation, using the conventional protocol, and the second one, after a preliminary incubation (half an hour at 37°C on an water thermostat – to reproduce, at least at minimum, the conditions within the human body) with Toxogonin® (active ingredient - obidoxime chloride, 1 mL ampoule, 250 mg/mL, manufactured by Merck Pharma GmbH). The blood samples were centrifuged immediately after collection. Each determination used 0.5 mL of serum, which was separated from the clot right after centrifugation (technical specifications of the kit producer being an interval of

maximum 4 hours), and processed after a maximal period of 24 hours (the kit producer recommendations are less than 7 days) while stored in refrigerator (at 2-8°C, never frozen), (11-13).

Several phases of the research were considered necessary, due to the need of obtaining answers on several issues regarding the new test.

I. Adding Tox, "in vitro", to a serum sample collected from a patient with acute OF poisoning, will generate different results for the levels of ChEs activity than by testing only the simple serum of the same patient ?

For this, blood samples were collected from patients admitted with acute OF intoxication and centrifuged as described. 0.5 mL from that serum was directly analyzed to determine the level of ChEs activity, and another 0.5 mL from the same sample was first incubated with Tox, being analyzed for the same parameter after the incubation. In the event of increasing values for the level of ChEs activity, we can consider that we have an "in vitro" effect of reactivation of the blocked enzyme through contact with Tox.

II. Are these results (increased values for the level of ChEs activity when is performed an initial incubation with Tox), the simple consequence of a colored substance insertion (Tox) in a colorimetric spectrophotometric working analyzer ?

For this, the new method was tested in patients without OF exposure : some associating liver diseases and some without any hepatopathy. Those samples were analyzed as simple serums and also, after an initial incubation period with Tox – with the new protocol. A lack of increase in ChEs activity for the samples associating incubation with Tox, both in patients with initially normal values of ChEs (subgroup non-intoxicated, without hepatopathy), or with initially decreased values (due to an impaired synthesis of ChEs secondary to liver disorders), can support the idea that the newly proposed test is characteristic for OF poisoning.

III. Which dilution of Tox has to be used for the serum incubation ?

Despite the temptation for using high concentration of Tox in order to obtain a maximal effect on ChEs reactivation, the risks for bias will increase with the use of large volumes or quantities of Tox. For example, the case of ibuprofen (mentioned in the technical references from the cholinesterase kit producer) is very suggestive : therapeutic serum concentration of 4 mg/dL associate no bias, at values of less than 20 mg/dL the interference is negligible (bias < 0.3 U/mL), but at concentrations over 40 mg/dL the error exceed 2.3 U/mL (14).

Thus, the dilution better to be used was estimated in relationship with the therapeutic level for Tox used in medical practice. The treatment is generally started with 2 ampoules of 250 mg Tox, for a total volume of blood of 5000 – 5500 mL, resulting in 0.1 mg / ml of blood. For a volume of 6 ml of blood collected in a vaccuette, results a need of 0.6 mg of Tox / vaccuette correspondent to an average of 2 ml of serum obtained by centrifugation from one vaccuette. A draft calculation associates 0.3 mg Tox for 1 mL serum, which signifies 0.15 mg Tox for the volume of 0.5 mL serum requested by the method. If we dilute the content of one ampoule of Tox (1 mL, containing 250 mg obidoxime) in proportion of 1/10 (0.5 mL Tox + 4, 5 mL NaCl 0.9%), 5 μL of this dilution will contain 0.125 mg.

In order to determine which dilution is the best to be used, 4 concentrations of Tox were tested for the smallest volume (5 μL) that was possible to be manipulated in the hospital laboratory : undiluted - for the amount of 1.25 mg/5 μL ; 1/10 - for the amount of 0.125 mg/5 μL ; 1/20 - for the amount of 0.0625 mg/5 μL ; 1/5 - for the

amount of 0.25 mg/5 μL.

IV. Is there any influence from the yellow color of the Tox used in the test, on the results offered by the spectrophotometer ?

For this, instead of serum, samples of NaCl 0.9% (without any ChEs) were investigated without and with a preliminary incubation with Tox, for spectrophotometric results on the level of ChEs activity. Ten samples were analyzed and the average difference between obidoxime incubated samples and those with only NaCl was considered as colorimetric influence of Tox, value that had to be subtracted from every result obtained for the reactivability of ChEs.

V. Is it necessary to constitute every time a fresh dilution for Tox, or is it possible to use a previously constituted dilution for many days (the whole surveillance period of an intoxicated patient), without interfering the rigourosity of the method ?

For this, in three of the patients included in the study, at different moments (a total of 19 comparative tests), the blood samples were comparatively assessed by incubating 0.5 mL of serum with 5 μL of Tox from a dilution instantly prepared on the moment of determination, and another 0.5 mL from the same sample of serum with Tox from a dilution prepared in the same week. Due to the known influence of sunlight on Tox, the prepared dilution was stored in a brown glass bottle.

All aspects of the clinical study were made with regard to the bioethics rules endorsed by European Union legislation, as well as the Romanian regulations for good clinical practice and clinical trials. The study protocols have the approval of the Bioethics Commission of the "Gr.T. Popa" University of Medicine and Pharmacy Iaşi.

Statistical analysis was carried out using SPSS (Statistical Package for the Social Sciences) 17 software for Windows 7.0. Comparisons of ChEs levels of activity at each time between the two methods used were assessed with unpaired *t*-test. For all tests, *p*-value less than 0.05 was considered significant.

RESULTS

Issue I. Values obtained for the level of ChEs activity determined using Vitros System Chemistry 5,1/FS on different samples of serum from 4 organophosphates poisoned patients, with the conventional method and a new method that involve a preliminary incubation of the serum (0.5 mL) with 5 μL of Tox (1,25 mg) for 30 minutes at 37°C are presented in Table I.

Increased values for the level of ChEs activity were considered as indicative for "in vitro" effect of reactivation of the blocked enzyme through contact with Tox.

Issue II. Values obtained for the level of ChEs activity on different serum samples from : A - patients without OF intoxication but associating liver disease (23 cases), and B - patients without any hepatopathy or insecticide exposure (23 cases), using the conventional method and a new method are presented in Table II.

Issue III. Comparative results for the level of ChEs activity determined with the conventional method and variations of the new methodology involving the preliminary incubation (30 minutes at 37°C) of

bation of the serum (0.5 mL for 30 minutes at 37°C with 5 μL of Tox (0.125 mg) 1/10 dilution, prepared in two manners: fresh, just before incubation with serum, and constituted previously with the occasion of the first determination are included in Table V.

DISCUSSION

The results obtained from analyzing issues I and II have supported our hypothesis that, in acute OF poisoning, additional information can be obtained using a laboratory method that test the effect of an "in vitro" incubation with Tox to generate a possible recovery in the level of ChEs activity. Results from Table II showed that in group A, level of ChEs activity is almost equal with both methods, because there is a decreased amount of enzyme synthesized by affected liver, while in group B, where ChEs activity is not influenced by anything, the differences between values obtained with both methods are inconclusive, with no statistical significance.

Technical aspects regarding the methodology of the test were assessed in issues III, IV and V revealing the best dilution of Tox to be used, which is 1/10, containing 0.125 mg / 5 μL (conclusion from issue III).

The presence of Tox in the sample (0.125 mg added to the 0.5 mL of serum) result in an artifact of 0.5 U/mL false increase in the level of ChEs activity which has to be subtracted from the values obtained with the newly proposed protocol (from those of samples incubated with obidoxime) - conclusion from issue IV, but this value was not statistically significant. Once constituted, the dilution of Tox can be safely used for at least one week, if stored in brown glass bottles (conclusion from issue V), because differences in the two dilutions used (fresh and previously prepared) is not statistically significant in patients analyzed.

CONCLUSIONS

Analyzing "in vitro" the Tox effect on restoring the level of ChEs activity resulted in a safe, non-expensive, easy to perform, quick (< 1 hour) test capable to offer new, interesting perspectives on OF intoxications. It clearly consists in an advantage for the diagnosis, prognostic evaluation and therapeutic orientation in organophosphate poisoning. These aspects are now evaluated in a prospective study, which will be finalized in May 2012. Finally, the desire of the authors is that professionals involved in the management of organophosphate poisonings will start to use the new proposed method, and communicate their personal considerations on this topic.

ACKNOWLEDGMENT

We are grateful to the „Gr.T. Popa" University of Medicine and Pharmacy Iaşi (grant

no. 6820 obtained in 2009 competition) for funding this study under the theme "New original in vitro method of assessing cholinesterase reactivability for optimizing the antidote treatment in organophosphate poisoning".

INVESTIGATING MEDICAL STUDENTS HEALTH CONCERNS DURING THEIR ACADEMIC STUDIES (Abstract): **The aim** of the study is to identify medical students' opinion regarding their health and thoughts related to their physical health in relation to their clinical practice. **Material and methods**: medical students enrolled in all years of study (from 1 to 6) answered to an online questionnaire. Socio-demographic, family, academic and health-related data were gathered. A series of items focused on students' opinion about physical health in relationship with the completion of their practical stages in different clinics. Dietary habits and lifestyle data were also collected. Statistical data were analyzed using *SPSS v.21*. **Results**: 220 students aged M = 21.92 ± 1.96 (19 to 32 years old), 2/3 living in urban area. 9.5% of them had a chronic disease. In the case of 5% of students, both parents were working abroad. 5% of respondents declared that they consumed drugs or psychotropic substances. 1/5 are smokers and 1/3 drink coffee daily. Students reported an average of 6.73 (±1.09) hours of sleep per night. Almost half of them were tense during clinical hours (48.2%). 20% of the students strongly agreed with the fact that they were always preoccupied with their health. 53,2% used supplements seasonally to improve their health. More than half of the students were afraid of developing cancer (53.2%), followed by diabetes (6.8%) and 58.6% claimed that they always have hand sanitizer on them. **Conclusions**: Medical education is a long and demanding academic training when different aspects influence students' psychological, physical and social health .The contact with patients, the knowledge about illness, suffering and dying, determines the individuals to deal with objective or imaginative fears and explaining this phenomenon has positive consequences for the personal and professional life of the future medical doctor. **Keywords**: MEDICAL STUDIES, STUDENTS, DIETARY HABITS, DISEASE, PHYSICAL HEALTH, MEDICAL STUDENT SYNDROME.

During their academic years, medical students are taught about diseases, how to identify symptoms and to give a correct diagnostic. It is proved that students can suffer from diseases they learn about and it is speeded among students who are trained in Psychology or Medical Sciences. When studying a psychological disturbance, students may experience more psychological distress regarding the members of their families or their own psychological health. Also, while learning about a physical disease, students can interpret a physical disturbance as a sign of a serious illness.

By misinterpreting their own physical symptoms, medical students could experi-

ence the fear that they suffer from a disease. Some studies showed that this kind of beliefs (about having a severe disease) is persistent in time, despite medical examination or laboratory analysis and it is a temporary kind of hypochondria. (1-2) This situation is like hypochondria and could be related to Medical Student Syndrome (MSS). Other used terms were nosophobia, hypochondriasis of medical students or medical student it is, a mild form of health anxiety or transient hypochondriasis.

In the case of hypochondria, the patient always seeks a medical diagnosis, but in case of MSS no increase in the number of medical consultations is revealed. So, students identified with MSS will not look more frequently to have a medical check but the belief or the fear that they were having a disease is present. This is a unique type of hypochondriasis which can lead to health anxiety in strong relationship with the diseases medical students focus their attention on during medical training.

The rates of MSS among medical students vary from 5% to 70% (3-5). Consequently, scientific reports regarding the effects of progressing through medical education on health anxiety are scarce and contradictory. Studies show that the fear of having a disease may persist over the years during medical studies (6-8) and that some factors influence the level of fear: personality traits, fantasy proneness, clinical year, thought suppression (9). Nevertheless, results focusing on medical students' stress, fear of illness or burnout present contradictory data when compared to non-medical students (10).

The aim of the study is to identify medical students' thoughts regarding their health and behaviors related to maintaining physical health.

MATERIAL AND METHODS

Participants and Instruments

The study was developed between January and March 2019. The research targeted medical students from all years of study and was divided in three parts: the first one collected socio-demographic, medical and academic data. The second part of the questionnaire consisted of a number of self-rated items developed with the purpose of identifying aspects related to students' health. The third part included items targeting their health-related behaviors regarding physical health or limiting exposure to diseases during practical stages and worries about catching a disease. The participants had to rate their responses on a Likert-like scale from 1 to 5 (*1 – strongly disagree; 2 – disagree; 3 – neutral; 4 – agree; 5 – strongly agree).*

A number of 220 medical students provided online answers to the questionnaire. Google Forms was used due to its familiarity with students.

Socio-demographic data (sex, age, year of study, environment, living arrangements), medical (chronic disease) and anthropometrical data (weight, height) were collected. Supplementary items were gathered related to academic results or family situation (siblings, level of education for both parents and having at least one parent working abroad).

Statistical analysis of data

Collected data were analyzed using IBM SPSS Statistics, version 23. Means and standard deviations were used for the descriptive analysis of socio-demographic, academic results and anthropometric data. Frequencies were used for analyzing the distribution of answers for the rest of the items. Independent Sample T-test were

used for the comparative analyses.

RESULTS

Demographic, academic and family-related data

All the participants were domestic students enrolled in the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi. Almost half of them (46.8%) were in their third year of study, followed by second year (15%), fourth year (12.7%), first and fifth year (both of them 8.2%) and sixth year (9.1%).

Most of the participants were female students (82.5%), with age ranging from 19 to 32 years old (M = 21.92 ± 1.96). This gender majority is specific to medical students. More women are usually enrolled in medical faculties.

Regarding their living environment, 78% of the participants declared that they were living in urban areas. Most of the students lived with their families and in rental accommodation or dorm rooms (33.6%, 38.6% respectively); a smaller percentage lived either alone (12.7%) or with their life partner (15%).

The admission process in the university is based on a final mark (minimum 5, maximum 10) resulted from a written exam with multiple answers, covering items from different disciplines (biology, chemistry and physics) and the mark from the baccalaureate exam. The mean admission mark for the researched sample is 8.76 (± 0.85). For the baccalaureate exam the mean was 9.26 ± 0.58.

One item investigated whether respondents have at least one parent working abroad. In case of 5% of the students, both parents were working abroad at the time of the investigation and another 14,1% declared that one parent is working in another country (9.1% for fathers and 5% for mothers).

Anthropometric, dietary habits, and health-related data

Students had to declare if they suffer from a chronic disease and 9.5% of them claimed that they had a chronic disease. As anthropometric data, it was obtained an M = 63.29 (± 12.26) for weight and M = 168.19 (± 8.22) for height.

Regarding the consumption of alcohol, tabaco, coffee, carbonated/energizing drinks or psychoactive substances, the first table presents the frequency of answers. Almost a fifth of the students (20.9%) smoke daily, 13.1% of the students drink alcohol monthly or weekly, almost half of them (45.9%) drink coffee every day, 51.8% occasionally drink carbonated drinks and 34.1% occasionally drink energizing drinks. Most students claimed that they never used ethnobotanicals (95.9%) or drugs (94.1%) and only a small percentage revealed that they have used them occasionally (3.6%, 5% respectively). So, around 5% of respondents declared that they consumed drugs or psychoactive substances (tab. I).

TABLE I

The consumption tobacco, drinks or drugs (%)

Frequency of use	Tobacco	Alcohol	Coffee	Carbonated drinks	Energizing drinks	Ethno-botanics	Drugs
Never	60	15	11.8	9.5	62.3	95.9	94.1
Occasionally	15.9	71.8	22.7	51.8	34.1	3.6	5
Monthly	0.9	7.3	1.4	12.3	1.4	0.5	0.5
Weekly	2.3	5.9	18.2	21.8	2.3	0	0.5
Daily	20.9	0	45.9	4.5	0	0	0

Students were also asked about their sleeping and dietary habits. Respondents reported an average of 6.73 (±1.09) hours of sleep per night, with a minimum of 3 and a maximum of 11. Also, 13.1% of the students reported that they wake up every night, while 59.5% of them wake up occasionally.

The students had a rich diet in fruits and vegetables (43.2%), sweets (25.9%) and fat (16.8%). Only 10.5% of the students self-rated as having a healthy and balanced diet.

Health-related thoughts and behaviors

Students were asked to read five statements and decide to what extent they agreed with them, in order to identify their concern about their physical health. Almost 20% of the students strongly agreed with the fact that they were always preoccupied with their health. Also, 11.1% of the students in our sample agree or strongly agree that people around them paid little attention to their health.

While consulting patients, 7.7% of the students are very concerned they could have the same disease. A small percentage (4.1%) strongly believe they have a disease the doctors haven't discovered yet. Finally, 21.9% of the students agree or strongly agree with the statement that there is something wrong with their bodies. The frequency of the answers is presented in second table.

We were also interested in students' feelings during their practical stages. Almost a quarter of students (22.7%) were scared for no apparent reason or they felt it was hard for them to calm down (21.9%).

TABLE II

The frequency of answers (%)

ITEMS	Strongly disagree	Disagree	Neutral	Agree	Strongly agree
I am very preoccupied with my health.	1.8	18.6	30.5	29.5	19.5
People around me pay little attention to my health.	33.2	36.4	19.4	9.7	1.4
While I consult patients, I am afraid I could have the same disease.	33.2	32.3	15.5	11.4	7.7
I think I have a disease the doctors haven`t discovered yet.	74.1	9.5	5.9	6.4	4.1
I always have the feeling there is something wrong with my body.	30.0	31.8	16.4	11.4	10.5

TABLE III

The distribution of answers to items regarding the feeling during practical stages (%)

ITEM	Strongly disagree	Disagree	Neutral	Agree	Strongly agree
I was scared for no apparent reason.	23.6	25.9	17.7	19.1	13.6
It was hard for me to calm down.	34.1	24.1	20.0	11.4	10.5
I had a hard time swallowing.	41.8	26.4	12.3	11.4	8.2
I lacked enthusiasm.	12.3	26.4	25.9	18.6	16.8
I was afraid I did not have enough time for all my assignments.	13.2	21.4	20.9	26.8	17.7
I felt tense.	8.2	22.7	20.9	26.8	21.4
Life doesn`t have a meaning.	39.1	17.3	12.7	13.2	17.7

Students agreed or strongly agreed that they had a hard time swallowing (19.4%), they lacked enthusiasm (35.4%), they were afraid they did not have enough time for all the assignments (44.5%), they were tense during clinical hours (48.2%) and, more importantly, they felt life didn't have a meaning (30.9%). The frequency of answers is presented in Table III.

Behaviors regarding physical health

More than one quarter of students (30.9%) believe they lose more hair than others; more than half of them carry hand sanitizing with them (58.6%), rarely take medication without medical prescription (69.5%), use dietary supplements seasonally to improve their health (53.2%) and never bit their nails (65.9%). 15.5% of the students in our sample think very frequently that they could have a serious affection.

Half of the students declared they were healthy (50.9%), while the rest declared various affections; the most common were digestive (15.5%), genital (7.3%) and endocrinological (5.9%) problems. More than half of the students were afraid of developing cancer (53.2%), followed by diabetes (6.8%).

Comparative analysis showed a significant difference between students with and without parents working abroad regarding the admission t (199) = 2.48, p = 0.002 and baccalaureate means t(207)a = 4.43, p = 0.004. The results showed that students with parents working in another country obtained lower marks for both baccalaureate (M*with* = 9.35, M*without* = 8.92) and faculty admission exams (M*with* = 8.46, M*without* = 8.83).

DISCUSSION

The present paper offers some preliminary results from a larger research focusing on medical students preoccupation for their health, especially during their medical training. It was pointed out by the scientific literature that students enrolled in Psychology or Medical sciences courses are more prone to experience fear of having a disease (physical or mental illness) than students enrolled in other specialties. The results of some studies showed contradictory rates concerning two aspects: the level of fear of having a disease or the tendency to identify themselves as having the signs of a studied physical or mental illness. With such rates ranging from 5 to 70%, various researchers tried to identify variables linked to this tendency (3, 5, 10).

Our study revealed that more than half of the respondents are afraid of developing cancer (53.2%), a major fear also identified by other studies led on medical students (9). Studies focusing on medical students revealed that 70% of them have groundless medical fears during training. On the contrary, some other studies found no difference regarding health-seeking behaviors and fear of illness between medical and non-medical students (19, 20).

Training in the medical sciences is an important source for medical knowledge. Due to the large amount of information and hard work, students tend to diagnose themselves or to self-administrate dietary supplements with no medical prescription in order to improve their physical and mental power. The rates for this study correspond to results obtained by other studies focusing on medical students: more than 50% in USA (11), 37.4% in Italy (12) or 76.1% in Saudi Arabia (13). Even if some studies point out that there is no significant difference between students with and without medical knowledge, other findings show that there are significant differences in the knowledge of health sciences and non-

health sciences students pertaining to health benefits and safety of the consumption of dietary supplements (14).

The present study identified that 1/5 of the students smoke and then 1/3 of them drink coffee daily. Also, 35% of the students drink energizing drinks. The use of alcohol, coffee and energizing drinks is also comparable with other studies. Aljaloud (2016) identified that 71.5% of students use energizing drinks (15). In a study conducted by Casuccio *et al* (16) it was revealed that 22% of medical students were regular consumers of energizing drinks. Moreover, the consumption of these drinks was found to be associated with a high rate of alcohol consumption and 45% of the students declared that they felt side-effects like insomnia, palpitations and irritability after the consumption of energizing drinks. Some other authors presented higher reports: 73,8% in Canada (17). Regarding the consumption of tobacco, studies show that the rates are decreasing, but this was associated with a worldwide phenomenon. With a percentage of smokers of 40, this study reveals an increased rate, compared to studies on medical students from Europe (19%), Africa (19%) or SUA (21%) (18).

CONCLUSIONS

Medical education is a long and demanding academic training. Apart from psychological aspects or social characteristics, other aspects influence students' psychological, physical and social health during their academic years. The contact with patients, the knowledge about illness, suffering and dying determines the individuals to deal with objective or imaginative fears. Even if studies prove that the fear of illness is not always a characteristic of medical students' life, medical teachers should consider this when new topics are presented. Also, explaining this phenomenon has positive consequences for the personal and professional life of the future doctor.

ACKNOWLEDGEMENTS

This paper presents a part of a larger research focusing on medical students and the influence of medical knowledge on students' behavior regarding the interest for their physical and mental health. Some of the results were presented as an oral presentation at International Conference for Medical Students - *CONGRESSIS 2019*, Iasi, Romania.

NEWS

ARE PETS A SOURCE OF ANTIBIOTIC RESISTANT INFECTIONS?

Macrolide-resistant Streptococcus pyogenes is an emerging problem with a great public health concern throughout the world. A study was carried out in order to investigate the possible role of pet animals in the epidemiology of such pathogen. For this purpose, nasal or oral swabs were collected from 115 pets (40 dogs and 75 cats) with respiratory illness. The collected swabs were cultured for isolation and identification of S. pyogenes. Of the 115 examined pet animals, S. pyogenes was recovered from 11 (9.6%), from which, the isolation rates among dogs and cats were 15% and 6.7%, respectively. Macrolide-resistant S. pyogenes was isolated from dogs and cats in the following rates 10 % and 5.3 %, respectively (Ahmed Samir, Khaled A. Abdel-Moein, Hala M. Zaher. Emergence of penicillin-macrolide-resistant Streptococcus pyogenes among pet animals: An ongoing public health threat. *Comp Immunol Microbiol Infect Dis* 2019; 12(68): 101390).

THEORETICAL AND PRACTICAL ASPECTS OF ^{18}F-FDG PET

THEORETICAL AND PRACTICAL ASPECTS OF ^{18}F-FDG PET (Abstract): The incidence of oncological diseases has become very high in the last decade, whether we refer to more or less developed countries. The incidence of the oncologic disease continue to increases in spite of substantial progress in the development of medicine and medical technologies. At the same time, an efficient treatment depends on an accurate and timely diagnostic. A solution for precise diagnostic is provided by nuclear medicine through the positron emission tomography (PET) technique, which allows an accurate evaluation of metabolism in different organs and tissues. PET permits timely identification of functional disturbances underlying the development of the disease. In the past decade's positron emission (PET) ^{18}F-fluorodeoxy-glucose (^{18}F-FDG) has been used to evaluate tumor patients. Evaluation of distribution, spread and proliferation of cancerous cells is considered to be useful for therapeutic guidance and therapeutic effect assessment. Thus, radiolabeled molecules, such as the [^{18}F]-2-Fluoro-2-deoxy-β-D-glucopyranose has been developed. Fluorine-18 is a short-lived positron emitting isotope which finds a massive use as a label for radiotracers used with the molecular imaging technique of PET. The Quality Control (QC) process concerns all the mechanisms, actions and tools developed to detect the presence of errors in a production batch. This review focuses on the importance of ^{18}F-FDG and our goal was to present some theoretical and practical aspects of the ^{18}F-FDG synthesis and what parameters and how should they be evaluated in QC laboratories. **Keywords***:* POSITRON EMISSION TOMOGRAPHY, ^{18}F-FDG SYNTHESIS, QUALITY CONTROL.

WHY [^{18}F]-FDG?

The [^{18}F]-FDG is a generic tumor-seeking radiopharmaceutical and it is widely used for the diagnostics of malignant tumors. Chemical name of [^{18}F]-FDG is [^{18}F]-2-Fluoro-2-deoxy-β-D-glucopyranose, identified by Chemical Abstract Service with registry number 63503-12-8, but more commonly referred to as ^{18}F-Fluorodeoxyglucose or simply FDG. This compound is a radioactive derivative of 2-deoxy-D-glucose labelled with

positron-emitting isotope ^{18}F in the position 2 of the glucose core structure as shown in the Figure 1. The radioactive fluorine undergoes beta decay through the emission of positrons, followed by their annihilation and subsequent emission of two 511 keV gamma photons. The longer half-life of ^{18}F, of almost 110 minutes, has allowed the commercial distribution of radiotracers to PET centers placed outside of clinical locations.

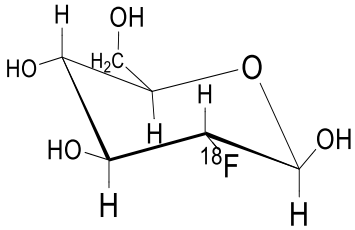

Fig. 1. The [^{18}F]-FDG structure

CHEMICAL ASPECTS BEYOND GLUCOSE METABOLISM

Most living organisms have as a primary source of energy a common monosaccharide found in nature, such as glucose. Glucose homeostasis plays an essential role in most fundamental aspects of life, and its dysregulation is associated with many important human diseases such as cancer (6). In the course of cancer progression, even in the availability of oxygen, there is a change in glucose metabolism from mitochondrial oxidative phosphorylation to a glucose dependent glycolytic pathway. To sustain the high energy demand required for rapid proliferation, cancerous cells increase their glucose uptake as well as their glycolytic rate, which can be up to tens or hundreds of times greater than that of normal cells (7). This atypical metabolic process is known as the Warburg effect. This metabolic phenomenon has been recognized as a hallmark of cancer and serves as a promising target for diagnosis and therapy of cancer (8).

The applicability of given radiopharmaceuticals in oncological diseases is based on the process of intensified glycolysis in neoplasms, described in 1926 by Otto Warburg (9). The transport of [^{18}F]-FDG in malignant tumor cells is due to the expression of a class of uniporter proteins, called glucose-transporters (GLUT1–4), the most active of them being GLUT1. The kinetics of glucose transport via GLUT1 has been explored since radioisotope use has become available (10). In the cell, the radiopharmaceutical is subjected to phosphorylation under the influence of the enzyme hexokinase, with the generation of [^{18}F]-FDG-6-phosphat which, due to its properties, is not involved in the tricarbonic acid cycle and is not ejected from the cell. In tumorous cells, the process of dephosphorylation is decreased due to the low activity of the enzyme phosphorylase (11). Thus, conditions arise for heightened FDG accumulation in malignant tumor cells. This phenomenon has been called the "metabolic trap" and the level of [^{18}F]-FDG accumulation in tumors does not depend on their microcirculation, since the radiopharmaceutical is actively transported to cells (12). Furthermore, the [^{18}F]-FDG is excreted by the kidneys and consequently a part of the radiopharmaceutical is inevitable physiologically absorbed in the urinary system.

METHODS OF OBTAINING [^{18}F]-FDG FOR PET

The [^{18}F]-FDG production is a multistep process that begins with a particle accelerator (by far the most efficient, useful and economically viable method) which produces the [^{18}F]-fluoride radionuclide through proton irradiation of oxygen-18

enriched water in a small enclosed volume, usually 0.5–2.5 mL (13). For obtaining radioactive fluorine, over 20 nuclear reactions are known, of which the most effective and widely used in the world is irradiation of oxygen-18 enriched water which provides fluoride [^{18}F] of high radioactivity under optimized conditions, achieved at cyclotron, even with low energy, in less than 1 hour of irradiation time (14). Nowadays most of the radiopharmaceutical laboratories use the nucleophilic substitution method for FDG production, introduced into practice by Hamacher and his collaborators in 1986 (15) while the European Pharmacopoeia still mentions the electrophilic route for FDG production (the precursor and possible impurities) as the alternative routes.

The ^{18}F-FDG was synthesized for the first time by Pacák and his colleagues in 1969 and it was evaluated as a PET tracer in the early 1980s (16, 17). Ido and his team exploited the high reactivity of molecular fluorine in the production of FDG by electrophilic fluorination and they did the first PET images in human (17). The significant differences between these two forms are the specific activity (radioactivity/mole) of the produced ^{18}F isotope. Nucleophilic ^{18}F-fluoride is produced by the $^{18}O(p,n)^{18}F$ nuclear reaction to give a high amount of radioactivity (>370 GBq/batch). Nucleophilic [^{18}F]-fluoride is produced with specific activity in the range of 10^2 GBq/μmol (12). Electrophilic [^{18}F]-F_2, on the other hand, has a much lower specific activity (100−600 MBq/μmol) because fluorine [^{19}F]-F_2 gas must be added as a carrier to extract the [^{18}F]-F_2 from the target (14). The specific activity becomes essential when working on ligand−receptor binding because the addition of a carrier ([^{19}F]-F_2) leads to increased mass of the final radiopharmaceutical, which may disturb any signal received by PET from radiopharmaceutical binding and may also cause pharmacological effects (14, 18). Because nucleophilic fluorination is the most important route for obtaining ^{18}F-labeled compounds, we will go directly to dealing with practical aspects of nucleophilic FDG production method.

After the required irradiation time (typically not more than one hour at 35 μA current) the radioactive [^{18}F]-fluoride is transferred to a radiopharmaceutical production laboratory for further conversion into [^{18}F]-FDG suitable for injection. The [^{18}F]-fluoride is collected inside an FDG synthesizer, placed in a hot cell. The radiochemical synthesis of 2-^{18}F-fluoro-2-deoxy-D-glucose can be carried out by means of an automated module leading to a product which becomes an injectable solution subjected to sterilizing filtration. The module uses a disposable cassette which contains the necessary reagent kit with the chemicals required for [^{18}F]-FDG synthesis. The reagent kit includes eluent solution, acetonitrile, precursor, ethanol, sodium hydroxide solution, buffer solution, an anion exchange column, a reverse phase and alumina N cartridges and sterile water for injection. The use of a module with a disposable cassette makes the duration of the synthesis process of about 30–35 min. In most cases, [^{18}F]-FDG synthesis is performed according to the two-stage method of Hamacher (15). The first steps in radiochemistry with [^{18}F]-fluoride ion are almost invariably the removal of bulk [^{18}O] water and the solubilization in an organic solvent. This is commonly achieved by trapping the [^{18}F]-fluoride ion onto an ion exchange resin, to allow the recovery of the expen-

sive [^{18}O]-water, followed by the elution of the [^{18}F]-fluoride ion in a small volume of an aqueous weak base (usually potassium carbonate). Water is then removed by two or three successive cycles of azeotrope evaporation with acetonitrile (at temperature >85°C for ~10 minutes). The addition of a Kryptand, such as Aminopolyether 2.2.2 (K2.2.2) or tetra butyl ammonium carbonate (TBA), during this process enables the [^{18}F]-fluoride ion to be subsequently solubilized in a polar aprotic solvent (such as acetonitrile) (13).

The precursor molecule for the radiochemical synthesis of [^{18}F]-FDG through nucleophilic substitution is 1,3,4,6-tetra-O-acetyl-2-O-trifluoromethanesulfonyl-b-D-manno-pyranose. It is commonly named mannose triflate and it is a sugar molecule containing a proper leaving group for a facile nucleophilic reaction, trifluoromethanesulfonyl group (usually called triflate). In order to achieve radiolabeling of glucose at the C_2 atom with radioactive [^{18}F]-fluoride through nucleophilic substitution, the other possible reaction centers are protected with four tetra-acetyl groups (named protecting groups). During the nucleophilic substitution reaction (~5 min at 80-90°C using anhydrous acetonitrile), the leaving group, triflate, is displaced by radioactive [^{18}F]-fluoride (13).

Removal of protective groups (the four acetyl protecting groups) in the synthesis of FDG is easily accomplished through acidic or basic hydrolysis. Both methods are equally effective but require different conditions, each with its advantages and disadvantages (a high temperature or the probability of obtaining by-products). However, the alkaline hydrolysis is the most commonly used method in commercial synthesis modules since it requires less time and lower temperatures (19). In this case to remove the acetyl groups, the [^{18}F]-labelled intermediate with intact acetyl groups is treated with mild base (1-2 M NaOH) at room temperature (may be performed directly on a C-18 cartridge) (20). However if alkaline hydrolysis is performed at higher temperatures the [^{18}F]-FDG has a potential for epimerization into [^{18}F]-Fluorodeoxymannose (FDM). The FDM should be treated as a radiochemical impurity that should be controlled in the FDG manufacturing process and also quantified during the quality control tests (21).

Purification of the final product can be performed by passing it through a series of anion exchange columns, a C-18 reverse phase column and an alumina column. This process will remove impurities, as well as unhydrolyzed and partially hydrolyzed intermediates, unreacted fluoride but will also help with neutralization and pH adjustment.

A final step in the synthesis of [^{18}F]-FDG is sterilizing filtration in which the purified [^{18}F]-FDG solution is passed through a vented 0.22 μm filter. Sterilization with steam may also be performed, but it is not required by European Pharmacopoeia (22). The filtered product (final [^{18}F]-FDG) is held in quarantine until it receives the final approval for patient use from the quality control department.

The FDG may be dispensed either into unit doses or in multi-dose vials using automated systems. This process must be done in aseptic conditions, in a *class A* environment, following the applicable *Good Manufacturing Practice* (GMP) regulations. The product vial and the outer lead shielding should be affixed with a label containing the relevant product information, such as: product name, total activi-

ty at reference time, expiration time.

The technology has also focused on increasing the efficiency of chemical labelling by reducing the time of synthesis and increasing the efficiency of the individual steps. The result is that, in a relatively short period of time, the yields of a single [^{18}F] production of FDG have increased from a few hundred to several thousand mCi (23). However, the problem with higher yields and higher specific activities has potentially serious implications for the radioactive stability of many biological drugs, such as [^{18}F]-FDG. These drugs degrade by radiolysis when exposed to large quantities of ionizing radiation with high linear energy transfer values (24). When the activity concentration of [^{18}F]-FDG is increased to hundreds of mCi/mL, [^{18}F]-fluoride is the main active product of auto radiolysis and becomes the most important radiochemical impurity.

QUALITY ASSURANCE AND QUALITY CONTROL GUIDELINES

In the clinical application of PET radiopharmaceuticals, it is important to assure the safety of the product. Many guidelines for the production of PET radiopharmaceuticals have been published in each country or region. A pharmacopeia is a regulatory source for the quality assurance (QA) of any drug product in the world. In Europe, the European Pharmacopeia (EP) is recognized as the official collection and is referenced in various forms (22). Precise procedures for the production of PET radiopharmaceuticals and their Quality Assurance (QA) / Quality Control (QC) are described in these guidelines. Thus the EP contributes to the quality of medicines and the protection of public health and also includes QA standards in the form of monographs for several PET drug products. Because [^{18}F]-FDG injection is the most commonly used PET radiopharmaceutical, the discussion of QA procedures in this article focuses on this drug. A careful examination of official sources, such as The European Pharmacopoeia (EP) and International Atomic Energy Agency (IAEA) for information on ^{18}F-FDG revealed the QA standards for PET drugs (13).

Quality control guarantees that the necessary and suitable tests are carried out and that the raw materials, packaging materials and products are released for use or sale, only if their quality is adequate. Quality control is not limited to laboratory operations but must be integrated into all activities and decisions concerning the quality of the radiopharmaceutical (25). A quality control laboratory has two primary functions: to test radiopharmaceutical and to test and analyze the raw materials and supplies used in the production of that radiopharmaceutical.

The [^{18}F]-FDG is an injectable radiopharmaceutical, and consequently each production unit must be manufactured accordance with the *Good Manufacturing Practice* (GMP) regulations. Documentation is an integral component of GMP and the quality management system. All processes must be documented in the form of *Standard Operating Procedures* (SOPs), and all personnel must follow these official procedures during the manufacturing and testing of [^{18}F]-FDG and all associated records must be collected and properly filed. The entire [^{18}F]-FDG manufacturing process may be confined to the cleanroom environment or within controlled zones to help ensure the pharmaceutical quality of the finished product. A clean and aseptic

environment are essential requirements in [^{18}F]-FDG manufacture, especially when the final injectable product is not subject to steam sterilization (26).

Quality control testing of [^{18}F]-FDG batches is done according to the guidelines outlined in the European Pharmacopoeia. Parameters given by this regulatory source, such as chemical identity and purity, radionuclidic and radiochemical identity and purity, have to be checked before releasing the product for human use (22). These tests can be accomplished using different types of radiation measurement equipment. Because of their short half-life, some radiopharmaceuticals may be released before completing all European Pharmacopeia recommended tests. The release of the product is not conditioned upon completion of all the tests as specified in [^{18}F]-FDG individual monographs, but they must be performed later, and the results recorded. It is a process that ensures compliance with product specifications regulated in the Pharmacopeia.

Daily QC testing comprises a visual inspection, as the product must be clear, colorless and free of particulates. The test should be performed before the drug product is released. The pH is determined on the final product of ^{18}F-florodeoxyglucose using pH paper and as acceptance criterion it must be between 4.5 and 8.5. This test must also be completed before the drug product is released.

In order to identify a radionuclide from a given sample, activity measurement are performed. The half-life is a measurable parameter and it is a characteristic of each radionuclide, allowing its identification (for [^{18}F]-FDG the half-life must be 105–115 minutes). PET drugs like [^{18}F]-FDG are based on [^{18}F] which is a positron emitter. The interaction with the surrounding electrons produces an annihilation reaction that releases two anti-collinear high energy photons (26). Each photon produces one current pulse proportional to its energy, which is amplified by the detector's electronics and produces a signal on the corresponding channel. A gamma spectrum is used in order to determine the radioisotopes present in a sample, as all PET tracers should produce a Gaussian bell curve centered in 511 keV, corresponding to the positron-electron resting mass energy (28).

Kryptofix (amino polyether) concentration for [^{18}F]-FDG approval has a limit because its presence over a certain concentration causes certain side effects, like apnea and convulsion (28). Although all automatic synthesis modules have multiple removal steps, the final [^{18}F]-FDG products must be tested before final release. The amino polyether test is performed by a spot test using a TLC silica gel plate. The central part of the spot due to the test solution should be more intense than that of the reference solution (2.2 mg/V, where V is the maximum recommended dose in milliliters) (22).

Different impurities may appear in the final radiopharmaceutical solution, coming from the manufacturing, cleaning or any other process during synthesis. These impurities are classified in the European Pharmacopoeia, which establishes that chromatographic techniques (such as TLC or HPLC) are suitable for estimation of their concentration (22). Different compounds will have different affinities for the mobile and stationary phases which in turn affect their migration speed expressed in the Retention Factor (RF) or Retention Time (RT) of radiotracer and reference standard match (30). The current European

Pharmacopoeia stipulates the minimum radiochemical purity for [^{18}F]-FDG should be no less than 95% of the total radioactivity while [^{18}F]-FDM fraction should not exceed 10% (22).

The endotoxin detection is based on spectrophotometry of a chromogenic substrate released in contact with lipopolysaccharides from the external membrane of different types of Gram-negative bacteria. According to the European Pharmacopoeia, the final radiopharmaceutical may be released before endotoxin testing is completed but could be immediate accomplished with a PTS system or later using a gel-clot test.

Sterility test is performed to detect the presence of viable microorganisms in the decayed sample. This control test is made once the radiopharmaceutical is fully decayed. Due to the short half-life of any radionuclide used in PET, this test is performed after the final product it was completely administered to patients.

CONCLUSIONS

The incorporation of fluorine-18 into a radiotracer combines the biochemical specificity of the tracer molecule with the high sensitivity of radioactivity detection. An example of the former is the incorporation of fluorine-18 into 2-deoxy-2-glucose to give [^{18}F]-2-fluoro-2-deoxy-2-glucose ([^{18}F]-FDG) as a radiotracer of glucose utilization. [^{18}F]-FDG, originally developed in the late 1970s, is now very widely used as a clinical research tool and as a diagnostic agent in oncology and neurology.

Positron emission tomography has advanced to become an important clinical diagnostic tool, but also a valuable technology used in research and drug finding and development. Increased demand for 2-deoxy-2-[^{18}F]-fluorodeoxyglucose for PET clinical investigations, has headed to the continuous optimization of the synthesis methods, leading to the compound being produced reliably, in the desired quantities and with higher purity.

A RAPID, SIMPLE AND SENSITIVE SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF NO FROM NO DONORS (Abstract): **Aim**. To develop and validate a spectrophotometric UV-VIS method for the determination of nitric oxide (NO) released from NO donors, such as nitric oxide-releasing nonsteroidal anti-inflammatory drugs (NO-NSAIDs), with poor solubility in aqueous medium. **Material and methods**: The method is based on the nitric oxide-mediated stress (nitrosative stress) through sulfanilamide that reacts with *N*-(1-naphthyl)ethylenediamine dihydrochloride to form a pink-red azo dye with maximum peak at 540nm. The method was validated in term of linearity, detection limit, quantification limit, precision, and accuracy. **Results**: The linearity of the method was proved for range of 0.78-100µM $NaNO_2$ with a correlation coefficient of 0.9998. The accuracy of the method was checked by recovery experiment performed at three concentrations, *i.e.*, 20 µM, 40 µM and 60µM $NaNO_2$ and the recovery (%) was found to be in the range of 98.34% and 101.96%. The low values of relative standard deviation (RSD) are indicative of the accuracy and reproducibility of the method. The precision of the method was studied as intraday and interday variations. An RSD less than 2% indicates that the method is precise. **Conclusions**: This research offers all the proofs that recommend the use of this method for the determination of NO released from NO donors, such as NO-NSAID, using a hydroalcoholic medium, as it has good sensitivity, precision, and accuracy. **Keywords:** NO-NSAID, GRIESS ASSAY, SPECTROPHOTOMETRY.

Nitric oxide-releasing nonsteroidal anti-inflammatory drugs (NO-NSAIDs) are a new class of anti-inflammatory drugs developed with the aim to reduce gastrointestinal side effects through NO release (1). NO is one member of a new class of signaling molecules with key role in a variety of biological processes including immune defense, inflammation, and neurotransmission. It is involved in regulating all aspects of our lives from waking, digestion, sexual function, perception of pain and pleasure, memory recall and sleeping (2, 3).

NO-NSAIDs are synthesized by the ester linkage of a NO-releasing moiety to conventional non-steroidal anti-inflamma-

tory drug (NSAID) (4) (fig. 1). Along with prostaglandins, NO released from NO-NSAIDs reduces the gastrointestinal injury by maintaining the mucosal blood flow, optimizing mucus and bicarbonate gastric secretion, and inhibiting activation of pro-inflammatory cells. As a result, NO may neutralize the detrimental effects of COX (5).

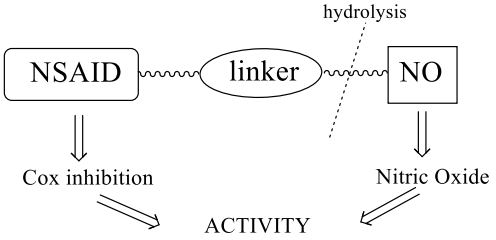

Fig. 1. General representation of NO-NSAIDs

For the detection and quantification of NO in complex biological systems and in physiological conditions, different methods can be used such as: chemiluminescence detection; fluorescence detection using 4.5-diaminofluorescein; conversion of Fe(II)-/oxyHb to metHb; electrochemical detection (amperometric NO-specific and porphyritic electrodes); Griess assay of NO_2^-, NO_3^-, and immunoassays using anti-nitrotyrosine antibodies. Many of these methods are indirect and have a low specificity for NO, because they interfere with other components of biological systems (6, 7).

Griess colorimetric assay is the most commonly used method for the measurement of NO due to the low cost and simple operation (8). It has been used extensively in the analysis of several biological samples such as plasma (serum), urine, saliva, and cell culture media. The method is based on indirect quantification of NO *via* spectrophotometric measurement of its stable NO_2^-, using aqueous medium. Decomposition product NO is rapidly oxidized to NO_2^- by oxygen. The half-life of NO in biological matrix is very short, ranging from less than 1 sec, in the presence of hemoglobin, to ~30 sec. This method involves two steps: firstly NO_2^- reacts with sulphanilamide in acidic media to produce a diazonium ion, which in the next step reacts with *N*-(1-naphthyl)ethylenediamine to form a pink-red azo dye (fig. 2). The absorbance of this adduct at 540 nm is linearly proportional with NO_2^- concentration in the sample (6, 7).

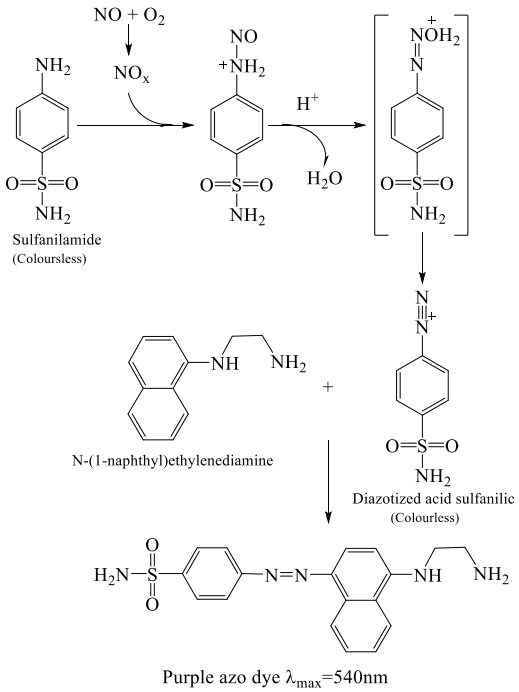

Fig. 2. Quantification of free nitric oxide using Griess colorimetric assay

In continuation of our efforts to discover new NO donors, new NO-NSAIDs have been synthesized by our research group, starting with indomethacin as conventional

NSAID. The aim of this study was to develop and validate a modified Griess assay which to increase the method sensitivity in hydro alcoholic medium and to be used for NO-NSAIDs that have a poor solubility in aqueous medium.

MATERIAL AND METHODS

Reagents and equipment

All used reagents and solvents were purchased from Sigma Aldrich and were of analytical reagent grade: sodium nitrite (>99% reference substance), phosphoric acid (≥85 wt. % in H_2O), sulfanilamide (SULF) (≥98%), *N*-(1-Naphthyl)ethylenediamine dihydrochloride (NED) (≥98%).

To measure the absorbance of the samples a micro plate reader (Tecan Sunrise Remote Microplate Reader TW/ML-Abbott F039306) was used, and the pH of phosphate buffer was measured with a Hanna Model Pack pH 21 digital pH-meter, calibrated with standard buffer solutions.

Preparation of standard stock solution

A fresh stock aqueous solution (0.1 M sodium nitrite in distilled water) was prepared by dissolving 6.9692 g of the reference substance in distilled water and diluting to 1,000 mL. This stock solution was standardized using the standard procedure reported in the *European Pharmacopoeia* and *Romanian Pharmacopoeia*, 10th edition (real molarity=0.0999, molarity factor=0.999). From this, a solution of 100 µM sodium nitrite was prepared by diluting 1 ml of the stock solution to 1000 ml with phosphate buffer (PBS) of pH = 7.4 (20mM in MeOH/H_2O=1/1 (*v/v*)).Working solutions, containing different sodium nitrite concentrations (100µM, 50µM, 25µM, 12.50µM, 6.25µM, 3.125µM, 1.56µM and 0.78µM) were prepared by dilution of solution of 100 µM sodium nitrite in PBS.

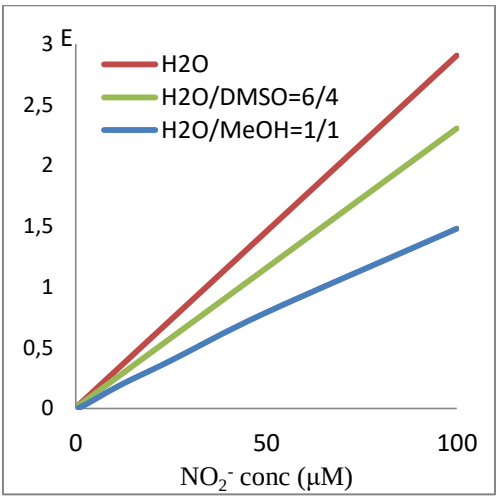

Fig. 3. Nitrite detection by the Griess assay using different solvents

Preparation of Griess reagents

The modified Griess reagent consists of NED solution (0.34%, *w/v*) in distilled water and SULF solution (3.4% *w/v*) in 10% (*w/v)* phosphoric acid.

Method validation

The developed method was validated by studying the following parameters: linearity, detection limit, quantification limit, precision, accuracy, in accordance with the guidelines on bioanalytical method validation (9-11).

Preparation of sodium nitrite standard curve

To avoid the precipitation of NO-NSAID derivatives and to allow hydrolysis of NO-releasing moiety different co-solvents like DMSO and MeOH were used, which were added to water. As noted in figure 3, the presence of the co-solvents interferes with the measurement of absorbance for the final azo dye compound and decreases the slope of the calibration curve for NO_2^-. Given the shorter assessment time, stability of the final azo dye, low cost of solvents, solubility of the NO-NSAID in a wide range of concentrations, we chose to

validate the modified Griess assay using MeOH as co-solvent.

In a micro plate reader, an aliquot of 170µL from the working sodium nitrite solution (in the range of 0.78-100µM) was added to 50µL SULF solution. After 10 min, 50µL NED solution was added and the absorbance of the formed pink-red azo dye was measured at λ_{max}=540 nm, after 20 min. A blank sample was prepared under the same conditions (170µL PBS, 50µL SULF and 50µL NED). The experiment was repeated 5 times for each concentration and the average absorbance was calculated. The calibration curve was constructed by plotting the average absorbance value *vs.* the corresponding nitrite concentration.

Precision

The precision of the method was studied as intraday and interday variation under optimal working conditions, by measuring the absorbance of the sample in triplicate. Three different concentrations of sodium nitrite (10µM, 25µM and 50µM), as reference substance, were used. The intraday precision was determined by absorbance measurements of each sample three times during the same day, while the interday precision was determined by absorbance measurements of the same sample for 3 days over a week.

Accuracy

In order to establish the accuracy of the developed method, different sodium nitrite stock solutions (20µM, 40µM and 60µM) were analyzed. For each sample4 determinations were performed.

Sensitivity

The sensitivity of the method developed for the measurement of $NO_2^-$was analyzed in terms of the limit of quantification and limit of detection.

RESULTS AND DISCUSSION

Linearity

Linearity was studied over a concentration range of 0.78-100 µM sodium nitrite. The average absorbance value was calculated for each concentration (tab. I) and was graphically represented vs. concentration (fig. 4). Statistical analysis of the experimental data leads to regression line equations. The linear regression data for the calibration curve showed good linear relationship over the concentration range. Linear regression equation was found to be f(x)= 0.0159*x + 0.0491.The standard error (SE) of regression curve and the *Pearson* correlation coefficient (r2) were also calculated.

TABLE I

Absorbance values of the samples, at different sodium nitrite concentrations

Concentration (µM)	Sample absorbance					
	Series 1	Series 2	Series 3	Series 4	Series 5	Average
100	1.64125	1.64325	1.643	1.64275	1.64	1.64205
50	0.8525	0.85375	0.854	0.85425	0.85625	0.85415
25	0.44975	0.45	0.45	0.45075	0.45025	0.45015
12.5	0.259	0.25925	0.259	0.25925	0.259	0.2591

0.78125	0.057	0.057	0.057	0.057	0.05775	0.05715
	Range 0.781-100 µM, Pearson coefficient (r^2)=0.99988					

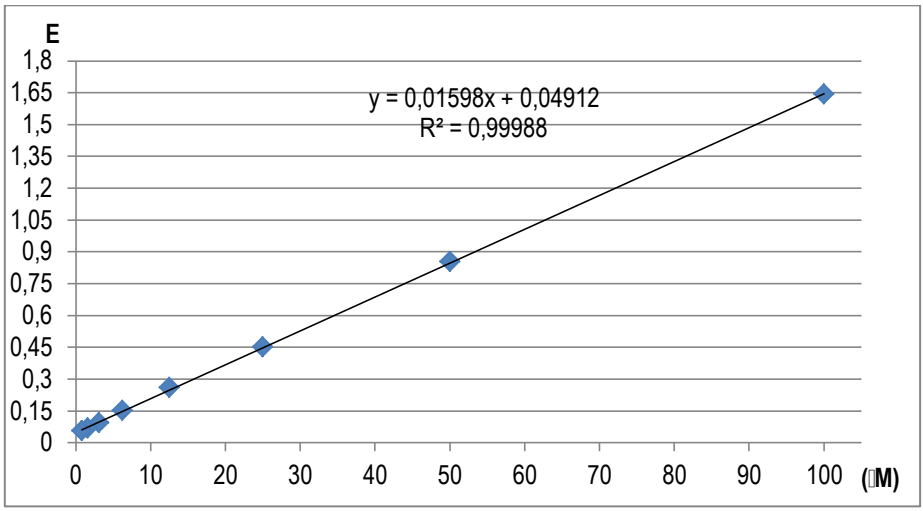

Fig. 4. Calibration curve for NO_2^- detection

Limit of quantification and detection

The limit of detection (LOD=3.3 x Standard error/Slope)was calculated to be 1.32 µM and the limit of quantification (LOQ=10 x Standard error/Slope*)* was 4.02 µM, meaning that our results are in agreement with other studies that used the calibration curve for quantitative measurements(12).

Accuracy

Sample concentration was calculated based on the experimental absorbance data and the regression curve equation, the results being presented in Table II. It was noticed that recovery was between 98.34% and 101.96% (100±2%) for the studied concentration range, and the coefficient of variation <2. The relative standard deviation (RSD) was also calculated. The results proved that the developed method has a high degree of accuracy.

TABLE II

The results related to the accuracy of the developed method

Concentration (µM)	Absorbance value	Calculated concentration (µM)	Recovery (%)	RSD (%)
20	0.375	20.393	101.96	1.38%
	0.365	19.767	98.84	
	0.371	20.143	100.71	
	0.367	19.892	99.46	
40	0.701	40.793	101.98	1.50%
	0.685	39.792	99.48	
	0.679	39.417	98.54	
	0.693	40.293	100.73	
60	1.017	60.568	100.95	1.53%
	0.992	59.004	98.34	
	0.999	59.442	99.07	
	1.023	60.944	101.57	

Precision

The precision could be expressed as the coefficient of variation (CV) or the relative standard deviation (RSD), and the results are presented in Table III. The obtained results support the reproducibility of the method. The RSD (%) values were less than 2%, confirming that the method has a high degree of accuracy and precision and thus can be used for the quantitative measurements of NO from different NO donors, such as NO-NSAIDs.

TABLE III

The results related to the precision of the developed method

Theoretic concentration (μM)	Intra-day precision		Inter-day precision	
	Concentration found (μM)	RSD (%)	Concentration found (μM)	RSD (%)
10	10.12	1.37%	9.87	1.69%
	9.95		10.2	
	9.85		9.97	
25	24.81	0.79%	24.76	0.80%
	24.96		24.88	
	25.2		25.15	
50	49.01	0.90%	48.95	0.75%
	48.85		49.62	
	49.68		49.55	

CONCLUSIONS

The developed UV-Vis method is quite simple, cheap, rapid, precise, accurate, reproducible, and sensitive for the determination of nitrite from different samples. It could be successfully used for the determination of NO released from new NO hybrid donors like NO-NSAIDs with high molecular weight and poor solubility in aqueous medium.

IRON DEFICIENCY AND ANEMIA AFTER BARIATRIC PROCEDURE - ROUX-EN-Y GASTRIC BYPASS

Obesity is a complex, multifactorial, and largely preventable disease, affecting, along with overweight, over a third of the world's population today. Treatment of obesity can be with diet, exercises and surgical treatment of obesity that involves restrictive surgical interventions like gastric sleeve, Roux-en-Y gastric bypass (RYGB), biliopancreatic diversion. Bariatric procedure RYGB reduce capacity for food intake and absorption of energy from the food. The downside is that reduce the main sites for absorption of essential vitamins and minerals, like folate, vitamin B12, calcium and iron. Iron deficiency and anemia are common in the long run after RYGB. Major falls in iron stores appeared more than 2 years after surgery, when many patients are no longer followed. Individualized advice on iron supplements and access to intravenous iron treatment when iron stores were depleted seemed to reduce the frequency of anemia. These patients need for lifelong individualized iron supplements. A better access to intravenous iron treatment can contribute to improve health after RYGB. (Sandvik J, Hole T, Klockner CA, *et al*. Intravenous Iron Treatment in the Prevention of Iron Deficiency and Anemia After Roux-en-Y Gastric Bypass. *Obes Surg* 2020; 30(5): 1745-1752).

DESIGN, CHARACTERIZATION AND BIOCOMPATIBILITY EVALUATION OF POLYMERIC NETWORKS AS CARRIERS FOR INDOMETHACIN MODIFIED RELEASE (Abstract): Pharmaceutical nanotechnology's progression expands drug versatility, utilizing carrier systems to efficiently deliver active ingredients to targeted tissues for controlled release within effective concentrations. Integrating nonsteroidal anti-inflammatory drugs (NSAIDs) into nano-systems holds potential for enhancing pharmacokinetic properties and diminishing adverse effects. **Aim**: Our study concentrated on formulating nanoparticles embedding indomethacin (IND), characterizing them, exploring drug release dynamics, and assessing their biocompatibility in rats. **Materials and methods:** IND was loaded within copolymeric networks comprising poly(2-hydroxyethyl methacrylate-co-3,9-divinyl-2,4,8,10-tetraoxaspiro [5.5]-undecane) and poly(aspartic acid) (PAS) as a protective colloid, employing a dispersion polymerization approach. Fourier transform infrared spectroscopy (FT-IR) characterized the copolymeric matrices, and spectrophotometric analysis via dissolution method evaluated in vitro IND release. In vivo biocompatibility was gauged by monitoring hematological, biochemical, and immune parameters in rats. **Results:** Our developed nano-systems effectively loaded IND within polymeric matrices. The kinetics of IND release were influenced by copolymer composition, with lower comonomer concentrations extending release duration. The investigated copolymer networks incorporating IND did not elicit significant hematological, biochemical, or immune changes when administered to rats. **Conclusions:** the studied polymer samples exhibited promising in vivo biocompatibility, positioning them as potential candidates for IND modified-release systems with prospective biomedical applications. **Keywords:** INDOMETHACIN, COPOLYMERS, MATRIX, IN VIVO BIOCOMPATIBILITY, RATS.

Nanotechnology is the scientific domain focused on manipulating matter at an almost atomic level to create fresh structures, materials, and devices. This technology holds the potential for significant advancements across various sectors, including medicine, consumer products, and industry. Nanomaterials typically range in size from 1 to 100 nanometers (1), and at this scale, they exhibit distinct properties that profoundly affect their physical, chemical, and biological characteristics (2). Pharmaceutical technology is constantly evolving, engaging in activities such as the preparation and manufacture of medicines to enhance pharmacological properties and minimize adverse effects. This aims to improve patient compliance with therapy and overall satisfaction with medical care (3).

Nanoparticles exhibit a higher cellular uptake efficiency compared to larger micro molecules, making them attractive candidates for efficient transport and delivery systems. In therapeutic contexts, drugs can be either incorporated within the particle matrix or affixed to the particle's surface. An effective drug targeting system should have the capacity to regulate the drug's behavior within the biological environment, particularly its pharmacokinetics (4,5).

Inflammatory diseases impact a considerable global population, and NSAIDs are frequently used in their treatment. In recent years, the utilization of nano-systems incorporating NSAIDs has shown promise in amplifying anti-inflammatory effects while reducing adverse effects (6). However, conventional NSAID treatments often entail weeks of administration, leading to undesired side effects and necessitating repeated dosing. NSAIDs function by inhibiting cyclooxygenase enzymes responsible for converting arachidonic acid into prostaglandins (7). Due to their short half-life and high protein binding, substantial doses of NSAIDs are required for efficacy, leading to adverse effects such as an increased risk of gastrointestinal and cardiovascular complications (8, 9).

In order to address these limitations, there is a growing interest in utilizing systems with dimensions ranging from a few tenths to several hundred nanometers. Nowadays, it is feasible to create biocompatible formulations with precise control over their shape, size, and surface charge, and to obtain innovative drug carrier for modified the NSAIDs release (10-14).

IND is an indole derivative NSAID, possessing anti-inflammatory, analgesic, and antipyretic properties. These effects are achieved by reducing the production of prostaglandins through the inhibition of cyclooxygenases. Notably, it exerts a more pronounced inhibition of COX-1 compared to the COX-2 enzyme (15).

Due to its strong anti-inflammatory properties and moderate analgesic effects, indomethacin is approved for use in both articular and extra-articular inflammations (such as pericarditis, pleurisy, and uveitis), dysmenorrhea, chronic pelvic pain, migraines, persistent arterial canal in newborns, and managing fever from Hodgkin's disease (7, 8). Literature indicates that indomethacin suppresses small intestinal motility and can inhibit stretch-dependent responses in visceral smooth muscle (16, 17), particularly in the gastrointestinal tract, mediated by mechanosensitive interstitial cells of Cajal located in the circular and longitudinal muscle layers (18). Indomethacin has also demonstrated beneficial effects in COVID-19 patients by counter-

acting the virus's mechanisms that exacerbate the disease. These mechanisms involve the inhibition of cyclooxygenases, regulation of the renin-angiotensin system, blocking of pro-apoptotic proteins, reduction of the excessive inflammatory response due to elevated bradykinin levels, and antiviral activity (19, 20)

Indomethacin belongs to Biopharmaceutics Classification System class II, characterized by its low solubility and high permeability (21). Given the limited utility of IND due to its adverse effects, particularly gastric irritation (22), integrating it into nano-systems and optimizing its release could yield several pharmacological advantages. This approach holds promise for reducing gastrointestinal side effects and fine-tuning its anti-inflammatory and antinociceptive effects following administration in laboratory animals (15).

Our **objective** was to develop polymeric networks capable of loading IND as carrier systems to facilitate modified drug release.

MATERIALS AND METHODS

Our research team synthesized matrices through copolymerization of poly 2-hydroxyethyl methacrylate (p-HM) with varying proportions of other polymers. We utilized poly(2-hydroxyethyl methacrylate-co-3,9-divinyl-2,4,8,10-tetraoxaspiro [5,5]-undecane) to create carrier systems for IND, incorporating three different concentrations of undecane (IND-U-1.75, IND-U-3.5, IND-U-10), effectively embedding IND (10 wt% of the copolymer weight, dissolved in ethanol/phosphate buffer solution at pH = 7.4). These macromolecular systems were synthesized via dispersion polymerization using 4,40-azobis (cyanopentanoic acid) as a radical initiator, alongside sodium lauryl sulfate as a surfactant and poly(aspartic acid) as a water-soluble condensation biocompatible and biodegradable polymer, which acted as a colloidal protector (23). This addition enhanced the absorption capacity of the network, bolstered its stability, and conferred resistance to chemical degradation, owing to the highly cross-linked nature of poly(aspartic acid), characterized by an amine-terminated aliphatic polyurea structure. These copolymer systems, incorporating IND, underwent physicochemical characterization. The presence of IND within the copolymer matrices was assessed using FT-IR. The in vitro drug release profile was determined spectrophotometrically via the dissolution method.

The biocompatibility of these nano-systems was examined in vivo by assessing their impact on various hematological, biochemical, and immune parameters in rats. Four groups, each comprising five healthy, non-genetically modified white male Wistar rats, were utilized. These rats were administered the test substances orally in a single dose using an eso-gastric tube. The groups included: C (control, receiving distilled water at a dosage of 0.1 ml/100 g body weight); p-HM (receiving p-HM); IND-U-1.75 (receiving IND-U-1.75); and IND-U-10 (receiving IND-U-10). One day and one week following the administration of the substances, 0.3 mL of blood was drawn from the lateral tail vein for laboratory analyses. The following determinations were conducted: leukocyte formula (including polymorphonuclear - PMN, lymphocytes - Ly, eosinophils - E, monocytes - M, basophils - B), serum levels of aspartate aminotransferase (AST),

alanine aminotransferase (ALT), urea, creatinine, complement, and the phagocytosis capacity of peripheral blood polymorphonuclear neutrophils (PMN), assessed through the nitroblue tetrazolium reduction (NBT) test. These investigations aimed to evaluate the impact of the tested substances on liver and kidney function, as well as the immune defense capacity of the laboratory animals.

The *in vivo* experiment protocol adhered to the guidelines set forth by the Ethics Commission of the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi, aligning with current European ethical regulations (24).

RESULTS

Polymeric networks containing IND were synthesized earlier with varying ratios of comonomers (23). We selected two of these networks for examination concerning their in vivo biocompatibility in rats. The aim is to utilize them subsequently to explore their impacts on inflammatory responses in acute and subacute inflammation models, which are experimentally induced in the laboratory.

Polymeric networks loaded with IND have been synthesized and characterized. FT-IR spectroscopy confirmed the presence of both comonomers, the conformation of the bioactive compound, and the loading process of IND onto the polymeric matrix. The absorption bands at 532 cm^{-1} and 927 cm^{-1}, alongside the shifting of major peaks of the polymers, verified the uptake of the drug by the two distinct networks (fig. 1).

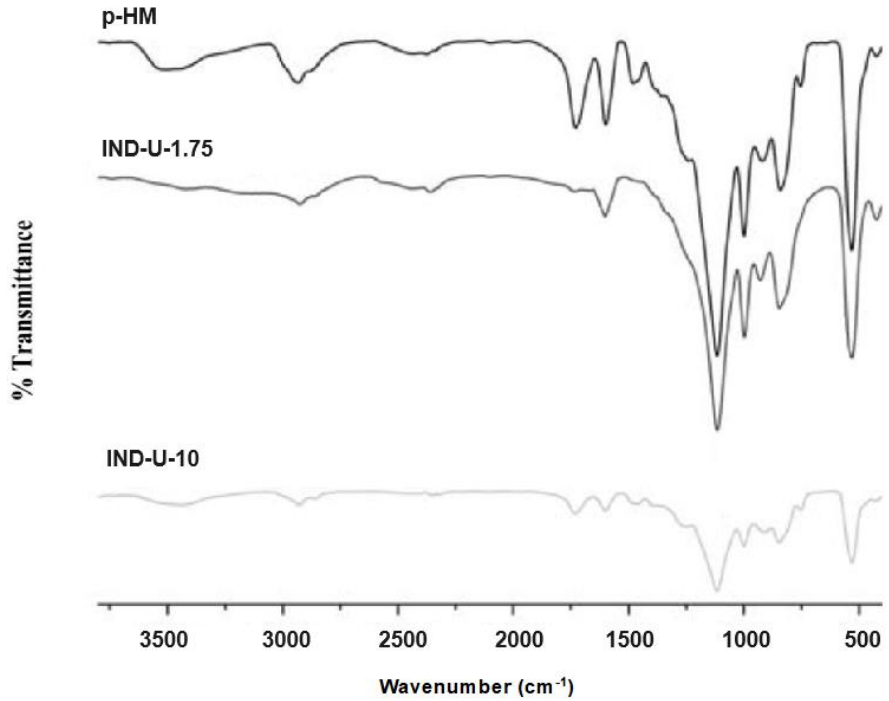

Fig. 1. FT-IR spectra of the copolymeric networks incorporating IND

DISCUSSION

Examining the in vitro kinetic profile of IND reveals that the percentage of undecane significantly impacts the drug release rate from the polymer matrices. Specifically, nearly 60% of the IND quantity is released from the IND-U-1.75 copolymer within the initial 120 minutes, and over 90% within 500 minutes, reaching a release plateau after 750 minutes. Conversely, in the system with a higher concentration of undecane (IND-U-10), the drug is released at a notably slower rate over time, with no observed release plateau even after 2500 minutes (fig. 2).

After one day, as well as after seven days in the experiment, no significant differences were observed in the percentage values of PMN, Ly, E, M, and B between groups C, p-HM, IND-U-1.75, and IND-U-10 (tab. I).

No notable changes were observed in the activity of ALT, AST, urea, and creatinine serum levels among the groups of animals studied. This indicates that the administration of the tested substances did not evidently impact the liver and kidney function at any of the assessment time points (tab. II).

Serum complement activity and phagocytosis capacity of PMN remained relatively stable after both 24 hours and one week in all studied groups. This implies that the investigated nano-systems had minimal impact on the immune defense capacity of the rats (tab. III).

Considering the restricted application of IND owing to its adverse effects, notably gastric irritation, incorporating it into nano-systems and refining its release mechanism could offer several pharmacological benefits. This strategy shows potential for mitigating gastrointestinal side effects and optimizing its anti-inflammatory and antinociceptive effects upon administration in laboratory animals. Literature sources have revealed diverse strategies for developing nano-formulations incorporating IND, employing either preformed polymers or lipids (25).

Over time, a variety of strategies have been employed to develop nano-systems for the transport and release of IND, including:

- incorporation of phospholipids or lipid emulsions with IND, utilizing lipid, surfactant, and co-solvent mixtures (26,27);
- formulation of liposomal IND, encompassing plurilamellar monophasic vesicles with components such as stearylamines, cholesterol, or chitosan, as well as sterically stabilized liposomes (28,29);
- development of bioconjugates of IND, including triacylglycerides containing indomethacin, bioconjugates with phosphatidylcholine, palmitic acid, and stearic acid (30,31);
- development of enteric nanoparticles containing IND, utilizing materials such as EUDRAGIT® L100, polyethylene glycol, and polysorbate 80 (32);
- preparation of amorphous nanosuspensions containing IND stabilized with polyvinylpyrrolidone, achieved through the aqueous wet milling method (33).
- obtaining of chitosan nanoparticles with IND through the ion gelation method by adding an aqueous solution of tripolyphosphate anions (34).

CONCLUSIONS

Polymeric matrices composed of poly(2-hydroxyethyl methacrylate-co-3,9-divinyl-2,4,8,10-tetraoxaspiro [5,5]-undecane) and poly(aspartic) acid were synthesized as platforms for the controlled release of IND. The kinetic profile of IND is contingent upon the copolymer composition, wherein a lower concentration of comonomer leads to a prolongation in drug release duration. Treatment with both types of copolymer networks incorporating IND did not induce significant hematological, biochemical, or immune alterations, indicating favorable in vivo biocompatibility. This suggests that these polymeric systems hold potential for controlled drug release, with potential applications in the biomedical field.

QUALITATIVE ASSESSMENT OF PRE- AND PRO-PROSTHETIC REHABILITATION OUTCOMES IN EXTENSIVE PARTIAL EDENTULISM (Abstract): **Aim** of this study was to evaluate the outcomes of the pre- and post-prosthetic rehabilitation of the prosthetic field status in patients with extensive partial edentulism. **Materials and methods:** This prospective research was conducted on a cohort of 194 patients (mean age 56.46 years ± 0.738 years). The study group included patients with extensive partial edentulism candidate to removable prosthetic treatment or implant-prosthetic therapy. The evaluation of the prosthetic field status during the pre-treatment stage and at the completion of the pre- and post-prosthetic stages was conducted by quantifying the variables associated with the following clinical-biological indices: general status; dental support; periodontal support; bone support; mucous support; occlusion support; mandibulo-cranial support. **Results:** Highly significant differences were recorded between primary and secondary clinical-biological indices after pre- and pro-prosthetic treatment. In the study group, 57.7% of cases remained steady, while 34.5% improved by 25%, and 7.7% by 50%. No cases reached a 75% improvement. **Conclusions:** Significant improvements were observed across most indices, particularly in secondary scores. Clinical indices, such as occlusion and mandibulo-cranial relationships, are the most responsive to pre- and post-prosthetic interventions. **Keywords:** EXTENSIVE PARTIAL EDENTULISM, PRE-PROSTHETIC, PRO-PROSTHETIC, REHABILITATION.

INTRODUCTION

Edentulism is recognized as a major public health issue, considering projections that the proportion of the population over 65 years old will significantly increase to 26% by 2030 (1, 2). The complications of extensive partial edentulism include dental migrations, extrusions, facial changes, and temporomandibular disorders (3). A successful prosthetic treatment must focus on the possibilities to improve all components of stomatognathic system muco-osseous addressing the common complications of the partial extensive edentulism (such as malocclusion, mandibular latero-deviations, TMJ pain, muscular disorders, abnormal cranial-mandibular relationships (3). Thus, pre- and pro-prosthetic stages are essential for correcting the unfavorable clinical-

biological indices of the prosthetic field, considering the inter-connection of the components of the stomatognathic system (4). Thus, optimal biomechanical stability of the prosthetic restorations can be reached only with favorable clinic-biological indices of the prosthetic field. Pre-prosthetic and pro-prosthetic procedures must address the potential etiologies from different perspectives (5), while the dental practitioner must have a comprehensive understanding of the status prosthetic field components status, including remaining teeth, periodontal indices, mucosal-osseus support, occlusion, as well as cranio-mandibular relationship (6). Alveolar bone resorption and unregular residual ridge are the most important complications of extensive partial edentulism. Also, occlusion and cranio-mandibular relationships are directly influenced by edentulism complications such as temporo-mandibular joint (TMJ) pathology (7). Systemic status (neuromuscular control, psychological state, overall health resilience) (8), local factors such as number and position of missing teeth, mandibular movement patterns, as well as financial criteria or patient' preferences must be considered in the planning of the prosthetic treatment (9).

AIM OF STUDY

The study aimed to evaluate the outcomes of the pre- and post-prosthetic rehabilitation of the prosthetic field status in patients with extensive partial edentulism.

MATERIALS AND METHODS

The prospective research was conducted on a cohort of 194 patients (age: mean age 56.46 years ± 0.738 years, range 41-78 years; gender: 105 men, 89 women). The study included patients with extensive partial edentulism candidate to removable prosthetic treatment in Clinical Base of Faculty of Dental Medicine, "Grigore T. Popa" University of Medicine and Pharmacy Iasi.

The evaluation of the prosthetic field status during the pre-treatment stage and at the completion of the pre- and post-prosthetic stages was conducted by quantifying the variables associated with the following clinical-biological indices:

- General status (GSI);
- Dental support (DSI);
- Periodontal support (PSI);
- Bone support (BSI);
- Mucous support (MSI);
- Occlusion support (OSI);
- Mandibulo-cranial support (MCSI).

The clinical-biological indices were measured using the clinical scoring scale developed within the Department of Extensive Partial Edentulism and Removable Restorations, Faculty of Dental Medicine, "Grigore T. Popa" U.M.Ph. Iași:

- 1 (low),
- 2 (medium),
- 3 (good),
- 4 (very good).

The status of the prosthetic field was evaluated during the pre-treatment stage (primary indices) and upon completion of the pre- and post-prosthetic stages (secondary indices). The quantification of clinical-biological indices during the initial stage outlines the therapeutic project framework, which serves as the basis for selecting non-specific and specific prosthetic field preparation procedures. The statistical analysis of the collected data was performed using *SPSS version 27.0*. The Marginal Homogeneity Test was used to compare primary

and secondary indices and assess statistical significance.

RESULTS

The table 1 presents the distribution of scores across different indices (primary and secondary), highlighting changes in general status, dental support, periodontal support, mucosal support, bone support, occlusion, mandibulo-cranial relationship, and total score. The results are analyzed using the Marginal Homogeneity Test, with significant differences noted for most indices.

General Status Indices (GSI):

-For the primary index, 90.2% of cases scored as "Very Good," while 9.8% scored as "Good."

-For the secondary index, 91.8% of cases scored as "Very Good," and 8.2% as "Good." No significant difference was observed when it was compared with primary GSI ($p = 0.083$).

Dental Support Indices (DSI):

-In the primary index, the scores were distributed as 10.3% "Very Good," 61.3% "Good," and 28.4% "Medium."

-For the secondary index, 45.4% scored as "Good" and "Very Good," respectively, with 9.3% scoring "Medium." A significant difference was observed when it was compared with primary DSI ($p < 0.001$).

Periodontal Support Indices (PSI):

-For the primary index, 57.7% of cases were "Very Good," 34% "Good," and 8.2% "Medium."

-The secondary index scored as 82.5% "Very Good," 16% "Good," and 1.5% "Medium." The difference was highly significant when compared with primary index ($p < 0.001$).

Mucosal Support Indices (MSI):

In the primary index, 28.9% scored as "Very Good," 59.8% as "Good," and 11.3% as "Medium."

For the secondary index, 35.6% scored "Very Good," 63.4% "Good," and 1% "Medium," with significant differences between primary and secondary indices ($p < 0.001$).

Bone Support Indices (BSI):

Primary scores were 38.7% "Very Good," 48.5% "Good," and 12.9% "Medium."

Secondary scores showed 46.9% "Very Good," 44.3% "Good," and 8.8% "Medium."

The differences were significant between primary and secondary indices ($p < 0.001$).

Occlusion support indices (OSI):

-For the primary index, 84% were classified as "Low," 6.7% as "Medium," 7.7% as "Good," and only 1.5% as "Very Good."

-Secondary scores shifted notably, with 44.3% as "Low," 15.5% as "Good," and 34% as "Very Good." This change was highly significant ($p < 0.001$).

Mandibulo-Cranial Relationship indices (MCRI):

-In the primary index, 33% scored "Very Good," 10.8% "Good," 7.7% "Medium," and 48.5% "Low."

-Secondary scores showed a significant improvement, with 57.7% as "Very Good," 8.8% as "Good," and only 23.2% as "Low" ($p < 0.001$).

Total Score:

-The primary index recorded 9.3% "Very Good," 69.6% "Good," and 21.1% "Medium."

-Secondary scores showed a shift, with 45.4% "Very Good," 47.4% "Good," and 7.2% "Medium," with highly significant difference when compared to primary index ($p < 0.001$).

TABLE I.

Qualitative scores of the prosthetic field (pre- *vs.* post-treatment)

SCORES		Low		Medium		Good		Very good		Marginal Homogeneity test
		N	%	n	%	n	%	n	%	
General status	Primary					19	9.8	175	90.2	p = 0.083
	Secondary					16	8.2	178	91.8	
Dental support	Primary			55	28.4	119	61.3	20	10.3	p < 0.001**
	Secondary			18	9.3	88	45.4	88	45.4	
Periodontal support	Primary			16	8.2	66	34.0	112	57.7	p < 0.001**
	Secondary			3	1.5	31	16.0	160	82.5	
Mucous support	Primary			22	11.3	116	59.8	56	28.9	p < 0.001**
	Secondary			2	1.0	123	63.4	69	35.6	
Bone support	Primary			25	12.9	94	48.5	75	38.7	p < 0.001**
	Secondary			17	8.8	86	44.3	91	46.9	
Occlusion	Primary	163	84.0	13	6.7	15	7.7	3	1.5	p < 0.001**
	Secondary	86	44.3	12	6.2	30	15.5	66	34.0	
Mandibulo-cranial relationship	Primary	94	48.5	15	7.7	21	10.8	64	33.0	p < 0.001**
	Secondary	45	23.2	20	10.3	17	8.8	112	57.7	
TOTAL SCORE	Primary			41	21.1	135	69.6	18	9.3	p < 0.001**
	Secondary			14	7.2	92	47.4	88	45.4	

The distribution of the clinical biological indices changes after the pre- and post-prosthetic stages is exposed further (Table 2; Fig.1). For DSI, 48.5% of cases maintained a steady state, while 49% exhibited a 25% improvement, and 2.6% showed a 50% improvement. No cases achieved a 75% improvement. For PSI, 70.6% of cases remained steady. Improvements were observed in 27.3% of cases at 25%, and 2.1% at 50%. No cases reached a 75% improvement. For MSI, 84.5% of cases remained steady, while 13.9% showed a 25% improvement, and 1.5% demonstrated a 50% improvement. There were no cases with a 75% improvement. For BSI, majority (88.7%) showed no change, while 10.3% experienced a 25% improvement, and 1.0% achieved a 50% improvement. No cases reached 75% improvement. Occlusal indices showed more dynamic changes: 52.1% remained steady, while 7.7% improved by 25%, 16.0% by 50%, and 24.2% by 75%. This index demonstrated the highest rate of significant improvement. For mandibulo-cranial relationships, 64.9% of cases showed no change, with 13.9% improving by 25%, 4.6% by 50%, and 16.5% achieving a 75% improvement. In the study group, 57.7% of cases remained steady, while 34.5% improved by 25%, and 7.7% by 50%. No cases reached a 75% improvement.

TABLE II.

Qualitative scores changes during pre- and pro-prosthetic treatment

SCORES CHANGES	Steady		Improvement 25%		Improvement 50%		Improvement 75%	
	n	%	n	%	n	%	n	%
General status	191	98.5	3	1.5				
Dental support	94	48.5	95	49.0	5	2.6		
Periodontal support	137	70.6	53	27.3	4	2.1

Mandibulo-cranial relationships	126	64.9	27	13.9	9	4.6	32	16.5
SCOR TOTAL	112	57.7	67	34.5	15	7.7		

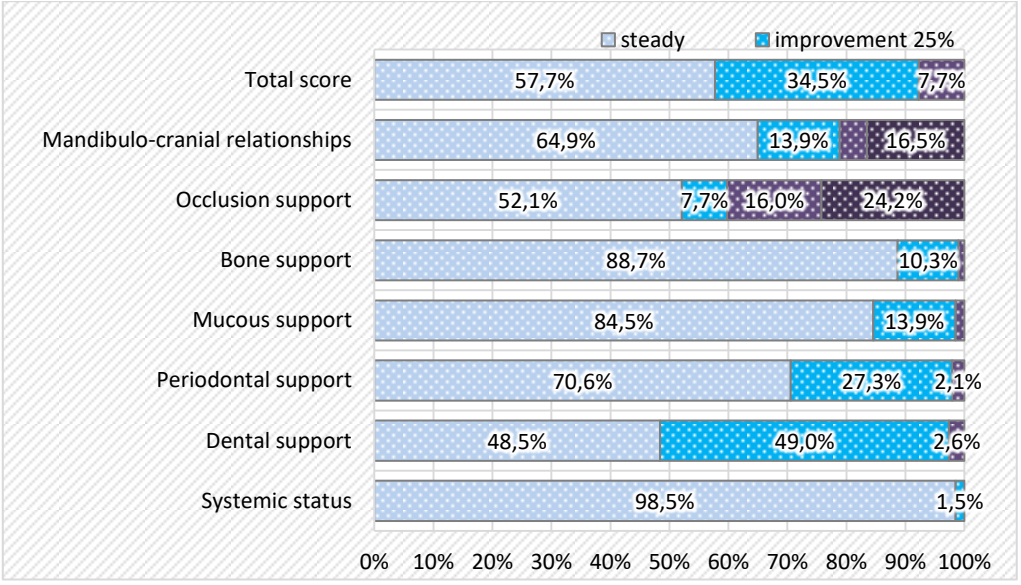

Fig. 1. Changes of clinical biological indices of prosthetic field after pre- and pro-prosthetic stages

DISCUSSION

Various studies have analyzed the prevalence of extensive partial edentulism and its implications, but a review highlighted a lack of research exploring the correlations between edentulism and biological factors (10). The evaluation of the prosthetic field involves important anatomical and physiological aspects, along with the identification of optimal strategies for the pre- and post-prosthetic stages. Ensuring the stability of the prosthetic field in edentulous patients before implementing prosthetic treatments is

essential (11).

In this context, the aim of our research was to use of a qualitative scoring system developed at the Faculty of Medicine, "Grigore T. Popa" U.M.Ph. Iași, in the evaluation of the outcomes of pre- and post-prosthetic preparation of the prosthetic field. A significant improvement in odontal support indices can be achieved through the treatment of carious lesions, non-carious lesions, and crown reshaping or resurfacing (12). Similarly, significant improvement in periodontal support indices is achieved through non-surgical therapy for periodontal disease, sometimes combined with specific surgical procedures during the post-prosthetic stage (flap surgeries, grafts, or guided tissue regeneration techniques) (13). Improvements in mucosal and bone support indices can be achieved through mucosal grafting interventions and bone augmentation procedures (14). Diagnosing occlusal and mandibulo-cranial relationship disorders is essential for prosthetic treatment planning and ensuring a favorable prognosis for future prosthetic restorations (15). Interventions aimed at improving occlusal indices, combined with transitional prosthetics, have allowed normalization of mandibulo-cranial relationships. When mandibular-cranial misalignment occurs, dysfunctions of the stomatognathic system are exacerbated, restricting therapeutic options (16). Improving occlusal indices is also necessary to avoid instability, aesthetic compromises, and inadequate contours of future dentures (17).

The relevance of clinical and biological indices as tools for planning prosthetic treatment in patients with extensive partial edentulism has been highlighted by similar studies utilizing expert systems (18-20). The scoring system used in this study can be further validated and refined in future research with larger study groups and various types of edentulism and prosthetic therapeutic solutions. Qualitative scoring systems can also be incorporated into expert systems or AI-based applications to optimize long-term outcomes of prosthetic treatments.

CONCLUSIONS

The qualitative scoring system allows the planning of the pre- and pro-prosthetic interventions requested to improve unfavorable prosthetic field of the edentulous patients as well as the evaluation of the outcomes of pre-prosthetic and pro-prosthetic therapeutic procedures in the rehabilitation of the prosthetic field for patients with extensive partial edentulism. Significant improvements were observed across most indices, particularly in secondary scores. Clinical indices, such as occlusion and mandibulo-cranial relationships, are the most responsive to pre- and post-prosthetic interventions. These changes reflect advancements in prosthetic rehabilitation outcomes, with notable improvements in periodontal, mucosal, and bone support, occlusion, mandibulo-cranial relationships, and overall scores.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

PATIENT RELATED PROGNOSTIC FACTORS IN HEAD NECK CANCERS: COMORBIDITIES AND AGE-FOCUS ON TUBERCULOSIS AND ON GERIATRIC ONCOLOGY (Abstract): Head and neck cancers are often diagnosed in the late stages, the evolution being often unfavorable even if the multimodal treatment is administered correctly. In principle, it can be considered that there are three categories of factors involved in prognosis: patient, tumor and treatment related-factors. The **aim** of the study was to highlight the involvement of patient-related factors in the prognosis of locally advanced, recurrent and metastatic head and neck cancers. **Materials and methods:** After the initial selection, including the identification of cases treated in the Oncology Clinic and the Oncology outpatient clinic, the study group included 190 patients. Among them, after applying the general inclusion and exclusion criteria, 149 cases of head and neck cancers were selected. Patients admitted to the oncological record in the period 2002-2021 with all anatomical locations of head and neck cancers, stage III and IV: nasopharynx, oropharynx, larynx, hypopharynx, oral cavity, glands salivation, nasal cavity and paranasal sinuses, cervical lymph node metastases of unspecified starting point - Cancers with Unknown Primary (CUP). **Results:** The presence of comorbidities in the case of patients with head and neck cancer, but especially pulmonary tuberculosis, active, reactivated or sequelae, is associated with an unfavorable prognosis. Studies are needed to analyze in more detail the implication of the association between pulmonary tuberculosis and each subtype of head and neck cancer. **Conclusions:** There is an increased incidence of neurological pathologies, especially stroke compared to the results published in the literature. In our study, age >65 years was not identified as a significant prognostic factor, but a tendency to reduce survival to more than 2 years in the case of geriatric patients should be mentioned. **Keywords:** HEAD AND NECK CANCERS, PROGNOSTIC, OS, COMORBIDITIES, TUBERCULOSIS, GERIATRIC.

INTRODUCTION

Head and neck cancers are often diagnosed in the late stages, the evolution being often unfavorable even if the multimodal treatment is administered correctly. In principle, it can be considered that there are three categories of factors involved in prognosis: patient, tumor and treatment

related-factors. If the histological tumor type, TNM staging, the anatomical tumor site, the biological and genetic profile and the type of treatment are factors recognized as being involved in the prognosis, the characteristics of the patient including age, gender, and comorbidities are less evaluated, without a consensus in the reported results. These factors could be directly involved in the prognosis but could also limit the option of oncological active therapies. If the impact of age is currently the subject of studies promoted by the Geriatric Oncology Society (SIOG), there seems to be a mutually reinforcing relationship between tuberculosis and head and neck cancer. Comorbidities are evaluated by doctors within prognostic scores and less individually (1-4).

The aim of the study was to highlight the involvement of patient-related factors in the prognosis of locally advanced, recurrent and metastatic head and neck cancers.

MATERIALS AND METHODS

After the initial selection, including the identification of cases treated in the Oncology Clinic and the Oncology outpatient clinic, the study group included 190 patients. Among them, after applying the general inclusion and exclusion criteria, 149 cases of head and neck cancers were selected.

Inclusion criteria

- Patients admitted to the oncological record in the period 2002-2021 with all anatomical locations of head and neck cancers, stage III and IV according to the International Classification of Diseases (ICD) version 10 of 2019: nasopharynx, oropharynx, larynx, hypopharynx, oral cavity, glands salivation, nasal cavity and paranasal sinuses, cervical lymph node metastases of unspecified starting point - Cancers with Unknown Primary (CUP);
- Patients for whom there was histopathological confirmation of the disease;
- Patients for whom the date of death is known;
- Patients staged according to AJCC TNM version 6;
- Patients who have undergone at least one type of active oncological treatment for curative or palliative purposes;
- Synchronous and metachronous cancers provided that the first location is in the head and neck area.

Exclusion criteria

- Cases declared oncological for objective reasons without histopathological confirmation;
- Patients alive or lost from evidence at the time of analysis;
- Patients for whom there are no data on the oncological therapies administered or who have only benefited from symptomatic palliative treatment;
- Patients with CUP with metastases in other anatomical regions than the cervical one;
- Patients diagnosed with another malignancy prior to the diagnosis of head and neck cancer;
- Patients with skin carcinomas including malignant melanoma in the head and neck region;
- After applying the general inclusion and exclusion criteria in the study group which included 147 cases, the mean and median age of the patients was 69.1 years, respectively 62 (32-88) years.

RESULTS

Median overall survival (OS) in the study lot was 10 months (1-192) (figs. 1, 2).

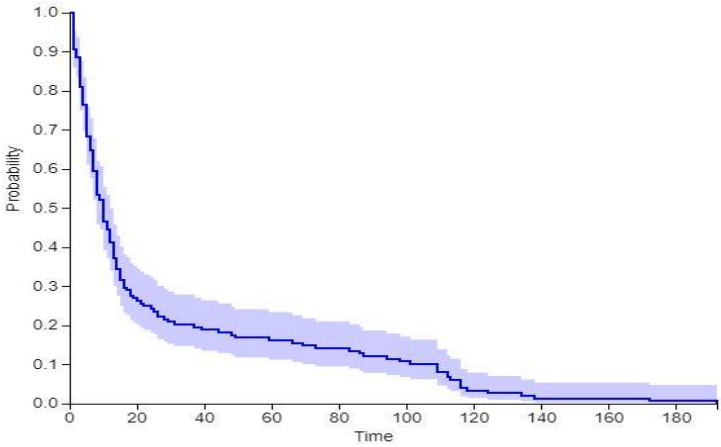

Fig. 1. Kaplan-Meier curves analyzing survival in head and neck cancers

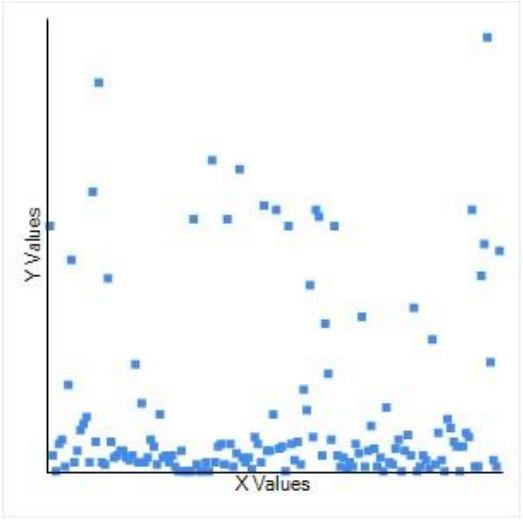

Fig. 2. Relationship of age (horizontal axis) with survival expressed in months (vertical axis)

The male gender was predominant in the study group, 129 cases (86.57%) being men and 19 (12.75%) females. The mean and median age of male patients was 61.4 and 62 (32-81) years, respectively. Median survival for the male patient group was 10 (1-192) months. Mean and median age of female patients was 65.1 and 63,5 (45-88) years, respectively, and median survival was 5 (1-113) months (fig. 3).

Only one case (0.7%), 66 years old, in the study group was diagnosed and treated for a nasopharyngeal neoplasm, with a median survival of 39 months. The second least common type of head and neck neoplasm was hypo-pharyngeal cancer, diag-

nosed in 17 cases (11.5%). The mean and median age was 63 and 61.5 (41-82) years, respectively, and the median OS was 5(1-112) months. CUP with cervical metastases were diagnosed in 18 cases (12%). The mean and median age was 63 and 61 (41-82) years, respectively, with a median survival of 6 (1-124) months in this cancer subtype. A number of 43 cases representing 28.9% of the total were located in the oral cavity, the mean and median age being 62.3 and 61 (32-88) years, respectively, and the median survival of 8 months (1-116) months. In the case of oropharyngeal cancers, the median OS of 10 (1-192 months) was identified in the group of 25 patients (16.8%) with mean and median age of 60.1 and 60 (44-79) years, respectively. The use of at least one of the treatments with a potential curative purpose (surgery, chemotherapy, radiotherapy) was a mandatory inclusion criterion.

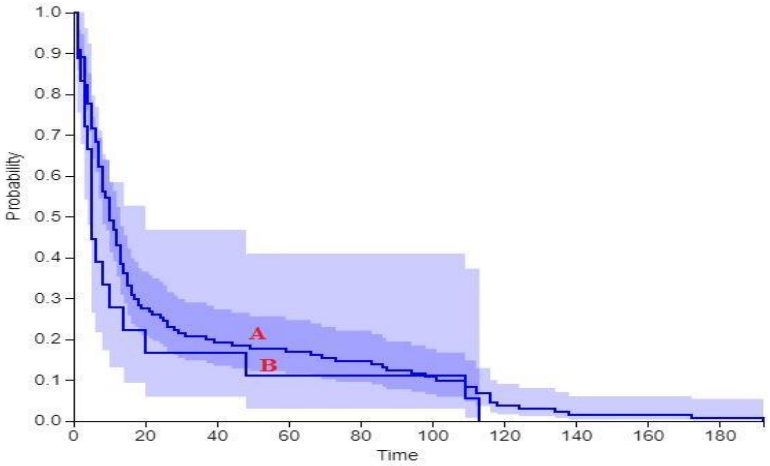

Fig. 3. Kaplan-Meier curves comparing survival in head and neck cancers by gender: A - men, B - female

The comorbidities reported (declaratively or based on the records of the medical documents presented by the patient) were identified in 62 cases (41.6%), 87 of the patients (53.38%) not declaring the presence of known pathologies. With a P=0.427 value, the association of comorbidities with median survival does not show statistical significance. In the group of patients without comorbidities, the median survival was 10 (1-138) months, and in the group of patients with comorbidities median OS was 11 (1-192) months. Hypertension, ischemic heart disease, type II diabetes mellitus (DM), and history of stroke were the most frequently reported associated diseases (figs. 4, 5). The presence of pulmonary tuberculosis either in medical history, as a disease reactivated during multimodal treatment, or identified as imaging sequela has been evaluated as a predictor of survival in head and neck cancers. Even though a negative correlation of pulmonary tuberculosis with prognosis was identified, it was not considered statistically significant (P=0.55). Active pulmonary tuberculosis or sequela of tuberculosis were identified in 13 cases (8.72%), the remaining 136

(91,27%) being cases without other comorbidities other than tuberculosis. The mean and median age of patients diagnosed with tuberculosis was 55,8 and 55 (32-71) years, respectively, and that of patients without a history of tuberculosis or active disease of 62,4 and 62 (41-88) years, respectively (figs. 6, 7).

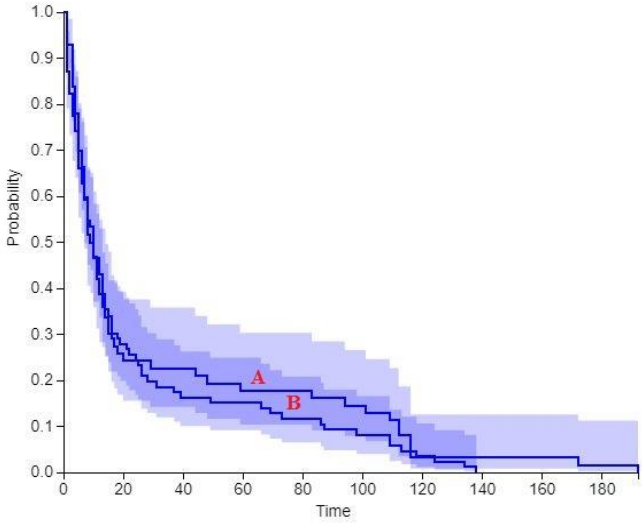

Fig. 4. Kaplan-Meier curves comparing survival in head and neck cancers according to the absence (A) or presence (B) of comorbidities

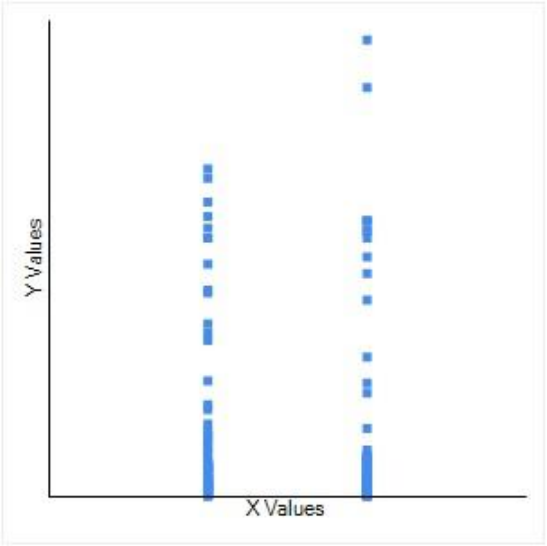

Fig. 5. Correlation of the presence of comorbidities (horizontal axis: left – no declared comorbidities, right – one or more comorbidities present) with survival expressed in months (vertical axis)

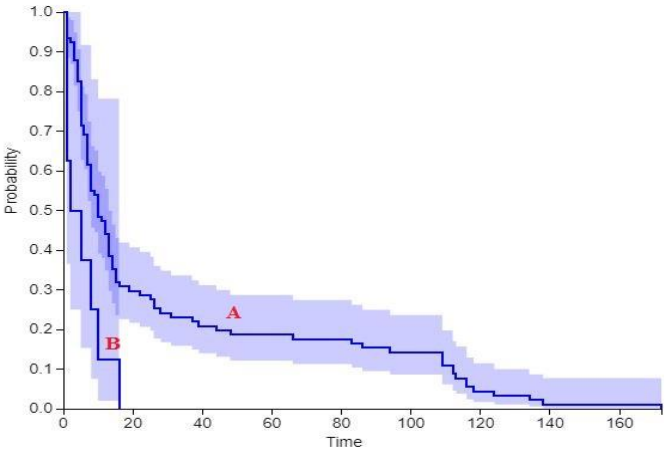

Fig. 6. Kaplan-Meier curves comparing survival in head and neck cancers according to the absence (A) or presence (B) of tuberculosis (active disease, reactivated or sequelae) after oncological diagnosis

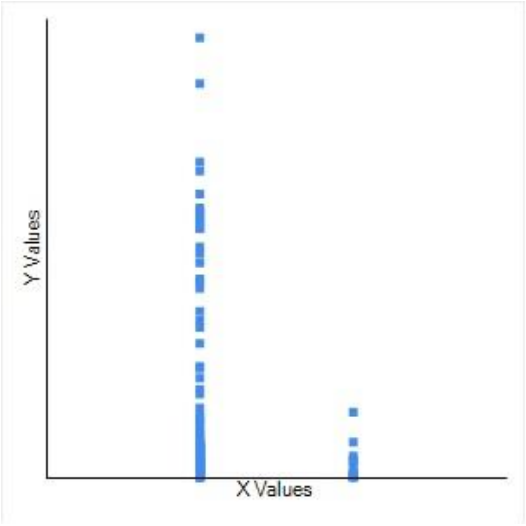

Fig. 7. Correlation of active disease, reactivated or sequelae of pulmonary tuberculosis (horizontal axis: left – no tuberculosis, right – tuberculosis) with OS in months (vertical axis)

For the correlation of age at diagnosis with the prognosis, the median OS was comparatively analyzed in the group of patients aged ≤65 years and >65 years. Even though a negative correlation was identified between advanced age and median survival, a p=0.4 value did not reveal a conclusive statistical significance. A number of 96 (64.4%) patients included in the study were aged ≤65 years, the mean and median age in this group being 56,4 and 57 (32-65) years, respectively. Median survival for patient

≤65 years was 9 (1-192) months. A number of 53 (35.6%) cases were diagnosed at ages >65 years. In this group, the mean and median age was 72.1 and 71 (66-88) years, respectively, and the median survival was 11 (1-134) months (figs. 8, 9).

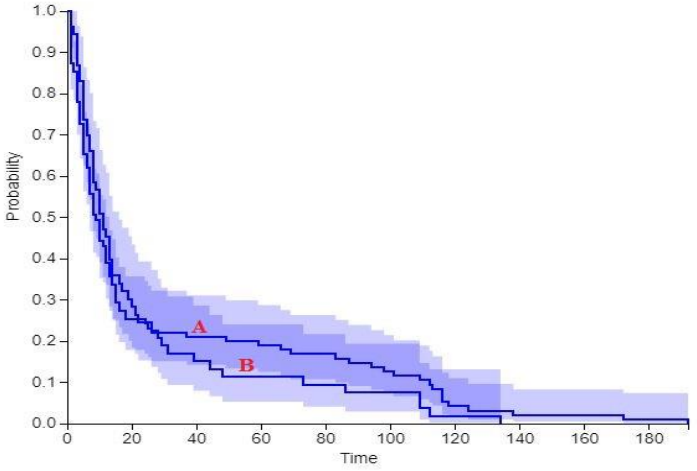

Fig. 8. Kaplan-Meier curves comparing survival in head and neck cancers by age: A ≤65 years, B>65 years

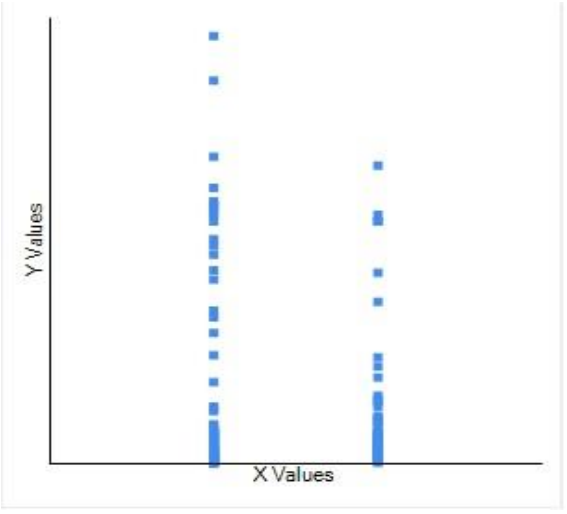

Fig. 9. Correlation of age (horizontal axis: left - age: ≤65 years, right - age >65 years with survival expressed in months (vertical axis)

The co-occurrence of comorbidities is identified as an unfavorable prognostic factor both in our study and in the literature. In the proposed study, hypertension and cardiovascular diseases, diabetes and neurological diseases are the most fre-

quently reported comorbidities in association with head and neck cancers. The advantage in terms of median OS in the group of patients without reported comorbidities is one month. Chronic obstructive pulmonary disease and dyslipidemia are reported in the literature as being among the most common pathologies associated with head and neck cancers, but are not found in the proposed analysis. It is possible that these diseases are underdiagnosed, and the identification of comorbidities based on medical records and patient statements is another possible source of error. It should be noted the high rate of chronic neurological pathologies associated with head and neck cancers, especially the sequelae of stroke, as possible consequences of the therapeutic neglect of hypertension and diabetes. The presence of comorbidities is associated with an increased risk of mortality 30 days after completion of treatment, and the possibility of survival at 1 year in the case of patients with severe comorbidities is considered below 50%. Active pulmonary tuberculosis, sequelae of tuberculosis or disease reactivation during oncological treatment is identified in 8.72% of head and neck cancers. Even if the negative correlation of the association of the two diseases with the prognosis was not statistically significant, lower survivals are noted in the group of patients who associate tuberculosis and head and neck cancer. The relationship between the two diseases is considered bidirectional, the presence of the disease in the antecedents favoring carcinogenesis. A cancer diagnosis can increase the risk of pulmonary tuberculosis by 2.9 times compared to the general population. The risk of tuberculosis in the case of patients with head and neck cancer is considered to be higher in the first 6 months after treatment, but remains high afterwards. The mechanism of this association is not elucidated, but it is assumed that nutritional status and immunosuppression associated with oncological therapies increase this risk. Referring to subjects without any cancer, the adjusted hazard ratio (HR) for pulmonary tuberculosis for patients with head and neck cancer not receiving chemotherapy and radiotherapy is 1,26, but it is 3,74 for patients with head and neck cancer receiving chemotherapy or radiotherapy. However, there are no consistent data to analyze each anatomical location of head and neck cancers (5-11).

Cases of multiple myeloma, leukemia, esophageal cancer, lung cancer, pancreatic cancer are also associated with an increased risk of developing primary or reactivated tuberculosis. In an endemic area of Korea, a 10-time higher incidence of tuberculosis is reported in patients diagnosed with cancer than in the general population. According to Preda *et al*. carcinogenesis induced by M. tuberculosis infection could be associated with some factors including immunosuppression, pro-inflammatory cytokines related to infection, and DNA damage (12, 13).

The study by Matsuo *et al*. mentions higher values of the risk of associating tuberculosis in patients with head and neck cancers, the authors considering that the risk being as much as 16 times higher than in the general population. In this context, the authors consider prophylactic therapy appropriate, especially for patients who require long-term treatment under continuous hospitalization, the risk being both for patients and for the community. Wang and colleagues consider the relationship be-

tween tuberculosis and cancer to be symbiotic, with both diseases having similarities in their effect on the immune system and pathogenesis (14-16).

In our study, using the threshold of 65 years to define geriatric patients, 35.6% of cases fell into this category. Median survival is superior (11 months) both for patients older than 65 years, as well as for those aged up to 65 years, in relation to the values obtained for the general group. Even though approximately 30% of head and neck cancers are elderly (>70 years), this subcategory of geriatric patients is underrepresented in clinical trials. However, there is a tendency to reduce survival rates after the first 2 years of follow-up. According to the MARCH-NC meta-analysis, only 5% of elderly patients are included in the database. Mere assessment of eligibility for maximal multimodality treatment based on age or Eastern Cooperative Oncology Group (ECOG) and Karnofsky performance indices cannot identify those patients for whom standard treatment may be detrimental. The use of scales and instruments that evaluate comorbidities, social, nutritional status and poly-medication confirms that applying the principles of geriatric oncology could limit acute and late adverse effects by identifying cases that require de-escalation of treatment. Thus Zhou *et al.* proposed a nomogram with prognostic purpose for elderly patients with cancers of the oral cavity. Hemoglobin level, neutrophil-to-lymphocyte ratio (NLR), body mass index (BMI) and nodal tumor invasion status are included in this nomogram. The Geriatric Oncology Society (SIOG) proposes, along with the G8 geriatric scale, the comprehensive geriatric assessment (CGA) for the pre-therapeutic identification of fragile patients. A G8 score $\leq$ 14 can be considered suggestive both for the prognosis and for the radiotherapy discontinuation rate and for a prolonged postoperative recovery. The Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) can be used to predict the adverse effects of chemotherapy. Evaluation using the G8 questionnaire includes 8 items (diet, weight loss, mobility, neuropsychiatric impairment, polymedication, age and self-reported health status) and is easier than CGA, De-escalation of radiotherapy treatment including both dose reduction total, the dose per fraction and the number of fractions, but also the reduction of target volumes are concepts addressed in geriatric oncology of head and neck cancers. At least 4 scales Charlson Comorbidity Index (CCI), Osaka head and neck comorbidity index (OHNCI), the Adult Comorbidity Evaluation-27 (ACE-27) Kaplan Feinstein Comorbidity Index (KFI) are currently used to evaluate comorbidities and their involvement in prognosis. However, as demonstrated by Kallogjeri *et al.* the use of scales such as ACE-27 is easy, but useful in predicting the impact of comorbidities on survival, especially in the case of more lethal cancers such as breast cancer and prostate cancer. Geriatric Depression Scale (GDS), Cumulative Illness Rating Scale-Geriatric, Mini-Nutritional Assessment, Functional Assessment of Cancer Therapy-General (FACT-G) are evaluation scales used to quantify some characteristics of geriatric patients, being useful in defining the administration criteria of active oncological therapy and especially tolerance to chemotherapy. The geriatric frailty present more intensely in the case of these patients can be explained by

the history of smoking and alcohol consumption, but also of cardiovascular and metabolic comorbidities. Being less represented in clinical trials, elderly patients with head and neck cancers must be included in trials to accurately identify prognostic factors and optimal therapeutic management (17-23).

CONCLUSIONS

The presence of comorbidities in the case of patients with head and neck cancer, but especially pulmonary tuberculosis, active, reactivated or sequelae, is associated with an unfavorable prognosis. Studies are needed to analyze in more detail the implication of the association between pulmonary tuberculosis and each subtype of head and neck cancer. There is an increased incidence of neurological pathologies, especially stroke compared to the results published in the literature. In our study, age >65 years was not identified as a significant prognostic factor, but a tendency to reduce survival to more than 2 years in the case of geriatric patients should be mentioned.

INSIGHTS ON THE ESTIMATE OF COSTS IN ROAD TRAFFIC ACCIDENTS (Abstract): Traffic road accidents represent a major challenge for public health at world level regarding the morbidity, mortality, but also the economic implications. This study is a systematical literature review with the objective to synthesize the knowledge relating the estimate of the road traffic accidents cost, identifying, selecting and evaluating the studies carried out up to the present time to reach a consensus on this matter. When we speak about the total cost of road accidents, we should be considered four main categories: costs in the event of death, costs in the case of non-fatal injury, costs generated by the material damage and administrative costs. This study has conducted an analysis of all components of the total cost of road traffic accidents and enabled a methodological framework for conducting accurate estimates in future studies. The need for studies on this subject is given by the necessity of ways to create, precedence and verification of the methods of road traffic accidents prevention and the traffic participants protection. Finally, a true picture of the economic impact of road traffic accidents allows a complex contouring of this public health problem. **Keywords**: ECONOMIC BURDEN, ESTIMATION, ROAD TRAFFIC ACCIDENTS

Traffic road accident is a fortuitous event, unpredictable, produced from the guilt of one or more participants in road traffic, which causes damage to the vehicles involved as well as the injury, mutilation or even death of the persons involved (1).

Traffic road accidents represent a major challenge for public health at world level regarding the morbidity, mortality, but also the economic implications. Following World Health Organization (WHO), all over the world are produced approximately 1,250,000 of deaths and between 20 and 50 million people are injured in road accidents. In the 2015 WHO's report, Romania appears with some 1861 deaths in 2013, representing a ratio of 8,7 to 100,000 inhabitants, in a slight decrease compared with previous years. These data point out that in comparison with the Western European states, in Romania, the mortality rate is still much higher, even though it is one of the countries which belong to the „Road Safety Program 2011-2020". The most affected category of road users is that of pedestrians, followed by drivers (2).

The economic consequences of this true traumatic outbreaks are hard to assess, at

the property damage is added the efforts to save the casualties, medical assistance granted to the survivors and economic loss by cutting off their productive activity or their invalidity (3-5).

Up to the present, in Romania has not been carried out an estimate of the total costs of road accidents, there isn't a methodological framework for achieving this. This study analyzes data from scientific literature regarding the calculation of these costs and proposes to create a foundation of the methodological framework stated above.

METHODOLOGY

This study is a systematical literature review with the objective to synthesize the knowledge relating the estimate of the road traffic accidents cost, identifying, selecting and evaluating the studies carried out up to the present time to reach a consensus on this matter. Data collection was carried out by searching the electronically databases platforms: PUBMED, RESEARCHGATE, WEB OF SCIENCE and GOOGLE ACADEMIC using combinations of keywords such as: „cost, traffic accidents, estimation, injury, death, economic burden". In this article, there were included studies containing information on the estimation and cost calculation methods of road accidents, the categories of costs which make up the total cost, the types of data, their origin and the way they have been analyzed and the problems encountered in collecting the data.

RESULTS AND DISCUSSION

When we speak about the total cost of road accidents, we should be considered four main categories: costs in the event of death, costs in the case of non-fatal injury, costs generated by the material damage and administrative costs (6-9).

Costs in the event of death

The costs in this category include: costs generated by receiving proper medical up to death, the costs relating to the handling of the corpse after death, the losses suffered by the family and the community, recouping the loss of life, recouping the lost productivity (9-11).

The costs generated by medical care

This category includes costs from pre-hospital emergency medical cares and intra-hospital emergency compartments medical care's costs (10). Most of the victims of road accidents benefit from these medical cares, and the costs they involve are related to the ambulance service (dispatching rooms, transport, medical cares at the spot) and to the emergency compartments (consult investigations, treatment) (12). Regarding intra-hospital medical treatment, in addition to expenditure related to the diagnostic and treatment, costs of hospitalization (accommodation and meal) should be considered and. Given the complexity of these medical cares, their costs are much higher in comparison with other subcategories (10, 13).

The costs relating to the handling of the corpse after death

These costs include the expenses which shall begin immediately after death: corpse transport, autopsy, beautifying, funerals (11, 14). Road traffic accidents are causing violent deaths, and this is the reason for which it is appropriate to carry out forensic autopsies of the victims. Even if this activity costs are related to the category for administrative costs, we decided to include it here to have a full frame of the costs related to the death of persons involved in a road traffic accident.

The losses suffered by the family and the community

This category refers to the loss for the community and family of the activities the deceased carried out on his free-time which include domestic activities (such as cleanliness, cooking, the care of children or other persons) or voluntary activities. All of this can be financially quantified with the rates of the persons who provide these services counter-cost (15, 16).

Recouping the loss of life

Recouping the loss of life is the capitalization of the pain, suffering, and mourning generated by the death of a person. Mishan, Miller, and Viscusi, have used three distinct approaches to assess the economic loss of life: "the court-award", "the injunction public" and "the willingness-to-pay". In Romania, these approaches may be assimilated with the decisions of the claims because of a penal lawsuit, respectively a civil lawsuit (16-21).

Recouping lost productivity

Krupp *et al* they suggested approaches for recouping lost productivity, as follows: "The gross-loss-of output", "the net-loss-of-output" and "value of time" (22). But for the study of the costs of road accidents, most of the authors have used the first approach, being considered the most simple and eloquent in this case (21, 23, 24). This approach calculates the costs relating to the age of the victim and estimated gains in the future. In Romania, the age at which begins productivity is 15 years, and the ending is 64 years (25). Also, it must be considered the unemployment rate, additional revenues included in the gross salary and it should not be forgotten the percentage of people who also work on the black market.

Costs in the case of non-fatal injury

In this category come the costs related to the: medical cares, temporary incapacity for work from the period of convalescent and permanent incapacity for work (16).

The costs generated by the medical care

In addition to the costs generated by pre-hospital emergency and intra-hospital emergency compartments medical cares described above, it adds the costs of primary, specialized long-term and recovery medical care. Primary medical care generates costs related to consulting, investigations and the treatment of the patients with less severe injuries, produced in road traffic accidents, which shall be made directly to the general practitioner. For calculating the costs of long-term specialized and recovery medical cares, it must be considered the periodic checks, home cares, the visits to the general practitioner, therapeutic reinterventions, and healing procedures (10, 26-28).

Costs due to the temporary incapacity for work

Temporary incapacity for work brings additional costs that include costs from adaptation to disability, the allowance of sick leave, loss of productivity and health or life insurance. For calculating the costs related to the adaptation to the disability, it should be considered the changes in the level of dwelling/motor vehicles and the medical devices (wheelchair, crutches, etc.) required for daily activities (22, 29). Per the laws of Romania, any person with a temporary incapacity for work receives an allowance for the sick leave arising because of the multiplication of the daily average calculation basis and the number of working days of sick leave (30). During the

last period, more people in Romania purchases life and private health insurance contracts, because of which the insurance companies, in the case of a temporary incapacity for work, are obliged to pay compensation to the insured (31).

To quantify loss of productivity due to the temporary incapacity for work it shall be considered both loss of productivity at the place of work, which is estimated by multiplying the days of sick leave with the daily gross earnings, and loss of productivity for family and community described earlier in the case of the costs related to death (32).

Costs due to the permanent incapacity to work

Estimating these costs implies: adaptation to disability, disability pension/compensation, lost productivity and health or life insurance. Depending on the degree of working capacity reduction, compensation can be paid monthly, monthly complementary personal budget and accompanying allowance (15, 22, 33). The loss in productivity is also, estimated based on the degree of working capacity reduction, starting from a total loss, in which case it is directly correlated with the loss of productivity in the event of death, described above, goes to the partial loss of working capacity, in which case the number of working hours decreases, the calculation of costs being made taking account the number of working hours lost. In terms of costs related to health or life insurance, compensation for permanent incapacity to work will be higher than if the temporary and will be directly proportional to the deficit (34-37).

Material damage costs

Costs generated by material damages include, in addition to repair costs of vehicles, private properties (houses, shops, fences etc.) or public properties (streets, indicator, guard rails, etc.) and the costs relating to the period in which those mentioned above cannot be used. Here we are talking about the costs of hiring/purchase another vehicle for personal use, public transport costs, the costs of the taxis use; also in the case of scrapping of vehicles for goods or persons transport, its owner will lose his daily income (24, 38).

Administrative costs

Administrative costs cover everything that is related to the road accident from the moment in which it takes place until the file is closed and includes the costs of firefighters and police interventions, the costs of medico-legal (autopsy, medico-legal certificate) and judiciary expenditure (33).

DISCUSSION

Proposal concerning the sources and methods of gathering data to estimate the total cost of traffic accidents in Romania

The conducted literature review allows us to establish a methodological framework for data collection required for the estimation of the total cost of road traffic accidents in Romania.

Having regard to the categories of costs resulting from the studied literature, we appreciate that to estimate the total cost of road traffic accidents it is necessary to collect data from a variety of sources and through different methods such as: analyzing databases of the Ministry of the Interior, Ministry of Health, Ministry of Labor, Family and Social Protection for the Elderly and the Ministry of Justice, analyzing

databases of insurance companies, interviews and questionnaires.

Data relating to the number, type, the severity of accidents, the number of injured or deceased victims, intervention duration, resources used (human and material), the types of material damage, etc. can be collected from the office of the Traffic Police (audits, expense reimbursements). To calculate the costs of injuries caused by traffic accidents, data (such as pre-hospital resources used, type, number, severity, and prognosis of injuries, treatment, investigations, intra-hospital resources used, accommodation and meals costs, etc.) are necessary-these data can be collected from the Ambulance Service, hospitals, general practitioner offices, by analyzing observation sheets, pre-hospital emergency records, Emergency unit records, consultation records and expense reports attached to them.

Calculating the costs related to handling corpses will be done by correlating the number of people killed with the fare imposed by the Forensic Medicine Services on autopsy and embalming corpses and tariffs of the companies that provide funeral services.

For the estimation of the costs of the losses suffered by family and community, it is necessary to use questionnaires to collect information on household and volunteer activities, duration and their frequency, because this information is then correlated with the rates charged by professionals for such activities. To capitalize loss of life, it is necessary to consult the court decisions regarding compensation in cases of road accidents. The costs related to the insurance (health, life and of the material property) will be estimated using data collected from insurance companies and will represent the sum of all compensation in case of road traffic accident considering the type of insurance and the type of damage.

Regarding the costs of adapting to disability, it is necessary to apply a questionnaire to disabled individuals and families of those with disabilities, showing the value of these costs or expenses. For loss of productivity, it is necessary to know the number of fatalities (Office of the Traffic Police), the number of persons with temporary incapacity for work and the period of incapacity and the number of those with permanent incapacity for work and the degree of loss of it and the number of reduced working hours, these figures can be collected from the Bureau of Medical Expertise and Recovery of work capacity.

Finally, in collecting the data shown above, consideration must be given to the following points: limited/restricted access to documents, documents may contain drafting error or may be incomplete, these problems must be identified, corrected and removed. Also, it must be taken into consideration the possibility that a part of the road accidents could not be declared to the police and it could be found only in the databases of the insurance companies.

CONCLUSIONS

When an estimate as accurately as possible of the total cost of road traffic accidents is desired, bear in mind that it is made up of a multitude of components, which requires a thorough analysis and, any difficulties which may arise during the data collection, should be considered, each time.

This study has conducted an analysis of all components of the total cost of road

traffic accidents and enabled a methodological framework for conducting accurate estimates in future studies.

The need for studies on this subject is given by the necessity of ways to create, precedence and verification of the methods of road traffic accidents prevention and the traffic participants protection. Last but not least, a true picture of the economic impact of road traffic accidents allows a complex contouring of this public health problem.

TRENDS IN PREMATURE MORTALITY: UNCONDITIONAL PROBABILITY OF DYING BETWEEN AGES OF 30 AND 70 FROM CARDIOVASCULAR DISEASE, REPUBLIC OF MOLDOVA, 2003-2015 (Abstract) **Aim:** To estimate the burden of premature mortality from major cardiovascular diseases among adults in the Republic of Moldova and to evaluate National target achieving of 1.5% annual relative reduction from 2013-2020. **Material and methods:** We conducted a population-based study. To assess the premature mortality impact was calculated the probability of dying between ages of 30 and 70 from major cardiovascular diseases in the Republic of Moldova following adjusted World Health Organization's methodology. **Results:** Along with the mortality chance up to the age of 70 years for people at the age of 30 years old because of cardiovascular diseases determined to be in decrease trend for the period 2003-2015 from 21.2% to 15.9% ($p<0.001$) is find a rising percentage change of +3.7% of unconditional probability of dying from cardiovascular disease between ages of 30 and 70 in the Republic of Moldova from 2013-2015 instead of planned reduction of -3%. **Conclusions:** These data can be used to inform development of policies that address the observed disparities of national target achieving. **Keywords:** CARDIOVASCULAR DISEASE, PREMATURE MORTALITY, PROBABILITY OF DYING.

Nowadays, cardiovascular disease (CD) is univocally acknowledged as the most serious challenge of the 21st century for public health on global and national level. Such declaration was achieved because of its first place in mortality and general disability ratings, clear loss of life quality and excessive costs. Therefore, CD prevention and control became one of the key elements for the strategy to fight against noncommunicable diseases, which were elaborated in recent years. According to statistics of World Health Organization (WHO), on global level noncommunicable diseases are responsible for a lot more deceases, compared to all other deceases in a sum, having a growth forecast from 38 million up to 52 million of deceases for the 2012-2030-year period (1). A major percentage of deceases (82%) caused by noncommunicable diseases, are due to four specific diseases: cardiovascular disease, cancer, respiratory chronic diseases and diabetes. As a result, they were named major noncommunicable diseases. From the total deaths caused by major noncommunicable CD has a highest proportion of 46.2% versus cancer (21.7%), chronic respiratory diseases (10.7%) and

diabetes (4%) (1).

For the year 2015 in Republic of Moldova major noncommunicable diseases were demonstrated the following distribution: CDs-58%, malignant tumors-15.2%, digestive system diseases-2% and diabetes-0.8%. Therefore, the burden of CD is a big challenge in Republic of Moldova too, having a stable proportion over than 55% for the last decade.

From those 38 million deaths caused by noncommunicable diseases in the year 2012, around 42% were registered as premature deaths, affecting the population of age younger than 70 years old. In 2012, CDs were responsible for the largest proportion of noncommunicable diseases deaths under the age of 70 (37%). At the same time, 48% of premature deaths caused by noncommunicable diseases, happened in countries with low and medium income, and 28%-well developed countries. It is very important to mention that a quite large part of premature deaths is apriority evitable. Deaths caused by CDs were lowered at quite a high rate in countries with a high income, thanks to governmental politics, which contributes for a healthy life style and providing an accessible and affordable medical assistance (1, 2).

The "epidemiological transition" phenomenon from infectious diseases to noncommunicable diseases was caused by the globalization effects, fast urbanization and population aging-low controlled factors by an individual, as well by the health system.

According to WHO declarations (1), the decrease of economical productivity caused by premature deaths, individual and national costs with a reference to noncommunicable diseases serves as an important barrier in poverty decrease and durable development of the country, specifically for countries with a low and medium income. Therefore, the decrease importance of premature mortality caused by noncommunicable diseases is undeniable, being set as the no. 1 global objective from the nine objectives established by global plan of actions for prevention and control of noncommunicable diseases. In this context, the nominalized document foresees a relative decrease of 25% of premature mortality cause by CDs, cancer, chronic respiratory diseases and diabetes until the year 2025, therefore being name as "25x25" objective.

Actual approaches for measuring of mortality phenomenon impact through the prism of premature deaths events, which "changes the accent from the classic focus upon deaths occurrence to centralization upon lost products because of these deaths" (3), offers the evaluation possibility for population's health in the context of life prolonging. Confirmed by the study of global burden of diseases in 2010 (GBD-2010), which estimated that in the period 1990-2010 simultaneously with the lightly decreasing trend for major CDs can be also seen an increase of 17-28% for years of potential life lost caused by ischemic heart disease and cerebrovascular disease, especially stroke (4).

Premature mortality represents the major criteria in the impact evaluation of noncommunicable diseases among the population (1). Therefore, ensuring the achieving of the No.1 global objective ("25x25") is a priority.

MATERIAL AND METHODS

The main study objective was to identify the evolution of premature mortality from CD in the Republic of Moldova for the period 2003-2015 and to determine the National target achieving of 1.5% annual

relative reduction in mortality from CD starting with 2013 year. This research is a population-based descriptive study.

To achieve the aim of the study was applied a descriptive method of investigation using the data and methodology provided by the WHO (1) and statistical data of the National Center of Health Management of the Republic of Moldova (2003-2015) (5).

To assess premature mortality from CD was calculated indicator of unconditional probability of dying between ages of 30 and 70 which is one of the 25 indicators recommended by WHO as monitoring measures for the prevention and control of noncommunicable diseases (1).

The study applied the WHO methodology of calculation to find out the probability of dying between ages of 30 and 70 from CD. The unconditional probability of dying between exact ages 30 and 70 from CDs for each year from the period 2003-2015 was estimated using age-specific death rates (in 5-year age groups).

The International Classification of Diseases codes used are: I00-I99.

First were calculated five-year death rates ($_5^*M_x$) using the equation (1):

$$_5^*M_x = \frac{\begin{matrix}Total\ deaths\ from\\ cardiovascular\ diseases\\ between\ exact\ age\ x\ and\ age\ x{+}5\end{matrix}}{\begin{matrix}Total\ population\ between\\ exact\ age\ x\ and\ age\ x{+}5\end{matrix}} \quad (1)$$

The probability of death for each five-year group ($_5^*q_x$) was calculated using the following formula (2):

$$_5^*q_x = \frac{_5^*M_x * 5}{1 + {}_5^*M_x * 2.5} \quad (2)$$

Unconditional probability of dying between ages of 30 and 70 from cardiovascular disease was calculated using the formula (3):

$$_{40}^*q_{30} = 1 - \prod_{x=30}^{65}(1 - {}_5^*q_x) \quad (3)$$

When between-group differences were compared the summary, percentages were shown with 95% confidence intervals. The significance of the differences between groups was estimated by z-test to compare two proportions.

RESULTS

WHO (1, 6) has established the core objective to reduce the premature mortality cause by CD, cancer, diabetes and chronic respiratory diseases by 25% until the year 2025 (referred as 25x25).

According to WHO strategies, Republic of Moldova has established a national intermediary objective of premature mortality reduction with in part specifications for each of the five priority noncommunicable diseases in the country: cardiovascular disease, cancer, digestive diseases, chronic respiratory diseases, and diabetes. Therefore, reduce percentage for premature mortality until the year 2020, having as a reference year 2013, has constituted for: CD-10%, malignant tumors-7%, digestive diseases, respiratory chronic diseases and diabetes by 10% (7, 8). The premature mortality from CD National Target is a 10% period reduction from 2013-2020 with a 1.5% annual reduction (9, 10).

The probability of dying between ages of 30 and 70 from major noncommunicable diseases was established by the WHO as a monitoring indicator of progresses for objectives achieving in the set amount of time.

The unconditional probability of dying from CD between ages of 30 and 70 by gender in the Republic of Moldova in 2003 and 2015 is shown in (tab. I).

TABLE I

Unconditional probability of dying between ages of 30 and 70 from cardiovascular disease by gender, Republic of Moldova, 2003-2015

Probability of dying 30-70, %		CI, 95%	Difference, (CI, 95%) *p value (z-test)*
2003 (year)			
Male	25.9	25.8, 26.0	8.5 % (8.4, 8.6) p<0.001, z=134.1
Female	17.4	17.3, 17.5	
Total	21.2	21.1, 21.3	
2015 (year)			
Male	21.8	21.7, 21.9	10.8% (10.7,10.9) p<0.001, z=201.9
Female	11.0	10.9, 11.1	
Total	15.9	15.8, 15.9	

In 2003, a 30-year-old individual male had a 25.9% (95% CI 25.8, 26.0) chance of dying from CD before the age of 70.

The study results found a chance of 17.4% (95% CI 17.3, 17.5) in case of 30-year-old individual female of dying from cardiovascular disease before her 70th birthday. In 2003, the unconditional probability of dying from cardiovascular disease between ages of 30 and 70 for males is greater than for females (p<0.001, z=134.1).

In 2015, a 30-year-old individual male had a 21.8% (95% CI 21.7, 21.9) and individual female had an 11.0% (95% CI 10.9, 11.1) chance of dying from CD before age of 70. This represents a greater chance of dying from cardiovascular disease a 30-year-old in 2015 individual male than individual female before his/her 70th birthday (p<0.001, z=201.9), as well as in 2003 (tab. II).

TABLE II

Unconditional probability of dying between ages of 30 and 70 from cardiovascular disease and noncommunicable diseases by gender, Republic of Moldova, 2003-2015

Probability of dying 30-70, %			Difference, (CI, 95%) *p value (z-test)*
	2003	2015	
Cardiovascular disease			
Total	21.2	15.9	5.3% (5.2, 5.4) p<0.001, z=96.5
Male	25.9	21.8	4.1% (4.0, 4.4) p<0.001, z=63.1
Female	17.4	11.0	6.4% (6.3, 6.5) p<0.001, z=127.7
Noncommunicable diseases			
Total	37.0	31.0	6.0% (5.9, 6.1) p<0.001, z=89.7
Male	44.6	40.4	4.2% (4.1, 4.4) p<0.001, z=55.7
Female	30.5	22.6	7.9% (7.8, 8.0) p<0.001, z=123.8

The individual males of 30-year-old had a decreasing trend for chance of dying before age of 70 by CD from 25,9% (95% CI 25.8, 26.0) in 2003 to 21.8% (95% CI 21.7, 21.9) in 2015 ($p<0.001$, $z=63.1$). The decreasing trend of unconditional probability of dying from CD in case of 30-year-old individual female was found to be from 17.4% (95% CI 17.3, 17.5) in 2003 to 11.0% (95% CI 10.9, 11.1) in 2015 ($p<0.001$, $z=127.7$).

The unconditional probability of dying between ages 30 and 70 from CD in the Republic of Moldova had a decreasing trend from 21.2% (CI 95% 21.1, 21.3) in 2003 to 15.9% (CI 95% 21.1, 21.3) in 2015 ($p<0.001$, $z=96.5$). In case of noncommunicable diseases together the individual males of 30-year-old had a decreasing trend for chance of dying before age of 70 from 44,6% (95% CI 44.5, 44.7) in 2003 to 40.4% (95% CI 40,3, 40.5) in 2015 ($p<0.001$, $z=55.7$).

The probability of dying before age of 70 from noncommunicable diseases had a decreasing trend in case of 30-year-old individual female from 30.5% (95% CI 30.4, 30.6) in 2003 to 22,6 % (95% CI 22.5, 22.7) in 2015 ($p<0.001$, $z=123.8$).

The unconditional probability of dying between ages 30 and 70 from noncommunicable diseases in the Republic of Moldova had a decreasing trend from 37,0% (95% CI 36.9, 37.1) in 2003 to 31.0% (95% CI 30,9, 31.1) in 2015 ($p<0.001$, $z=89.7$). Percentage change in unconditional probability of dying between exact ages 30 and 70 from CDs was related to the period of whole investigation from 2003 to 2015. To monitor progress in attaining the National target reducing premature mortality from CD by 2020, percentage change in unconditional probability of dying between exact ages 30 and 70 from cardiovascular diseases was related to the period from 2013 to 2015 as well (fig. 1).

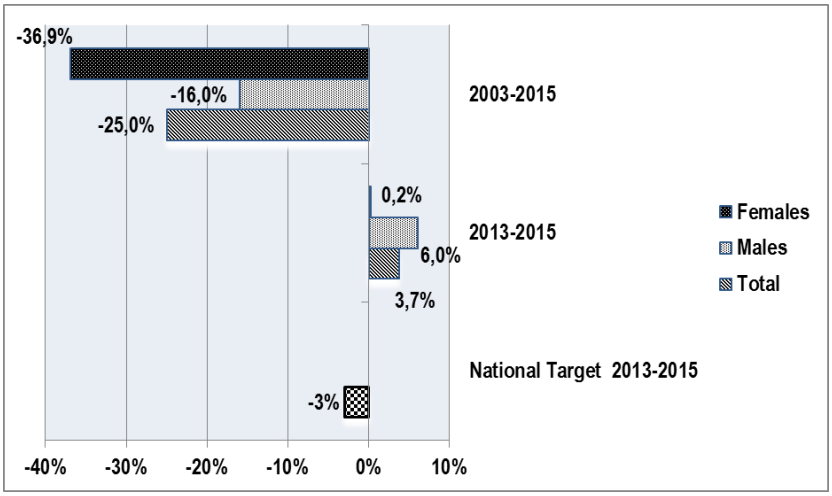

Fig. 1. Percentage change in probability of dying between exact ages 30 and 70 from cardiovascular disease, 2003-2015 and 2013-2015, Republic of Moldova

Change of the probability of dying from CD between ages 30 and 70 from 2003-2015 in the Republic of Moldova represented a 36.9% reduction for males and

16% reduction for females. The chance of dying from cardiovascular disease a 30-year-old individual before age 70 from entire population were found to have a decreasing change of 25%.

The premature mortality from CD national target is a 10% period reduction from 2013-2020 with a 1.5% annual reduction. According this, in 2015 referred to 2013 the expected achieving in premature mortality from CD is 3% reduction.

Despite this, change from 2013-2015 produced the adverse increasing trends comparing to decreasing change 2003-2015. The percentage change of unconditional probability of dying between ages of 30 and 70 by major CDs was estimated as following: +6.0% for males, +0.2% for females, and +3.7% for whole investigated population.

DISCUSSION

According the World Health Organization Global status report on noncommunicable diseases 2014 (1) in 2012, unconditional probability of dying from one of the main noncommunicable diseases between ages of 30 and 70 years was 19%. This, probability varied by region, from 15% in the region of Americas to 25% in the South-East Asia Region. WHO have determined dispersion by country, from greater than 30% especially in low- and middle-income countries to less than 10% in seven countries (Australia, Israel, Italy, Japan, Republic of Korea, Sweden and Switzerland).

In 2012, a 30-year individual from the Republic of Moldova had a 30.7% chance of dying from major noncommunicable diseases before his or her 70th birthday which is the one of the highest level around the world.

In the frame of 2013-2020 national targets achieving the differences over time in describing evolution from 2003-2015 and increasing evolution from 2013-2015 of percentage change of unconditional probability of dying between age 30 and 70 from CD are of great interest. That the adverse upward changes from 2013-2015 must be taken in account to turn trends into decreasing direction again to achieve 2020 National Target of reducing premature mortality from CD.

CONCLUSIONS

1. During the investigation period of 2003-2015, men at the age of 30 years compared to women of the same age identify superior level of frequency for probability of dying until the age of 70 because of a major CD in Republic of Moldova ($p<0.001$);

2. The mortality chance up to the age of 70 years for people at the age of 30 years old because of CDs, as well as for major noncommunicable diseases decrease for the period 2003-2015, respectively 21.2%-15.9% ($p<0.001$) and 37.0%-31.0% ($p<0.001$);

3. Percentage changes (2013-2015) of +3.7% for unconditional probability of dying from CD of a 30-year-old person up to the age of 70 years referred to 2013 year versus those planned as a decrease of 3% for the same period be a warning for nation objective achieving 2013-2020.

OPEN RADIOCARPAL DORSAL FRACTURE-DISLOCATION ASSOCIATED WITH CHRONIC DISTAL RADIOULNAR JOINT DISLOCATION: A CASE REPORT (Abstract): Radiocarpal dislocations are rare clinical entity often caused by high-energy trauma. According to Dumontier are classified into type I: pure radiocarpal dislocations and type II: fractures-dislocations or associated with other injuries. Treatment of these lesions is still controversial in terms of reduction of dislocation and fixation: orthopedic/surgical, K-wires/ external fixator ± ligament reconstruction. We present the case of a 32-years-old male patient, presenting a radiocarpal dislocation Dumontier II, with volar soft tissue injuries type III B Gustilo Anderson associated with an old distal radioulnar joint dislocation. Surgical treatment consisted of antibiotics combined, tetanus prophylaxis, debridement, fasciotomy, open reduction and external fixation, decompression of the median nerve and Z-plasty of cutaneous defect. 3 months postoperatively results were satisfactory, the patient resumed activity level before the accident.
Keywords: RADIO-CARPAL DISLOCATION, OPEN, WRIST, SURGERY.

Radiocarpal dislocation is a rare dislocation with an incidence of only 0.2% (1, 2). It is generally found in young men as a result of high energy trauma, being associated with a high comorbidity and poor functional outcomes (3). According to Moneim (1) and Dumontier (2) radio-carpal dislocations are divided into pure radiocarpal dislocations (type I) and fracture-dislocation or associated to other lesions (type II) (1, 2). It has been published in the literature small series of cases in which there was no consensus about optimum method of treatment (2, 4-8). Some author prefer open reduction and fixation (2, 5) other cast immobilization (8), both reporting good results.

CASE REPORT

A 32-years-old right-handed male, was admitted in the emergency department after an accidental fall from 4 meters. He presented a "dinner fork" deformity of left wrist, a volar III B Gustillo Anderson open fracture, heavy contaminated, and functional impotence.

Local examination revealed paresthesia in the median nerve territory and absent radial pulse with low Doppler signal.

Radiological examination showed a radiocarpal dislocation, Dumontier type I, Moneim I and a chronic dorsal distal ra-

dioulnar joint dislocation. CT scan confirmed the diagnoses and revealed a minor dorsal distal radius comminution.

From the patient's personal history we found out that seven years ago suffered a fracture of the left radius, orthopedic treated.

There was an unsuccessful attempt of reduction in the emergency department under intravenous sedation. The wrist was immobilized on a splint and tetanus and antibiotic prophylaxis in dual therapy (third generation cephalosporin and aminoglycoside) was initiated.

In the operating room under general anesthesia was performed debridement and irrigation of the wound, anterior fasciotomy of the left forearm, exploration of the radial and ulnar neurovascular bundle, decompression and external neurolysis of the median nerve by opening the carpal tunnel, reduction under fluoroscopic control and external fixation. Cutaneous defect of the forearm was covered by Z-plasty.

Fig. 1. Initial clinical aspect

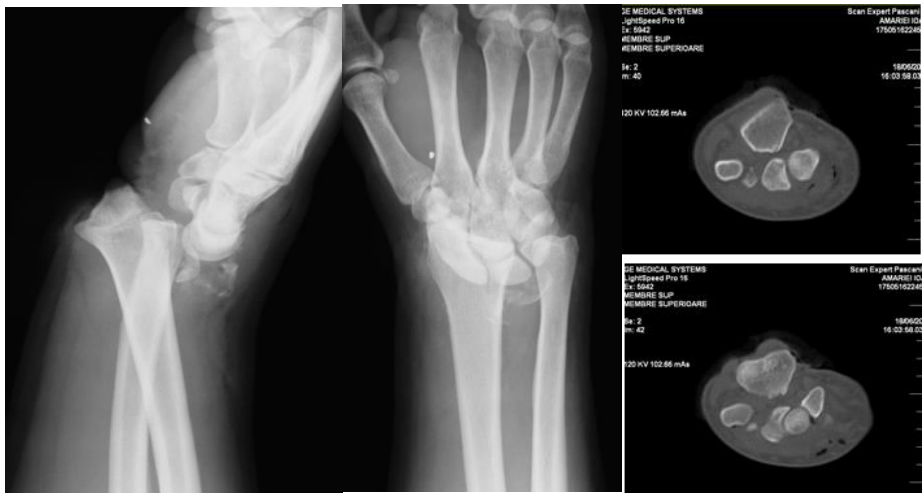

Fig. 2. Initial X-rays. AP view and lateral view

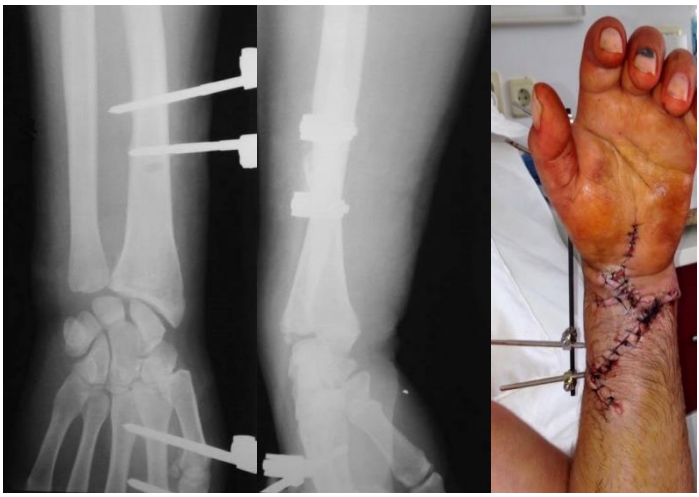

Fig. 3. Cross-sectional CT views

Fig. 1. Immediate postoperative radiographic and clinical aspect

Postoperative evolution was favorable, peripheral pulse was normal and paresthesia in the median territory ceased.

Unfortunately distal radio-ulnar dislocation could not be reduced, opting for functional treatment. Physical therapy was initiated first day postoperatively.

10 days after the intervention the patient was discharged with instructions for clinical and radiological follow-up after 2, 4, 8 and 12 weeks.

Radiological control of 4 weeks identified a dorsal radio-carpal subluxation. The patient refused surgical reintervention.

External fixator was suppressed at 8 weeks postoperatively and a functional recovery program was initiated.

Fig. 2. Clinical results after 12 months

At 3 months, postoperatively the patient had a palmar flexion of 47°, 45° extension, the Disabilities score of the Arm, Shoulder and Hand (DASH) was 28.3 (range 0-100), and the Mayo Wrist Score 60, which is considered a satisfactory result.

DISCUSSION

Starting with the first radiocarpal dislocation reported in the literature by

Varadompun N. in 1926 (8) and continuing with the series of cases reported by Dunn (7), Moneim M.S. (1) and Dumontier C. (2), the treatment of these clinical entities did not reached consensus.

These dislocations are extremely rare, the most common being type II (9). The diagnosis is best achieved by standard radiography (9), but we opiniate for CT scans which brings valuable information on the degree of comminution of the radial styloid process or dorsal/ volar rim of the radius.

Frequently dorsal radiocarpal dislocations are commonly associated with compression of the median nerve that requires decompression (10).

In type I dislocation, treatment is dictated by the possibility of achieving articular congruity and by stability of the reduction. It is imperative to check under fluoroscopy the radiocarpal stability in dynamics in flexion-extension and inclinations to establish the indication for surgical treatment (9).

Stable reductions can be treated orthopedic (8) while unstable reductions require pining (2, 10) or external fixation (2, 11) associated with open (11) or arthroscopic ligamentous repair (6).

CONCLUSIONS

Regardless urgent reduction and efficient contention, radiocarpal dislocations are serious clinical entities with unpredictable prognosis. Due to peculiarities of our patient anatomy, perfect reduction was impossible. Despite radiologic imperfect outcome, patient`s functional outcome was satisfactory. Radiocarpal dislocations require further investigation to establish optimal treatment method connection between treatment and outcome.

BURNOUT AND ALEXITHYMIA AMONG FORENSIC PHYSICIANS (Abstract): **The aim** of the study was to identify the relationship between the level of burnout subdomains and alexithymia among forensic physicians working in forensic institutions in Romania. **Material and methods**: A number of 37 forensic physicians were included in the survey. Burnout and alexithymia were measured by using the *Maslach Burnout Inventory* and *Toronto Alexithymia Scale.* The obtained data were processed using the *SPSS 17.00* statistical software. **Results**: The subjects obtained an average of 43.27±3.71, which corresponds to a low level of alexithymia. For burnout scores, we have obtained M=14.97±13.13 for emotional exhaustion, M=7.91±6.87 for depersonalization and M=33.18±10.59 for personal accomplishment (low-level for emotional exhaustion and medium-level burnout for the other two factors). Among the socio-demographic variables, only the age correlated positively with the burnout factor personal accomplishment. Positive correlations were identified between burnout factors and TAS-20. Comparative analysis results are important for the presence of insomnia, depression, teaching activity and looking for professional support after critical events. **Conclusions**: Scores for forensic physicians are low-level for emotional exhaustion and medium-level for two subdomains and low-level for alexithymia. Factors revealed by the comparative analysis are important to adjust professional activity and to find strategies to cope with stressful professional events. **Keywords:** FORENSIC PHYSICIANS, EMOTIONAL EXHAUSTION, BURNOUT, ALEXITHYMIA.

The burnout syndrome was originally described in relation to the healthcare profession or educators, professions that usually provide care. Burnout is characterized by a high level of emotional exhaustion, a high level of depersonalization and a low level of personal accomplishment. The most important factors related to burnout are the individual ones like personality traits such as neuroticism, extraversion, depression, conscientiousness, alexithymia or type A behavior or socio-demographic and environmental factors such as age, gender, length of experience, working conditions, number of work hours, multiple tasks in a short period, insufficient payment and reward, relationship with colleagues and superiors, or conflicting values (1).

Burnout was considered endemic in the last decades among healthcare profession-

als (2) and it was proved to be associated with a low level of professional performance and with difficult relationships with colleagues and patients. Some studies targeting the different medical specialties identified among doctors suffering from burnout a higher risk of suicidal thoughts, engagement in risky behaviors like tobacco or alcohol, and an increasing number of medical errors.

In a study of Gleichgerrcht and Decety they proved that physicians who have difficulty regulating their negative arousal and describing and identifying emotions are more prone to emotional exhaustion, detachment, and a low sense of personal accomplishment (3). On the other hand, the ability to be aware of emotions and the tendency to help others is in strong correlation with the sense of compassion. Identifying emotions is important in dealing with occupational stress (4, 5). This brings consistent help in clinical practice, where the doctor-patient relationship is important and represents the basis of a trustworthy and more appropriate medical evaluation (3).

Professionals facing critical events are more exposed to high levels of burnout and these scores may result in later psychological distress.

The aim of the study is to identify the relationship between burnout levels for each separate domain and the score for alexithymia among forensic physicians. We wanted to find a correlation between the association of the capacity to identify and describe emotions and levels of emotional exhaustion, depersonalization and personal achievement. As a secondary goal, socio-demographic characteristics and the self-evaluated presence of depression, insomnia and the impact of critical events was established. Less information is available about professional activity, burnout or related factors among forensic physicians in Romania.

MATERIAL AND METHODS

A group of 37 forensic physicians working in 11 different forensic institutions from Romania answered two questionnaires. The research was approved by the Legal Medicine Institute of Iaşi. The questionnaires were self-administered and socio-demographic data were recorded on a separate sheet. The participants were informed about the goal of the study, data privacy and dissemination of results and informed consent was obtained before filling in the questionnaires.

The burnout syndrome was evaluated using the *Maslach Burnout Inventory (MBI)*. The MBI is a 22-items questionnaire used for measuring 3 domains: emotional exhaustion (describing the feeling of being exhausted and drained by one's work, fatigued at the very idea of work, chronic fatigue, sleeping and physical troubles), depersonalization (describing emotional coldness and impersonal reactions to the beneficiaries of one's work – leading to cynicism and negative attitudes with regard to patients or colleagues, feelings of guilt, avoidance of social contacts and withdrawal into oneself), and personal achievement (describing feelings of competence and accomplishment in one's work with other people) (8). The burnout score represents evaluation at three levels: for emotional exhaustion: low (17 or lower), medium (18-29) and high level (over 30) and Cronbach's alpha coefficient was 0.85; for depersonalization, a score under 5 means a low level, a score of 6 - 11 is medium and one over 12 is high and we obtained a Cronbach's alpha of 0.69. For the personal

achievement domain, a total of 33 points or fewer characterizes a high level of burnout, one between and including 34-39 defines a medium level of burnout and a total greater than 40 shows low-level with Cronbach's alpha coefficient 0.82.

To evaluate alexithymia, we have used the *Toronto Alexithymia Scale (TAS)* to assess difficulties with emotional processing and emotional awareness. Forensic physicians rated personal statements on a Likert– scale of 1 (strongly disagree) to 5 (strongly disagree). The scores of the 20 items represent three domains: difficulty of describing feelings, difficulty of identifying feelings, and externally oriented thinking. The third scale evaluates the tendency of individuals to focus their attention externally. It is in fact a cognitive style that avoids introspective thought. A general alexithymia score is calculated as the sum of these three subscales and the final scores provide the level of alexithymia: subjects not having alexithymia (scores equal to or less than 51), subjects having borderline alexithymia (scores of 52 to 60), and subjects having scores equal to or greater than 61 are characterized by alexithymia.

Socio-demographic data were also registered, including: age, gender, department, number of children, length of experience, the self-evaluated presence of depression and insomnia, the use of pills to cope with stress or to evaluate which critical events impressed them the most during their professional work.

RESULTS AND DISCUSSION

Descriptive analysis

The study included 37 forensic physicians: 17 males, (45.95%) and 20 females (54.05%), from 11 forensic medicine institutions in 11 counties, with a mean age of 39.13±11.78 (with a minimum of 25 years and a maximum of 64 years). Considering the professional level, 17 (45.95%) are residents, 3 (8.11%) are specialists physicians and 17 (45.95%) are senior consultants. Regarding the length of experience as a forensic doctor, M=10.61±10.65 years of work experience was recorded, with a minimum of 1 year and a maximum of 32 years. The number of work hours per week was 33.51±9.56 and the mean number of medical shifts per month was 2.94±2.1. Almost ¼ (N=9, 24.32%) of the subjects have academic teaching activity.

Seven subjects (18.92%) were in a relationship, 21 (56.76%) were married, 4 (10.81%) were divorced and 5 (13.51%) were single; 17 subjects have declared that their partner has the same profession (47.22%).

The data collected also focused on recording the subjects' number of children. Over half of them (N=19, 51.35%) did not have children, 10 (27.03%) had one child and 8 (21.62%) of the surveyed forensic doctors had 2 children.

Regarding the alexithymia scale TAS-20, the cut-off scoring is the following: less than or equal to 51 (low-level alexithymia or no alexithymia), greater than or equal to 61 (high-level alexithymia) and 52-60 is possible alexithymia. Our participants obtained an average of 43.27 ± 3.71, which corresponds to low-level alexithymia.

The MBI is comprised of three factors: emotional exhaustion - our subjects obtained an average of 14.97±13.13 in this factor, which corresponds to a low level of burnout, depersonalization-our subjects obtained an average of 7.91±6.87 in this factor, which corresponds to a medium level of burnout and personal accomplishment - our subjects obtained an average of

33.18±10.59 in this factor, which corresponds to a medium level of burnout.

Correlational analysis

To make the correlational analysis and to know which tests we should use in our statistical analysis, we first tested the normality of our data distribution. For this, we used the *Kolmogorov-Smirnov* (K-S) test for all the variables we investigated. For the total score of the *Toronto Alexithymia Scale* we obtained K-S z=0.120, p=0.195 and because p > 0, we conclude that for this variable our scores are normally distributed. For the three factors of TAS-20: difficulty describing feelings K-S z=0.137, p=0.076; difficulty identifying feelings K-S z=0.156, p=0.024 and externally oriented thinking K-S z=0.120, p=0.196. We can see that for almost all the factors of the TAS-20, the score distributions are normal, except for the difficulty identifying feelings, because p<0.05. For the factors of the MBI we obtained the following results: emotional exhaustion K-S z=0.168, p=0.010; depersonalization K-S z=0.195, p=0.001 and personal accomplishment K-S z=0.175, p=0.006 and we can say that the scores are not normally distributed, since for all the factors p<0.05. For the other socio-demographic variables that we considered in this correlational analysis we obtained the following results: age - K-S z=0.160, p=0.018; number of children - K-S z=0.402, p<0.001; years of experience - K-S z=0.263, p< 0.001; hours per week - K-S z=0.300, p<0.001; shifts per month - K-S z=0.222, p<0.001. Since almost none of these variables are distributed normally, especially the burnout factors, to perform the correlational analysis, we used Spearman correlations, a non-parametric test. The results between subdomains of burnout and the other variables in our study are presented in Table I.

TABLE I

Correlation analysis burnout domains - TAS–20 and other socio-demographic variables

	Variables	Emotional Exhaustion	Depersonalization	Personal Accomplishment
TAS-20	Difficulty identifying feelings	**R= .400*, p = .014**	**R = .374*, p = .023**	**R = -.399*, p = .014**
	Difficulty describing feelings	R = .288, p = .083	R = .126, p = .459	R = -.238, p = .157
	Externally oriented thinking	R = .193, p = .253	**R = .339*, p = .040**	R = -.087, p = .610
	Total score in alexithymia	R = .317, p = .056	**R = .342*, p = .038**	R = -.323, p = .051
Variables	Age	R = .130, p = .443	R = -.016, p = .926	**R = .324*, p = .050**
	Number of children	R = -.055, p = .746	R = -.052, p = .758	R = .283, p = .090
	Experience in years	R = .045, p = .796	R = -.225, p = .187	R = .293, p = .082
	Work hours/week	R = .317, p = .064	R = -.105, p = .547	R = .168, p = .336
	Shifts/month	R = -.032, p = .859	R = -.074, p = .684	R = .274, p = .123

No correlation was identified between the following variables: number of children, years of work experience, the number of hours per week or the number of shifts per month and the factors of burnout: emotional exhaustion, depersonalization and personal accomplishment. Among the socio-demographic variables, only the age correlated positively with the burnout factor personal accomplishment. On the other hand, we can see that positive correlations are highlighted between TAS-20's factor

difficulty identifying feelings and the burnout factors: emotional exhaustion and depersonalization while the factor difficulty identifying feelings correlates negatively with personal accomplishment. Also, both the TAS-20's externally oriented thinking factor and the total score in alexithymia correlate positively with the burnout factor depersonalization. Despite this, the TAS-20 factor difficulty describing feelings did not correlate with any of the burnout factors.

Comparative analysis

To identify statistically significant differences, we used the t-test for independent samples even though the scores for most of the variables we analyzed were not distributed normally. There are a lot of authors that suggest that Independent Sample T-Tests are sufficiently robust and can be used even if not all the variables that we analyze are distributed normally. After statistical processing, no statistically significant differences were found between subjects per their gender regarding the burnout factors: emotional exhaustion, depersonalization and personal accomplishment or regarding the TAS-20 factors or the total score of TAS-20.

A recent study focusing on burnout in medical residents suggests that significant differences between male and female subjects have been identified. Gender seems to play an important role when it is about protective factors against burnout: male residents mention social support from colleagues more often, while female residents consider more often that home resources are protective factors against emotional exhaustion (6). Our lot was a small one and comparative analysis was difficult to perform considering these criteria.

Statistical differences have not been observed between the burnout factors (emotional exhaustion, depersonalization, personal accomplishment) in cases when the participant's partner works in the medical field, when the victims of the cases they work on are children, whether these children have been abused sexually or physically, whether women have been abused sexually, whether they have faced aggressive prisoners' suicides, whether they talk to a family member or whether they talk to nobody when they are affected by an event at work or whether they suffer from chronic diseases.

Regarding teaching activity (at universities or forensic institutions), there are significant differences in emotional exhaustion ($t(35) = 2.08$, $p = 0.045$), in that those with no teaching activity show lower values ($M = 12.53$) than those who teach ($M = 22.55$), the ones with teaching activity showing a higher level of emotional exhaustion. There are also significant differences in personal accomplishment ($t(35) = 4.77$, $p < 0.001$); those who do not teach have obtained lower values ($M = 30.39$) than those who teach ($M = 41.88$), the ones with teaching activity showing a higher level of personal accomplishment.

Regarding whether the participants have witnessed a critical event or not in the last five years, there are significant differences in emotional exhaustion ($t(35) = 2.96$, $p = 0.006$), in that those who have not witnessed any critical events show lower values ($M = 8.60$) than those who have ($M = 19.31$), the latter showing a higher level of emotional exhaustion.

When it comes to the cases our participants have worked on, there are significant differences in personal accomplishment, concerning some of the things that affect them the most, for example, decomposing

bodies (t (35) =4.51, p=0.001); the participants who have worked on this kind of cases (M=42.00) show higher levels of personal accomplishment than those who haven't (M=32.68).

When they were affected by an event at work, the participants who talked to one of their colleagues obtained significant differences in personal accomplishment (t (35) =2.51, p=0.017); those who talked to one of their colleagues obtained higher results in personal accomplishment (M=36.76) than those who did not (M=28.50). Also, there were significant differences in personal accomplishment if the participants talked to a specialist (psychologist, psychotherapist, social worker, officer) (t (34) =4.45, p<0.001); those who talked to a specialist (M=41.50) showed higher levels of personal accomplishment than those who did not (M=33.11).

When we consider if the participants suffer from insomnia, we obtain significant differences in emotional exhaustion (t (35) =2.74, p=0.019), those who suffer from insomnia (M=26.00) obtaining higher scores in emotional exhaustion than those who do not suffer from insomnia (M=10.88).

When we consider if the participants suffer from depression, we also obtain significant differences in emotional exhaustion (t (35) =4.93, p<0.001), those who suffer from depression (M=33.83) obtaining higher scores in emotional exhaustion than those who do not suffer from depression (M=11.32).

Regarding the drugs the participants take to relieve stress, we have obtained significant differences in emotional exhaustion (t (35) =3.15, p=0.003), the participants who take drugs to relieve stress (M=30.40) obtaining higher scores in emotional exhaustion than those who do not (M=12.56).

We have obtained significant differences in emotional exhaustion, when it comes to whether the participants think the specialty they chose has changed their vision of life (t (35) =3.41, p=0.002), the participants who think that the specialty they chose has changed their vision of life (M=17.85) have obtained higher scores than those who do not think the same (M=7.20).

All the variables presented above were considered as grouping variables when we wanted to determine if there were any significant statistical differences concerning the total scores at TAS-20, but none of the differences were statistically significant.

Regression analysis

The correlational study emphasized the influence of some variables on others (for example, the statistically significant connection between some of the alexithymia factors and some burnout factors). To identify the most effective model for estimating the burnout factors, multiple linear regression was used by the hierarchical method and the following prediction models were defined for emotional exhaustion, depersonalization and personal accomplishment. The results are presented in Table II.

For the depersonalization factor, none of the three predictive models proved to be significant.

Of the three models where emotional exhaustion was the criterion, only the first one was found to be significant. This consists of the difficulty identifying feelings factor and it explains 11% of the variance of emotional exhaustion. Also, the alexithymia factor difficulty identifying feelings has a significant influence on emotional exhaustion

(p=0.026) explaining most of the variance of the dependent variable (b=0.852, beta=0.367), its effect on the criterion being positive. So, based on these results, we appreciate that the more present this alexithymia factor (difficulty identifying feelings) is in a person's structure, the higher the emotional exhaustion scores will be.

TABLE II
Regression analysis burnout domains – TAS-20

	Models	Test	Emotional Exhaustion	Depersonalization	Personal Accomplishment
Step 1	Difficulty identifying feelings	R^2 adjusted	0.110	0.000	0.131
		ΔR^2	0.134	0.028	0.155
		F	**5.437***	0.995	**6.409***
Step 2	Difficulty identifying feelings, difficulty describing feelings	R^2 adjusted	0.087	-0.018	0.105
		ΔR^2	0.003	0.011	0.000
		F	2.720	0.676	3.119
Step 3	Difficulty identifying feelings, difficulty describing feelings, externally oriented thinking	R^2 adjusted	0.060	0.026	0.088
		ΔR^2	0.000	0.068	0.009
		F	1.762	1.314	2.153

Of the three models where personal accomplishment was the criterion, only the first one was found to be significant as well. This consists of the difficulty identifying feelings factor and it explains 13.1% of the variance of personal accomplishment. Also, the alexithymia factor difficulty identifying feelings has a significant influence on personal accomplishment (p=0.016) explaining most of the variance of the dependent variable (b=-0.737, beta=-0.393), its effect on the criterion being negative. This way, based on these results, we appreciate that the more present this alexithymia factor (difficulty identifying feelings) is in a person's structure, the lower the personal accomplishment scores will be. Our results confirm a recent study proving that only a single aspect of the alexithymia construct serves as a possibly independent predisposing factor for specific burnout dimensions (7).

From the results obtained we can see that the age correlated positively with personal accomplishment, this meaning that the older our participants get, the more personal accomplishments they will obtain. Also, significant correlations were highlighted between alexithymia factor difficulty identifying feelings and all the burnout factors: emotional exhaustion, depersonalization and personal accomplishment, this meaning that the more difficulties our participants will have in identifying feelings, the more feelings of emotional exhaustion and depersonalization they will experience and the fewer problems they will have in identifying feelings, the more accomplished they will feel personally. At the same time, alexithymia factor externally oriented thinking and the total score in alexithymia correlated positively with the burnout factor depersonalization, which means that the more alexithymia they will experience or the more they will have an externally oriented thinking style, the more they will experience feelings of depersonalization.

Regarding teaching activity, there are significant differences in emotional ex-

haustion; the participants with no teaching activity feel less emotionally exhausted than those who teach, but the ones who teach show a higher level of personal accomplishment than those who do not.

Also, the participants who have witnessed a critical event in the last five years show higher levels of emotional exhaustion than those who haven't witnessed such an event.

When it comes to the cases our participants have worked on, there are significant differences in personal accomplishment regarding some of the things that affect the participants the most, for example, decomposing bodies; those who have worked on this kind of cases show higher levels of personal accomplishment than those who haven't.

When they were affected by an event at work, the participants who talked to one of their colleagues or to a specialist (psychologist, psychotherapist, social worker, officer) obtained significant differences in personal accomplishment, those who talked to one of these categories obtained higher results in personal accomplishment than those who did not.

When we consider if the participants suffer from insomnia, depression or whether they take drugs to relieve stress, we also obtain significant differences in emotional exhaustion, those who suffer from insomnia or depression or who take drugs to relieve stress obtaining higher scores in emotional exhaustion than those who do not.

We have obtained significant differences in emotional exhaustion when it comes to whether the participants think that the specialty they chose has changed their vision of life; the participants who think that the specialty they chose has changed their vision of life have obtained higher scores than those do not think the same.

Additionally, the linear regression results showed that alexithymia factor difficulty describing feelings has a positive effect on the criterion emotional exhaustion, so we can appreciate that the more present this alexithymia factor (difficulty identifying feelings) is in a person's structure, the higher the emotional exhaustion scores will be. At the same time, the alexithymia factor difficulty identifying feelings also has a significant influence on personal accomplishment, its effect on the criterion being negative; this way, we can appreciate that the more present this alexithymia factor (difficulty identifying feelings) is in a person's structure, the lower the personal accomplishment scores will be.

One of the strengths of the present study is because less literature is available regarding forensic physicians. The limitation of the study is represented by the small number of subjects included in the research.

CONCLUSIONS

Scores for forensic physicians are low-level for emotional exhaustion and medium-level for two subdomains and low-level for alexithymia. Factors revealed by the comparative analysis are important to adjust professional activity and to find strategies to cope with stressful professional events.

NEWS

INFLUENCE OF APPLICATION OF CHLORHEXIDINE GEL AND CURCUMIN GEL AS AN ADJUNCT TO SCALING AND ROOT PLANING

Periodontitis describes a group of related diseases resulting in the destruction of the tissues that support the tooth. The most common destructive disease of the periodontal attachment apparatus is initiated by oral microflora. Scaling and root planning remains the "gold standard" treatment for periodontal diseases against which other treatments are compared. However, after nonsurgical therapy, several deep periodontal pockets may persist and in such cases, the treatment consists of surgical procedures. Since the systemic antibiotics therapy has various disadvantages such as the development of resistant bacteria and also requires higher dosage to attain required gingival crevicular fluid concentration at the target site, this led to use of local drug delivery system. The aim of a study realized by a group of researchers was to evaluate the efficacy of subgingival application of chlorhexidine gel and curcumin gel as an adjunct to SRP in the treatment of mild to moderate (4–6 mm) periodontal pockets. The study was conducted on thirty chronic periodontitis patients who were divided into two groups as control and experimental groups using a split-mouth design. After scaling and root planning, chlorhexidine gel was applied in control and curcumin gel in experimental groups. The plaque index, gingival index, sulcus bleeding index, probing pocket depth were recorded at baseline and subsequently after 1 month and 45 days. The results revealed that both chlorhexidine gel and curcumin gel have an effect on mild to moderate periodontal pockets in chronic periodontitis patients, but greater reduction was observed in the experimental group than the control group. It can be concluded that both control and experimental gel can be used as an adjunct to scaling and root planning, but the curcumin gel was more effective than the chlorhexidine gel in the treatment of mild to moderate periodontal pockets with a significant reduction in the indices scores when compared to the baseline values. (Hugar SS, Patil S, Metgud R, Nanjwade B, Hugar SM. Influence of application of chlorhexidine gel and curcumin gel as an adjunct to scaling and root planning: A interventional study. *J Nat Sci Biol Med.* 2016 Jul-Dec; 7(2):149-154).

LOCALIZED FIBROUS TUMOR OF THE PLEURA UN UNUSUAL CAUSE OF SEVERE HYPOGLYCAEMIA. CASE REPORT (Abstract): Localized fibrous tumors of the pleura are rare. If there are symptomatic, the symptoms are based on hormone production or size. Complete resection offers the best results. However, recurrence is reported in a significant number of patients. Usually no oncologic treatment is necessary. **Keywords**: SOLITARY TUMOR OF THE PLEURA, HYPOGLYCAEMIA, THORACIC SURGERY.

Localized fibrous tumors of the pleura are rare and originate from primitive mesenchymal cells sub mesothelial tissue (1). These tumors usually arise from visceral pleura (in 80% of the cases). Benign and malignant forms have been defined by histological criteria. Surgery is curative in most cases. These tumors may locally recur despite complete excision and benign histology (1). We present a case of a giant fibrous tumor of pleura completely resected.

CASE REPORT

A 63-year-old man presented to us with progressive breathlessness and severe hypoglycemia. At the time of hypoglycemic crisis, convulsions and syncope were observed. On the chest radiography we observed a complete opacification of left hemithorax (fig. 1). A CT scan of the thorax showed a large mass occupying the entire left hemithorax with a completely collapsed underlying left lung, descending aorta and other mediastinal structures strongly, thereby shifting them to the right side (fig. 2).

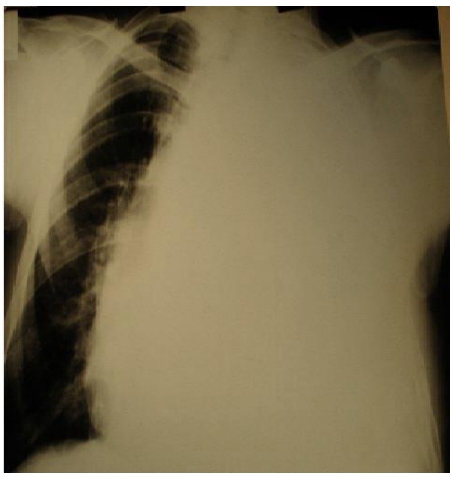

Fig. 1. Radiography with a complete opacification of left hemithorax**.**

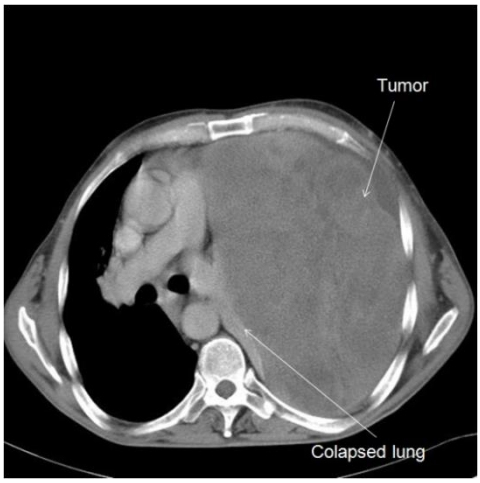

Fig. 2. Chest computed tomography scan showing a huge mass filling the entire left hemithorax.

We completely resected the mass by left postero-lateral thoracotomy (fig. 3).

During the surgery we discovered a huge encapsulated mass arising from visceral pleura.

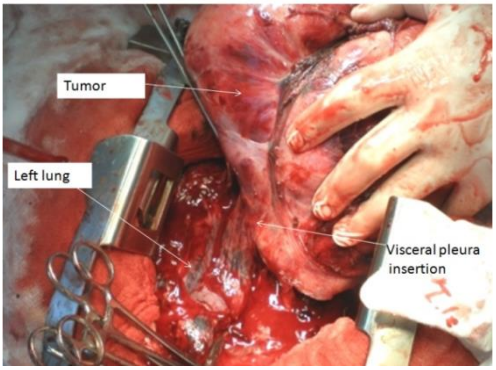

Fig. 3. Intra-operative view of the tumor.

The resected tumor was measuring 34cm in its largest dimension and weigh 3.800 g. After resection the left lung has fully re expanded. Postoperative, the glycaemia profile was normalized. Histopathological features were consistent with a solitary fibrous tumor. After an interdisciplinary discussion, no postoperative adjuvant therapy was necessary**.**

DISCUSSION

There are two types of primary pleural tumors: diffuse and solitary (1, 2). Diffuse variety is the malignant mesothelioma. Localized fibrous tumors of the pleura are relatively rare (600 cases having been reported previously (3)) and usually asymptomatic.

Cardillo et al found that 87% of solitary fibrous tumors in their series originated in the visceral pleura and only 13% in the parietal pleura (4).

In our case the symptoms were based on size and hormone production. The hypoglycemia, as in our case, is seen in 2% to 4% of cases, due to production of insulin-like growthfactor-2 by the tumor (1, 2, 5), and is more common in women. 80% of the localized tumors of the pleura are benign (1, 4).

England (6) described three histopathologic characteristics associated with malignancy: hyper cellularity, crowding and overlapping of nuclei, high mitotic activity > 4 mitoses/10 high-power fields. Using these criteria, 12% to 33% of solitary fibrous tumors of pleura could be considered as malignant.

A CT scan cannot differentiate between benign and malignant fibrous tumors of the pleura. For the most authors, tomographic guided biopsies are usually unhelpful in differentiating between benign and malignant pleural tumors with an accuracy rate less than 50 % (1, 4). Some authors consider that whole-body FDG PET is a noninvasive technique to readily and accurately differentiate benign from malignant masses, as the uptake in malignant mesothelioma would be very high (7).

Usually, the surgical intervention is re-

quired for both diagnosis and treatment. Complete resection offers the best results. The probability of recurrence is greater with malignant disease, but complete excision offers the best possibility of cure even in malignant forms. *Video assisted Thoracoscopic Surgery* (VATS) may be attempted for appropriate tumors, but conversion to open technique should be employed if margin clearance cannot be done with VATS. Some authors recommend VATS for lesions less than 5cm (2). In our case the tumor was not eligible for a minimal invasive treatment. Previously reports shows that safe surgery is possible in such patients despite poor a low forced expiratory volume (FEV1) (8). For this reason, we didn't explore the preoperative respiratory function for our patient.

In some cases, preoperative percutaneous embolization has been reported to be useful in reducing perioperative blood loss (9).

The overall operative mortality ranges from1.5% to 12% because of hemodynamic changes associated with decompressing the mediastinal structures (2). England and associates concur that the patients with incomplete excision will all die of their disease in less of five years (2).

Radiotherapy and chemotherapy have been undertaken for locally recurrent or inoperable malignant tumors but the long-term results are debatable (2).

CONCLUSIONS

The association of large pulmonary mass and hypoglycemia should highlight the possible diagnosis of localized fibrous tumor of the pleura. Surgery is the main treatment which should be attempt even in recurrent or very large tumors (10).

PANCREATIC CANCER CT IMAGING: COMPARISON WITH SURGERY (Abstract): **Aim:** To establish the best protocol for pancreatic computer tomography and criteria for staging (mainly for vascular invasion). **Material and methods**: Our research included 49 consecutive patients with pancreatic cancer examined at the Iasi "Sf. Spiridon" Hospital between January and December 2014 with a Siemens 16 Emotion CT unit. CT protocol included no enhanced CT and pancreatic phase of the superior abdomen, portal venous phase of the abdomen and pelvis. **Results and discussion**: The study patients were stratified into 5 age groups and the most frequently affected by pancreatic cancer were the patients aged 60 to 79 years. For T staging the extension in the per pancreatic fat tissue, into surrounding organs (5 patients had extension in other organs) and vessels was evaluated. We determined the degree of contact between the tumor and the artery, thrombosis and deformity of the veins and we have found 8 resettable lesions, 28 tumors in stage T3 and 13 pancreatic cancers in stage T4. Thirty-three patients had lymphadenopathies and 31 of them had distant metastases. **Conclusions**: Our study proved that computed tomography is a good method of examination for pancreatic cancer when the right imaging protocol is used; during the pancreatic phase the arteries and the tumor are well depicted, liver metastases are best evaluated during the portal venous phase. The best criterion for arterial invasion is tumor contiguity with more than half of vessel circumference, and for vein invasion deformity or thrombosis. Comparison with surgical staging was o good backup for the radiologist and depicted several differences with imaging staging, more often understating than over staging. **Keywords**: PANCREATIC CANCER, VASCULAR INVASION, COMPUTED TOMOGRAPHY

The incidence rates for exocrine pancreatic cancer worldwide equal its mortality rates (5%) and the main risk factors are diabetes mellitus, chronic pancreatitis, biliary stones, and smoking (1,2). The most frequent pancreatic malignancy is ductal adenocarcinoma which has nonspecific symptoms and blood tests, so imaging methods are very important for the diagnosis. Computed tomography (CT) is the method of choice for pretherapeutic evaluation of pancreatic malignant tumors (evaluates with maximum accuracy the tumoral extension into surrounding organs, vessels, lymph node involvement, distant metastasis) and follow-up after treatment (3,4). CT is widely available and is a validated tool for the diagnosis of pancreatic malignan-

cies because it depicts the tumor mass (with maximum lesion-to pancreatic parenchyma attenuation difference during the pancreatic phase), evaluates very well the arterial and venous invasion and detects hepatic metastases (5, 6). CT is widely available and is a validated tool for the diagnosis of pancreatic malignancies because depicts the tumor, evaluates very well the invasion in arteries and veins and detects hepatic metastases (5, 6). Computed tomography depicts in case of pancreatic cancer a poorly defined, isodense mass on non-enhanced CT which becomes hypo attenuating after contrast medium injection; the maximal contrast between the tumor and pancreatic parenchyma appears in fact in the pancreatic phase (between the arterial and portal venous phase) when the pancreas fully enhances and the tumor remains hypodense (7).

MATERIAL AND METHODS

Our research included 49 consecutive patients with pancreatic cancer examined at the Iasi "Sf. Spiridon" Hospital between January and December 2014 with a Siemens 16 Emotion CT unit; 36 (73.46 %) patients were surgically treated. The patients were examined in the morning, after digestive preparation (ingestion of 500 ml of 2% dilution of iodinated contrast medium). The imaging protocol included:

- non-enhanced CT of the superior abdomen,
- injection of 1-1.5 ml/kg, 370 – 400 mg I/ml nonionic hypoosmolar iodinated contrast medium, 3-3.5 ml per second;
- pancreatic phase of the superior abdomen – 20-30 seconds after the beginning of contrast medium injection;
- portal venous phase of the abdomen and pelvic regions – 70 - 80 seconds after the beginning of contrast medium injection;
- equilibrium phase of the hepatic region – when we have to characterize liver lesions.

We have studied the per pancreatic (including the vascular extension) and distant extension of the tumor, vascular extension of each tumor and compared it with the surgical protocol. The results were processed and interpreted by statistical methods (tables, figures, p, trend).

RESULTS AND DISCUSSION

Age-group distribution. The patients were stratified into 5 age groups: 30-39 years (1 patient, 2.04 %), 50-59 (7; 14.28%), 60-69 (22; 44.89%), 70-79 (15; 30.61%) and over 80 (4; 8.16%).

Gender distribution. The gender differences in prevalence were significant ($p<0.05$), 31 (63.26 %) of patients being males and 18 (36.73 %) females.

Computed tomography depicts in case of pancreatic cancer a poorly defined, isodense mass on non-enhanced CT which becomes hypo attenuating after contrast medium injection; the maximum tumor-to pancreatic parenchyma contrast occurs in fact during the pancreatic phase (between the arterial and portal venous phase) when the pancreas fully enhances and the tumor remains hypodense (7).

Criteria for resectability of pancreatic cancer are: lack of distant metastasis, no invasion of superior mesenteric and celiac arteries, and limited invasion of superior mesenteric vein to allow vein reconstruction (8, 9). In all cases of pancreatic cancer, according to the data in the literature, computed tomography depicted a poorly defined, isodense mass on non-enhanced CT, which became hypo attenuating after con-

trast medium injection (with the maximum contrast between the tumor and pancreatic parenchyma in the pancreatic phase) (7). For T staging we evaluated the extension into the per pancreatic fat tissue (present in 10 cases – 20.40%), surrounding organs (5 – 10.20 % patients had extension into other organs, such as duodenum, jejunum, stomach) and vessels, but in fact vascular invasion of the superior mesenteric artery and vein and of the celiac artery is essential. We have found 8 (16.32 %) resectable lesions (T1 and T2 tumors), 28 (57.14%) tumors in stage T3 (locally advanced but potentially resectable) and 13 (26.53 %) pancreatic cancers in stage T4 (unresectable tumors).

All vessels around the pancreas were examined in 3 planes (axial sections, sagittal and coronal reconstructions) and the degree of contact between the tumor and the vessel, stenosis, thrombosis and deformity was determined. The criteria used for assessing the vascular extension were the degree of contact between the tumor and the artery and for veins we added deformity and thrombosis. Tumoral invasion was found in 74 vessels: 40 (49.38 %) arteries (5–6.17 % celiac artery, 8–9.87 % hepatic artery, 8– 9.87 % superior mesenteric artery, 19–23.45 splenic artery) and in 34 (41.97 %) veins (22–27.16 % in the splenic vein and 12–14.81 % in superior mesenteric vein). Of the tumors with vascular extension only 13 (26.53 %) were not resectable (the ones with invasion of the celiac artery and superior mesenteric artery) and 28 were locally advanced (venous extension to one or more than one vein) (fig. 1).

In vascular invasion cases we found: contiguity of tumor to vessel on 75-100% of the circumference in 20 cases (24.69 %), 50-75% in 9 (11.11 %) cases, and 25-50% in 16 (19.75 %) cases, venous thrombosis in 18 (22.22 %) and venous deformity in 11 (13.58 %) cases. Tumor-to-vessel contiguity of less than 25% was found in 7 (8.64 %) cases and was not considered predictive for vascular invasion. Comparing with surgery we had only 3 (3.70%) cases of under staged vascular invasion and the best correlation between CT imaging and surgical reports for vascular invasion was contiguity of tumor to vessel on more than 50% of the circumference.

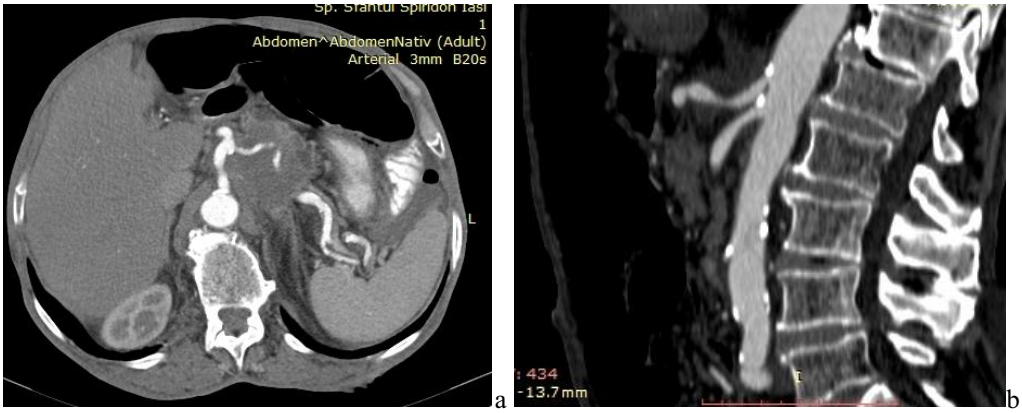

Fig. 1. Abdominal CT, pancreatic phase a – axial sections, b - sagittal reformates: celiac artery invasion

Regional lymphadenopathies were considered present when lymph nodes measured more than 10 mm in axial diameter, but if the lymph nodes were round or had an important contrast medium uptake, an axial diameter of 5-6 mm was considered pathological (fig. 2). We found 33 (67.34 %) patients with lymph node enlargement; when comparing CT with surgical findings, 3 (6.12 %) patients were under staged and 2 (4.08%) patients over staged.

Liver metastases are usually hypodense nodular lesions on non-enhanced and contrast enhanced CT and in our study we found 25 (51.02%) patients with typical pattern of liver metastasis. Comparing the CT diagnosis with pathological findings we found 3 more cases with secondary hepatic lesions, under staging being due to the fact that CT missed the isodense or small lesions (less than 10 mm in diameter). Peritoneal carcionomatosis was found in 6 cases (ascites, soft tissue infiltration of the omentum and nodular peritoneal thickening of the), compared with 10 cases at surgery (small lesions were not visible at CT) (fig. 3).

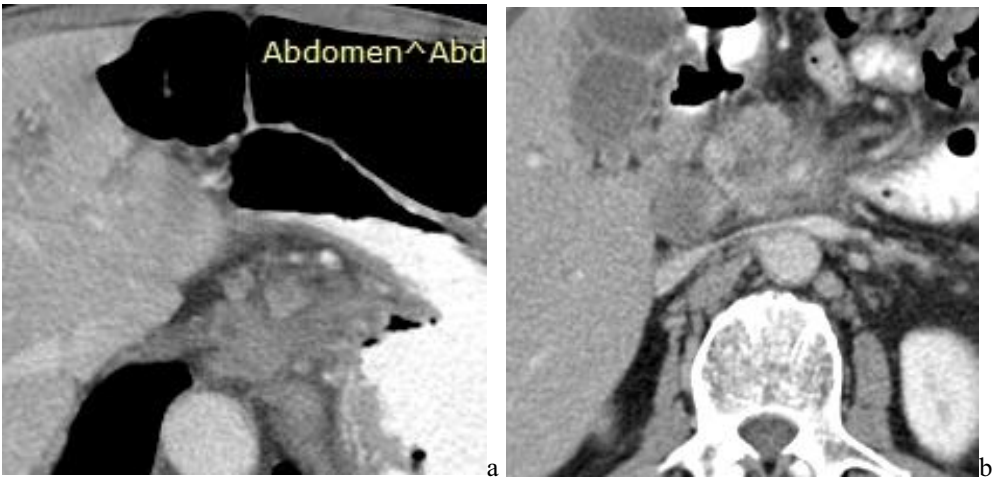

Fig. 2. Abdominal CT, portal venous phase a, b - lymphadenopathies

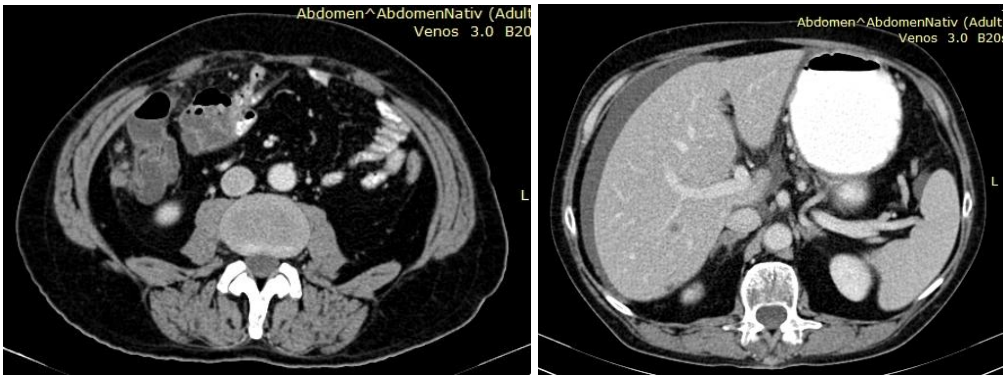

Fig. 3. Abdominal CT, portal venous phase – a - peritoneal carcionimatosis, b – hepatic metastases

Comparing CT imaging of pancreatic cancer extension with surgical evaluation, more cases of under staging than over staging were found (tab. I).

TABLE I

Pancreatic cancer extension - comparison between computed tomography and surgery

CT versus surgery	No.	%
Vascular invasion over staged	0	0 %
Vascular invasion under staged	3	3.70
Lymph nodes over staged	2	4.08
Lymph nodes under staged	3	6.12
Hepatic metastases over staged	0	0 %
Hepatic metastases under staged	3	6.12
Peritoneal carcionomatosis over staged	0	0 %
Peritoneal carcionomatosis under staged	4	8.16

CONCLUSIONS

Our study demonstrates that computed tomography is a good method for examination of pancreatic cancer when the right imaging protocol is used; the arteries and the tumor are well depicted during the pancreatic phase and liver metastases are best evaluated during the in portal venous phase. The best criterion for arterial invasion is tumor contiguity to more than half of vessel perimeter, and for vein invasion deformity or thrombosis. Comparison with surgical staging was o good backup for the radiologist and depicted several differences with imaging staging, more often under staging than over staging.

DILEMMAS IN THE ATTITUDE TOWARDS SUICIDE

B. Carasevici
University of Medicine and Pharmacy "Grigore T. Popa" – Iaşi
Faculty of Medicine
Department of Public Health and Health Management

DILEMMAS IN THE ATTITUDE TOWARDS SUICIDE (Abstract): Although apparently easy to define, the suicidal act or attempt raises complex and difficult problems due to the multitude of conditions and situations that can lead to it. In all cases the suicide's definition has always centred on the intention of one person to deliberately cause his or her death in an active manner. Defining suicide has been consecutively the temptation of philosophers, sociologists, theologians, psychologists and psychiatrists. From an epistemological point of view the suicide is an open concept without precise borders, yet not incoherent. Scientists have constantly tried to establish evaluation criteria of suicidal acts but these are variable. One can even assume that there is an infinity of combinations of characteristics that would legitimize the label of suicide, although none of them can be particularized in any way. Not even death itself represents a necessary condition for the evaluation of an act as suicide. **Keywords:** suicidal act, open concept, death by suicide.

Various attempts to define the suicide have been made in time by philosophers, sociologists, theologians, psychologists and psychiatrists. Sociologists, following the descriptive conclusions of E. Durkheim, regard suicide as the conscious assumption of a deadly risk (1). Certain psychiatrists, followers of Karl Menninger, are in striking opposition, believing that suicidal attitude is beyond mental integrity and consciousness. They state that any self-aggressive behaviour can be considered suicidal, and any lethal result of such behaviour can be qualified as suicide. In his attempt to come as closely as possible to an accurate definition of suicide Tom Beauchamp established three evaluation criteria for any suicidal act: the individual intentionally causes his/her death, there is no coercion in this respect from any other individuals and death is caused by circumstances especially created for the suicidal act purpose (2). Regardless of the accuracy of these criteria used in the identification and evaluation of the suicidal act, such a complex phenomenon cannot be comprised in a single succinct definition. It can occur in very different circumstances and can be performed through various methods. Motivation is often vague, mysterious and incomprehensible for both specialists and people who are close to the person who commits suicide.

From an epistemological perspective suicide appears as an open concept, without precise borders, without lacking coherence. There have been some attempts to establish evaluation criteria for a certain act in order to classify it as suicide, but these are variable. One could legitimately assert that there

is an infinity of combinations of characteristics that would justify labelling an action as suicide, yet they cannot be particularized, as not even death itself represents a necessary condition for evaluating an action as suicide (3).

Consequently, although it is apparently easy to define the suicide or suicide attempt, it still raises plenty of complex and difficult issues, due to the multitude of conditions and situations it can occur in. In both reductionist approaches and more liberal perspectives the definition of suicide focused on the intention of that individual to deliberately cause his/her death, in an active manner (4). The ones in favour of the reductionist approach were more radical and emphasized the self-destructive intention, establishing at the same time the purpose and the obvious motivation of the intention and the action. There is a very short distance from defining suicide in such a way to becoming judgemental; judgement requires pros and cons, leading to the paradox that the evaluation of the motivation is taken into account more than the existence of a desire to die. Many times the intention can be caused by the desire to change a certain state of things, which actually distances this act from suicide proper. The examples of people who commit suicide in order to end the pain in terminal illnesses such as cancer or of those who want to avoid betrayal during wartime are quite illustrative for the complexity of the issue. In these circumstances, suicide cannot be defined without a complex analysis of its dimensions as intention, deliberate act and consequences.

PHILOSOPHICAL AND MORAL CONSIDERATIONS

For thousands of years, religious traditions have imposed a very peremptory attitude on societies towards suicide. In India, the Upanishads tradition recognizes the suicidal act as a decent, sometimes heroic way of dying, yet only by drowning, fire or starvation. Later on, Hinduism and Jainism accepted and allowed passive self-destruction through starvation and asceticism. This form of passive self-destruction dedicated to certain deities is still opposed to certain active suicide methods, actually prohibited by the Hindi religion. In time, Buddhism adopted a very clear attitude towards any form of self-destruction. Escaping from a world of suffering was not allowed by means of suicide, the alternative being a change of attitude towards the self and the world. In the history of the Far East, two self-destructive modalities, in other words two motivations of the suicidal act were allowed, namely honour and revenge.

In ancient and medieval China, a man's suicide was disapproved because the man's duty was to support his family. Women did not have the same duty, on the contrary, they were often forced to defend their honour by suicide. As well as this, in both India and China, the cremation of the wife on a funeral pyre, together with the deceased husband was a common practiced, that persisted for many years. As long as the wife expressed her consent, this practice could be regarded as an act of suicide, accepted and even imposed by the society.

The European medieval religious tradition adopted an exceptional attitude according to which death is preferable to the betrayal of God. Thus, imposed apostasy represented the cause of many admitted suicides in both the Christian and the Judaic religions. The Islam, another monotheist religion, forbids suicide on the grounds of

God's supreme right upon any life. Consequently, the Islamic tradition forbids, through its Prophet's words, included in the Sunnah, the burial of the one whose death is caused by suicide, the Koran stating that "no soul is allowed to die unless God allows it at a certain moment".

The idea of gods' sovereignty upon human life is also to be found in the Greek philosopher's writings. The personal authority on someone's own life is limited by the priority of gods' sovereignty, suicide being regarded thus as an usurpation of divine power (5).

The same arguments were brought forward in medieval Christianity. Thomas Aquinas claimed that suicide represented an offense against one's own person, against the society and especially against God, since man belonged to his creator, who had offered him the gift of life. This concept of gift of God represented for many contemporary theologians the basic argument in their opposing the suicidal act. This opposition has not always been unanimously embraced. Thus, David Hume, in his essay On Suicide, claims that "God does not immediately appear in any activity, yet He governs everything by those general and immutable laws that have been established from the very beginning". Consequently, suicide may be part of the pre-established destiny of every human being, being regarded any other death cause (6).

We should nevertheless point out the differences between religious viewpoints and those based on moral grounds. Starting from various theories of morals, the Stoics or the Romantics of the 19th century displayed an attitude opposed to that of the church, looking for socially rooted arguments. This way, the attitude towards suicide was less radical during the 20th century. Even Theology raised the question whether suicide represents an act of self-sacrifice or self-suppression. The sinful dimension of suicide regarded as a crime against one's self is gradually lost; especially when related to medical issues, suicide becomes a more complex problem that transcends theological, philosophical or sociological areas (7).

The media mentions suicide cases very often all over the world. One argument against those who commit suicide is most of the times obvious and it seems to be shared by most people. The suicidal act is judged as cowardice in front of the hardships of life. Landsberg's objection is that "Hannibal's or Seneca's ways of dying could hardly be regarded as acts of cowardice". He also adds that "there are certainly more people who do not commit suicide because they are too coward to do it than people who commit suicide because they are coward". This does neither imply that Landsberg views suicide as act of heroism or that je justifies suicide for a noble purpose. He simply shows that the suicidal act is not merely a cowardly action, as most often labelled (8).

For Cioran, the absurdity of life is what causes a feeling of repulsion towards it. Moreover, he considers that the pursuit of truth is a battle in vain, as death is the only certainty of life. Starting from these premises, Cioran develops, in an almost Schopenhauerian manner, an ethics of renouncement. Unlike Schopenhauer, where the tragedy is more profound, as will is present in absolutely everything, influencing both the phenomenological and the intelligible worlds, Cioran still hopes that life is the only refuge. From this perspective, he states: "There are no arguments for living. On the heights of despair, the pas-

sion for the absurd is the only thing that can still throw a demonic light on chaos". It becomes evident, that under the dominance of the absurd, life loses its meaning. In this cases, suicide remains, for existentialist thinkers, a valid solution. The issue is no longer considered from a moral perspective, as Cioran himself states: "here we must think beyond normative conventions, as the issues addresses the human condition directly" (9).

CLINICAL FORMS OF SUICIDE

The suicide is probably the most dramatic and challenging clinical situation a psychiatrist is confronted with. It does not only represent a functional problem that could be addressed by means of therapeutic techniques, but also an existential issue, in both the proper and the philosophical meanings of the term (10, 11, 12). It is not about getting to lead a better life but about life being worth living or not. The fact that the starting point in the treatment of a potentially suicidal patient is seen in such different terms by the therapist and the patient qualifies the suicide as an extremely difficult case, since the psychiatrist duty goes beyond helping his/her patient by technical means. More precisely, the former is supposed to persuade the patient to alter his/her most profound beliefs and attitudes concerning life.

From a clinical viewpoint, the suicidal phenomenon displays numerous individual variations, yet some common traits have been identified (13):

- the purpose envisaged by suicide is the need to find a solution
- the target to be achieved is suspending the state of consciousness, stopping the flow of consciousness
- the triggering stimulus is uncontrollable psychical pain
- frustrate the common stressor in suicide is represented by frustrated psychological needs
- the person who commits suicide experiences an overwhelming feeling of helplessness and despair
- the inner attitude leading to autolytic actions is ambivalence, that is experiencing two contrary tendencies: of self-destruction and of planning a rescue
- the cognitive status of suicidal people is constriction, a major narrowing of the cognitive field and of the capacity to produce response alternatives
- the common action in suicide is escaping, avoidance to confront certain situations perceived as stressful (13, 14)

G. Ionescu enumerates the following forms of suicide: the idea of suicide, the suicide attempt, dissimulated suicide, suicidal drive and chronic suicide (15).

- **The idea of suicide** is not necessarily pathological in nature as it can also appear in the larger area of normality. It is probably exacerbated in crisis situations, when the individual cannot access a response method that s/he considers satisfactory.
- **The suicide attempt** is a failed suicidal act. As far as their truthfulness is concerned, suicide attempts could be placed on a bipolar axis, having as extremes full authenticity and provability.
- **Dissimulated suicide** often surprises due to the preoccupation of the subject for the feelings and wellbeing of the people around

him/her, especially those of the family members. The subject appeals to dissimulation in order to make sure s/he does not impose too heavy a moral and social burden on the loved ones, who are most often likely to experience self-culpability feelings.

- **Suicidal drive** explains the suicidal act as an expression of an irresistible, impossible to repress tendency of the individual to end his/her own life. Like any drive, the suicidal drive is transient so that the individual, once saved, is surprised by his own gesture.
- **Chronic suicide** includes the following situations:
  - risk behaviours taken to extremes to aberrant behaviours
  - refusal for absolutely necessary surgical interventions
  - refusal of absolutely necessary medical treatment
  - continuing to take drugs or drink alcohol in cases when the physical, psychic and professional degradation of the person is obvious

As opposed to various other types of psychological disorders, the suicidal state is not one that could gradually improve or worsen, but it represents a radical event that occurs at one given moment, is totally unpredictable and often irreversible.

ETHICAL ASPECTS

For the psychiatrist the ethics of suicide centres firstly upon the moral justification and the limits of an intervention policy. Thomas Szasz is known for his vehement attack against the traditional psychiatric approach of suicide, claiming that "accomplished suicide is generally the expression of an individual desire for greater autonomy and particulary for self-control upon one's own death". He considers that intervention in the suicidal behaviour is always inappropriate, actually diminishing the individual's freedom and reflecting the coercive patronizing attitude of the therapist (16).

Suicide faces thus the psychiatrist with a dilemma from both a professional and a human point of view. The therapist is challenged by the need to choose between saving a person's life, as stated in the Hippocratic Oath, and his duty to respect a personal decision, according to the ethical principle of individual autonomy (17). The critical moment extends to the point where the psychiatrist's right to interfere becomes the direct consequence of establishing an individual's ability or inability to decide upon his/her own life. Regardless of all these dilemmas, suicide prevention remains a desiderate and a reality at the same time, being regulated by national programmes adopted even by the most liberal countries as far as an attitude towards individual freedom is concerned (18).

The utilitarianism and other philosophical theories are not able to provide all necessary arguments for evaluating the value of life, as, from a moral viewpoint, life should be respected for its intrinsic value and consequently there might appear divergences of views between the psychiatrist and his/her potentially suicidal patient. The psychiatrist justifies his/her intervention pleading for the value of life, while the patient can quote arguments related to the quality of his/her life, disregarding the value of life in itself. The difficult task of the psychiatrist is reflected in his/her attitude that should replace the paternalist

approach with persuasion. He/she should make the patient perceive the new meanings his/her life might gain, allowing him/her at the same time to be completely free in making a decision.

CONCLUSIONS

All rational arguments in favour of suicide, such as avoiding pain or dishonour, actually plead in favour of giving up a certain quality of life, without actually inquiring whether death is better than life. The images of both death itself and life in its intrinsic dimension are equally difficult to perceive. Even psychiatric pathology can offer countless examples of delirium-hallucinating states related to experiences and identities that occur after death. Regarded from a life's value perspective, suicide cannot have a specifically moral representation, as morality implies a series of rules and principles that are the very grounds of life. Suicide ends up thus representing a decision beyond the sphere of moral arguments and other people's judgements. Consequently, the reason for which suicide should be prevented starts from the value of life in itself, and the medical intervention in the suicidal act is justified by the very belief in the value of life.

Suicide prevention is unfortunately still a mere palliative method, all positive results having just an individual character, while suicide rates remain, except few variations, quite constant. Suicide remains thus a ubiquitous, universal and perennial phenomenon, whose social impact and resonance cannot be neglected.

PREDICTORS OF SUICIDE RISK IN INCARCERATED MALE OFFENDERS: THE ROLE OF PERSONALITY DISORDERS (Abstract). **Aim:** This paper summarizes the results of a cross-sectional study aimed at exploring the role of personality disorders in predicting the suicide risk among males imprisoned for various offenses. **Material and methods:** The data set used in analyses was based on the responses of 124 males imprisoned for various violent or non-violent offenses (M_{age} = 32.39 years, SD = 8.43 years). Male offenders were interviewed using a form for demographic data and information on suicidal history. Also, they completed the Suicide Behaviors Questionnaire-Revised, as part of a broader protocol used in an ongoing study focused on the psychosocial and pharmacological aspects relevant to the diagnosis and management of personality disorders among inmates. **Results:** At the time of data collection, forty-three respondents (34.7%) were diagnosed with at least one personality disorder. Data were analyzed using hierarchical multiple linear regression. The frequency of suicide attempts during the periods of freedom and during incarceration were significant predictors of suicide risk. Moreover, the diagnosis of personality disorder brought a significant addition to the power of final regression model, explaining almost 8% of the variance in suicide risk among the inmates. **Conclusions:** The findings highlight the importance of implementing prevention programs in correctional institutions, with screening and monitoring of inmates diagnosed with severe mental disorders as an important component. **Keywords:** Male offenders, personality disorders, suicide risk, predictors.

Research data in forensic psychiatry suggest that a considerable proportion of males and females incarcerated in correctional institutions suffer from a chronic and pervasive mental disorder (1). Of the clinical entities encountered among prisoners, personality disorders are prevalent. According to a meta-analysis of about 23000 prisoners from 12 countries in Europe, USA and Australia, 65% of men in correctional institutions and 42% of incarcerated women had a diagnosis of personality disorder (2). On the other hand, it is recognized that people with personality disorders are at high risk for suicidal behaviors, which represent a stress factor for correctional officers.

Personality disorders (e.g., antisocial, borderline, paranoid, schizotypal, etc.) are fairly common among both male and female inmates (2, 3, 4). The general pattern of dysfunctional symptoms includes cognitions, affective symptoms, reactions and behaviors that deviate markedly from the expectation of the individual's culture and are associated with significant impairments

in professional and interpersonal functioning (5). This pattern is pervasive, stable over time, consistent across a variety of situations and contexts of everyday life and is not due to the direct effects of substance abuse or any other general medical condition. Compared with other clinical entities (depression excluded), personality disorders are associated with a higher risk of suicide (6, 7, 8, 9). On the other hand, all over the world, inmates are a population particularly vulnerable to suicide spectrum behaviors, as confirmed by epidemiological data (10, 11, 12). Personality disorders are one of the risk factors for suicidal behaviors among prisoners (11, 13, 14, 15). Most studies focused on the role played by mental disorders (personality spectrum disorders included) in attempted or completed suicide by inmates were conducted in US and UK. Data were also reported for other countries, such as Austria (16) and the Netherlands (17). This paper summarized the results of a study conducted in Romania on a sample of 124 inmates.

MATERIAL AND METHODS

The data set used in quantitative analyses was based on the responses of 124 male incarcerated for various offenses in two correctional facilities from Botosani and Iasi. Recruitment of female inmates was not possible as both are male correctional institutions. The first of these correctional institutions accommodates pre-trial detainees and inmates in a semi-open confinement. The correctional facility from Iasi has three units (open, closed or maximum security) and accommodates male inmates serving long-term sentences. Inmates on remand in custody or inmates in quarantine were excluded from the study. The interviewed inmates were aged 18 to 56 years (M_{age} = 32.39 years, SD = 8.43 years). Sixty-five (52.4%) were non-recidivists, the remaining being recidivists with two (N = 25; 20.2%), three (N = 21; 16.9%) or more than three prior convictions (N = 13; 10.5%). Depending on the nature of the crime they committed, inmates were divided into two subgroups: a) inmates who had committed violent crimes (e.g., attempted murder, qualified murder, robbery accompanied by murder, rape with/without sequestration, rape and robbery, attempted rape, human trafficking, etc., N = 44) and b) inmates who had committed non-violent crimes (e.g., complicity to theft and deception, driving without a license, illegally carrying a weapons, illegal crossing of border, etc., N = 80).

Inmates were interviewed individually using a form for obtaining demographic and legal data and information on suicidal history. Also, they completed the SBQ-R (18), as part of a broader protocol used in an ongoing study focused on the psychosocial and pharmacological aspects which are relevant to the diagnosis and management of personality disorders among inmates. At the time of interviews, according to medical records forty-three of the respondents (34.7%) had a diagnosis of at least one personality disorder (codes F60-F61 based on ICD-10/19). Distribution of prisoners by diagnosed personality disorders was as follows: paranoid personality disorder (N = 1; code F60.0), antisocial personality disorder (N = 18; code F60.2), emotional unstable (N = 4; code F60.30) or borderline personality disorder (N = 14; code F60.31), other personality disorders (N = 3; code F60.8) and mixed personality disorder (N = 3; code F61.0). Inmates who had enduring personality change not attributable to brain damage or disease were excluded from the

study. Most study inmates presented various other current organic diseases or antecedents.

Suicide risk was assessed with SBQ-R. This instrument is known through its simplicity and parsimoniality and allows clinical psychologists or psychiatrists who provide assistance to patients with various mental disorders and/or suicide history to obtain valuable information. The reduced number of items and their simple wording recommend the SBQ-R as a screening tool that is useful for identifying the suicide risk in individuals of different ages and health conditions. The SBQ-R is a four-item self-report scale that measures distinct aspects of suicidal behavior: lifetime suicidal ideation and/or behavior (item 1), the frequency of suicidal ideation in the past year (item 2), the communication of suicidal thoughts to others (item 3), and the likelihood of attempting suicide in the future (item 4). Participants are asked to check the number behind the statement that best applies to them. Each statement is provided with five, six or seven available responses. Each item is scored on a 0 to 6 scale and the total score is obtained by summing the scores for the four items (possible range: 3-18). Higher scores indicate higher levels of risk for suicidal behavior. Data of an exploratory factor analysis (by principal components extraction with *Varimax* rotation and eigenvalue > 1.00) carried out on the entire sample of inmates yielded a one-latent factor that accounted for 72.8% of the total variance in item scores. The standardized values of item loadings ranged from 0.71 to 0.93. In our study, internal consistency was satisfactory: 0.83 - total sample, 0.80 – inmates with personality disorders, 0.77 – inmates without personality disorders.

To determine the role of a diagnosis of personality disorder in predicting suicide risk among male imprisoned for various offenses we used hierarchical multiple linear regression. In the successive steps of the analysis we entered as independent variables only those variables for which preliminary analyses yielded significant relationships with SBQ-R score (i.e., the dependent variable). The diagnosis of personality disorder (PD) has been introduced as a dummy-type independent variable (1 = present, 0 = absent/reference category). A similar strategy has been used to recode the number of convictions (non-recidivists = 1, recidivists = 0/reference category) and type of criminal offense (violent offenses = 1, non-violent offenses = 0/reference category). For all analyses, the critical level of statistical significance was set at $p < 0.05$ (two-tailed).

RESULTS and discussion

Significant differences between inmates diagnosed with PD and those without PD (Table I) were obtained in terms of age ($\chi^2 = 15.11$, $df = 3$, $p < 0.01$), education level ($\chi^2 = 10.81$; $df = 3$, $p < 0.05$), the number of convictions ($\chi^2 = 4.38$; $df = 1$; $p < 0.05$) and type of criminal offense ($\chi^2 = 7.06$; $df = 1$; $p < 0.01$). Most inmates with PD were aged 26 to 35 years (66.7%) and had 5 to 8 years of formal education (58.1%). The group of inmates without PD was more heterogeneous in terms of age. On the other hand, in this group most inmates had 9 to 12 years of formal education (54.3%), followed by inmates with 5 to 8 years of education (33.3%). Over sixty percent of inmates diagnosed with PD (compared to only 40.7% of those without PD) were recidivists, and 51.2% of the inmates with PD (compared to only 27.2% of those without PD) committed violent crimes.

TABLE I
Cross-tabulation between demographic/forensic characteristics and psychiatric condition

Variables	Prisoners with PD (N = 43)	Prisoners without PD (N = 81)	χ^2

Violent offenses (N = 44)	22 (51.2%)	22 (27.2%)	

Note: * $p < 0.05$; ** $p < 0.01$

Regardless of the legal status and psychiatric condition, inmates with a history of attempted suicide during periods of freedom (N = 21) committed one to ten attempts (M = 2.80; SD = 2.67), all cases with parasuicidal behaviors being excluded. Also, inmates with a history of attempted suicide in periods of detention including the current one (N = 18) had attempted suicide one to six times (M = 2.16; SD = 1.24). On the other hand, compared to inmates without PD, those diagnosed with mental disorders had committed, on average, more suicide attempts both when out of prison ($M_{\text{inmates with PD}} = 1.23$; $SD_{\text{inmates with PD}} = 2.35$; $M_{\text{inmates without PD}} = 0.07$; $SD_{\text{inmates without PD}} = 0.34$; $t = 3.20$; $df = 122$; $p < 0.01$; $d = 0.83$), and when in prison ($M_{\text{inmates with PD}} = 0.83$; $SD_{\text{inmates with PD}} = 1.34$; $M_{\text{inmates without PD}} = 0.03$; $SD_{\text{inmates without PD}} = 0.24$; $t = 3.87$; $df = 122$; $p < 0.001$; $d = 1.00$). For these differences the effect sizes were larger. Moreover, inmates with PD had significantly higher score on SBQ-R ($M_{\text{inmates with PD}} = 9.09$; $SD_{\text{inmates with PD}} = 5.49$; $M_{\text{inmates without PD}} = 3.72$; $SD_{\text{inmates without PD}} = 1.78$; $t = 8.04$; $df = 122$; $p < 0.001$), with a very large effect size ($d = 1.39$).

Compared with non-recidivists (N = 65), the recidivists (N = 59) had a higher suicide risk based on SBQ-R score. Suicide risk was also higher among inmates who committed violent offenses ($M_{\text{non-recidivists}} = 4.83$; $SD_{\text{non-recidivists}} = 3.58$; $M_{\text{recidivists}} = 6.42$; $SD_{\text{recidivists}} = 4.96$; $t = -2.06$; $df = 122$; $p < 0.05$). Although for the previous comparisons the effect sizes were

modest (d = 0.37 şi d = 0.38), the number of convictions and type of crimes were entered as independent variables in the regression analysis.

Table II summarizes the results of the hierarchical multiple linear regression analyses. Along with the constant, the number of convictions, type of offense, number of suicide attempts committed in periods of freedom and history of suicide attempts in periods of detention (model 01) explained approximately 50% of variance in SBQ-R score, the resulting regression model being statistically significant (F = 28.98; $df_{regression}$ = 4; $df_{residual}$ = 119; p < 0.001). However, the positive predictors of suicide risk were only the number of suicide attempts in periods of freedom (β = 0.27; p < 0.01) and the frequency of suicide attempts in periods of detention (β = 0.48; p < 0.001). The first of these independent variables explained only 5.42% of the variance in suicide risk, while the second variable had a larger contribution (15.76%).

TABLE II

Results of hierarchical multiple linear regression

Model	Independent variables	B	SE	β	r^2_{sp}
01	**No. of convictions**	0.56	0.59	0.06	-

*R = 0.75; F = 31.67 ***; R^2 = 0.573; Δ R^2 = 0.080 ******					

Note: The constant has been included into all models. ** p < 0.01; *** p < 0.001

In a second step of analysis, the independent variable related to the presence of a personality disorder diagnosis was entered, thus resulting a statistically significant model (F = 31.67, $df_{regression}$ = 5, $df_{residual}$ = 118, p < 0.001). Along with the constant, the independent variables entered into the model accounted for 57.3% of variance in SBQ-R score. When the presence of a personality disorder was entered as an independent variable, the explanatory power of the final regression model improved by 8% (ΔR^2 = 0.080), this increase being statistically significant (F_{change} = 20.00; df_1 = 1; df_2 = 118; p < 0.001). The number of suicide attempts committed in periods of freedom and the attempts committed during detention remained positive predictors of suicide risk (β = 0.21 and p < 0.01, β = 0.38 and p < 0.001), explaining 3.09% and 9.67% respectively of the variance in the dependent variable. Also, the presence of a personality disorder was a positive predictor of suicide risk (β = 0.32; p < .001), explaining about 8% of the variance in the score on SBQ-R.

The aim of this study was to explore the role of personality disorders diagnosed

among inmates in predicting suicide risk. The criterion considered in the strategy for quantitative analysis of raw data was inmates' vulnerability to engage in (new) suicidal behaviors. This variable was captured using SBQ-R (18). A higher frequency of prior suicide attempts and the presence of a clinically diagnosed personality disorder were associated with a higher suicide risk. The presence of a personality disorder in inmates explained about 8% of the variance in SBQ-R score distribution. This result is consistent with data reported in a case-control study conducted in Austria by Fruehwald and his colleagues (16) who in a sample of 252 inmates (almost all male) have identified the presence of a psychiatric diagnosis as an important predictor of suicide completion (OR = 17.4; $p < 0.001$). Suicide risk is even higher when associated with crisis episodes that are specific to personality disorders, especially with the severe ones (e.g. borderline or schizotypal). During such episodes, suicide is often either demonstrative or manipulative (20), or impulsive (6, 20) and does not necessarily imply a wish to die. However, besides the suicide risk associated with episodes of crisis, patients diagnosed with personality disorders may present chronic suicidal behavior (22) that is often lethal, especially when the medical condition of such patients does not improve. Moreover, by its implications for psychological and social functioning of human individuals in general, deprivation of liberty, especially life or long-term prison sentences, can complicate the symptoms of personality disorders through major crises that inmates face with. Often, these crises occurs within the first days of incarceration when the risk for suicidal behaviors is higher (14) and the committed acts are associated with feelings of helplessness and despair. The risk of death following an attempted suicide increases significantly in inmates serving life sentences (23).

Also, in our final regression model the number of suicide attempts committed by inmates while out of prison and the frequency of suicide attempts committed in periods of detention explained approximately 3.1% and 10%, respectively of the variance in suicide risk. These results are consistent with those reported by other studies (16, 17, 23). The difference in the explanatory power of these two variables can be explained by the different life circumstances in time of freedom and imprisonment. Thus, when the released inmates with known personality disorders are trying to readjust after serving a sentence of imprisonment, suicide acts that may have a sporadic and conjectural or chronic character tend to be associated with the stressful life events which cause impairments in patients with personality disorders, existential crises, psychotic episodes specific to some personality disorders (e.g. borderline) or pharmacological treatment failure/lack of psychological support. Conversely, the periods of detention imply some differences in terms of risk factors. For example, in addition to the above-mentioned factors, the physical and administrative prison environment (e.g. custodial regime, organization of detention cells, lack of socialization activities, supervision of large numbers of inmates, low vigilance of prison guards, etc.) and psychological factors (e.g., frustration related to legal sentence, shock of incarceration, need to adapt to an unknown environment and varying emotional pressures or conflicts with other inmates or administrative staff) can help create conditions favorable to the development of sui-

cidal behaviors.

This study has some limitations. Thus, the sample of incarcerated offenders with a diagnosis of personality disorder was relatively small, and consisted solely of men. Although the interview protocol contained much more questions on the family of origin climate, history of socialization, education, current marital status, personal and family medical history, risk behaviors and traumatic life experiences that we considered as being relevant for understanding the antecedents of mental disorders diagnosed in some of the participants in this study, due to the relatively small sample size the multivariate data are not presented in this paper. Moreover, due to administrative limitations related to time allocated for interviews visits, the clinical status of each participant was based solely on medical records and general clinical findings during interviews. Over three quarters of inmates with personality disorders also had other mental disorders (in various combinations), but their disproportionate distribution made grouping for statistically relevant comparisons impossible. Also, some of offenders in the control group had other mental disorders (e.g. epilepsy, mood disorder, schizophrenia, etc.) which were not included in multivariate analysis. In a future case-control study we aim at collecting data from a larger and more demographically and clinically heterogeneous sample of incarcerated offenders with mental disorders and to compare it both with a sample of offenders without a previous history of or current psychiatric problems and with a nonclinically matched sample based on community population. In addition, we plan to compare the suicide risk associated with personality disorders in male and female offending with the risk associated with other mental disorders recognized as having suicide spectrum complications, such as depressive and bipolar disorder or schizophrenia (24, 25).

CONCLUSIONS

Suicide spectrum behaviors are a common phenomenon in the general prison population. Risk factors include some demographic variables, personality vulnerabilities, history of suicide, and severe mental disorder (personality disorders included). Life adversities and certain characteristics of prison environment act as precipitating factors. These factual data highlight the importance of implementing prevention programs in correctional institutions, with screening and monitoring of inmates diagnosed with severe mental disorders as an important component. The care of inmates diagnosed with personality disorders who are at high suicide risk requires a multifaceted approach, including administrative measures, rigorous drug treatment plan and psychotherapeutic interventions. The therapeutic approach must concentrate on enhancing emotional functioning, reducing impulsive behaviors and identifying effective coping strategies to deal with factors of psychological stress underlying the suicidal behavior.

THE MAST CELL: FROM THE OLD STRUCTURE TO THE NEW FUNCTIONS (Abstract): Initially viewed as the central pawn in the pathologic chain of allergic reactions, the mast cell, although described microscopically over a century ago, remains an enigma. The richness of substances preformed and deposited within the cytoplasmic granules characteristic for this cell or newly synthesized after the activation of membrane receptors triggered a peculiar interest for the clarification of the intimate relationship established by the mast cell with the antigens or with the other immune cells, within the connective extracellular matrix. Nowadays, the origin of mast cell is established and its behavior is explained in accordance with the nature of the molecules stored within the cytoplasm. However, the mast cell keep displaying new abilities in other pathological conditions, justifying the major interest linked to the position and role performed in supporting the development and progression of tumor cells, especially through the involvement in tumor neoangiogenesis. This review focus on the complex functions of the mast cell, highlighting its pathogenic potential based on the activation process and mediators' biological properties. **Keywords**: MAST CELL, MEDIATORS, CARCINOGENESIS, ANGIOGENESIS.

Discovered over a century ago by Paul Ehrlich (1), the mast cells were associated for a long time only with the pathological events responsible for the initial stages of allergic reactions. Located predominantly in the perivascular territories, they are difficult to identify within the complex cell population that inhabits the loose connective tissue. At first, Ehrlich believed them to be involved in the nutritive support of the connective tissue where they are dispersed, due to the contents of their cytoplasmic granules. After 5 decades from their description the presence of high quantities of heparin was noticed in the granules of mast cells, but only at the middle of the past century the link between these cells and the type I hypersensitivity reactions (anaphylaxis) was pointed out (2, 3).

The origin of this cell raised numerous controversies explaining the variability in mast cell classification among the cell types present in the connective matrix. The intimate relationship between mast cells and the connective tissue led to the initial idea that mast cell derive from undifferentiated mesenchymal cells (4). Later, results of numerous studies suggested a link between mast cells precursors and cells of the immune system differentiated in the bone

marrow. Taking into account the structural and functional similarities between the basophiles and the mast cells, a theory of a common bi-potent precursor in the marrow (both for the mast cell and basophile line) was proposed, being deemed as valid for a long period of time (5-7). It is worth mentioning that complementary data revealed indirectly the presence of mast cell precursors in the liver and yolk sac cells, but in the absence of specific markers their existence was until recently impossible to prove (8, 9). Only two years ago, advanced immunologic methods were able to demonstrate the origin of mast cells in the aorta-gonad-mesonephros region (10) – area where the hematopoiesis is also initiated during human embryogenesis (11). This evidence not only complements the knowledge on mast cells origin, but also opens new perspectives for understanding the behavior of these cells, whose morphological aspect could be considered as insignificant.

Unlike other hematopoietic cells which differentiate and mature in the hematogeneous bone marrow, after which they enter the blood stream, the precursors of mast cells migrate early through the blood in the connective tissues of the body, where the maturation process is completed (12). They survive in the connective tissue up to 12 weeks, being capable of mitotic activity induced by specific activation factors (13, 14).

Mast cells are dispersed throughout the body, being located mainly in the skin, respiratory and digestive tract (15, 16), either in subepithelial areas (superficial dermis or *lamina propria*), either in the more profound loose connective tissue where they are concentrated mostly perivascular or around the nerves, follicles, and muscle fibers (16). The mature mast cells are unable to migrate, the dispersion ability in other connective areas being specific only to mast cell precursors (17). The intimate mechanism of preferential recruitment of mast cells in certain territories of the human body is still incompletely elucidated, the main impediments being those related to the small number of mast cell precursors and to the difficulty of their precise identification in the bone marrow and connective tissue (18-21).

MAST CELL: STRUCTURE AND ULTRASTRUCTURE

Mast cells are medium size cells (approximately 20-30 μm), oval in shape, with a spherical nucleus located in the center or slightly eccentrically, and a cytoplasm with a granular contents which cannot be easily observed in standard coloration. After fixation with glutaraldehyde and stain with toluidine blue, the cytoplasmic granules of the mast cells, rich in heparin, can be revealed, as they color metachromatically in purple red (16). In electron microscopy, the cytoplasm of the mast cell, with an irregular appearance consequent to the emergence of short and uneven microvilli, contains, besides the abundance of granules, a rudimentary RER, numerous mitochondria and well developed Golgi (16).

MAST CELL GRANULES

The complex functions of mast cells are mirrored in their ability to synthesize and release a series of biologically active molecules. Once activated, they can quickly discharge the preformed mediators stored in the cytoplasmic granules, but also synthesize several new mediators based on the membranous lipids (16, 22). Among the preformed mediators we can count histamines, serotonin, β-glucuronidase, chy-

mase, and tryptase, together with cytokines and growth factors such as TNF-α, IL-4, IL-15 or TGF-β and VEGF, while the neoformed/neosynthesized mediators comprise prostaglandin D2, E2, and leukotrienes B4 and C4, elaborated on the bases of membranous lipids, but also other molecules such as IL-10, IL-12, IL-5 or GM-CSF, PDGF, TGF-β, VEGF, and nitric oxide (Table I). Based on their contents, the matured mast cells are currently classified in two categories: tryptase/chymase-positive mast cells (MCs_{TC}), which store in the cytoplasmic granules tryptase, chymase, and carboxypeptidases, and tryptase-positive mast cells (MCs_T), which store only tryptase (23, 24). MC_T are mainly distributed in the *lamina propria* of the digestive and respiratory mucosa, while MC_{TC} are mostly present in the dermis of the skin (24). Recently, a third type of mast cells was described, observed in patients with asthma and eosinophilic esophagitis, which store tryptase and carboxipeptidase A3, but not chymase (25, 26). The differentiation of mast cell types involves also the receptors on their surface, the expression of C5aR – the receptor for the C5a component of the complement system being recorded in cutaneous and pulmonary MC_{TC}, while lacking in MC_T from the respiratory mucosa (27).

TABLE I

The main pre-formed and neo-formed mediators secreted by the mast cell

(adapted from 24)

Cytokine Family	Cytokines
Pre-formed mediators	
Biogenic Amines	Histamine, Serotonin (5-HT), Dopamine
Lysosomal Enzymes	β-hexosaminidase, β-glucuronidase, β-D-galactosidase, Arylsulphatase A,Cathepsins C, B, L, D, and E
Proteases	Chymase, Tryptase,Carboxypeptidase A, Cathepsin G, Granzyme B, Matrix metalloproteinases
Proteoglycans	Serglycin (Heparin and Chondroitin sulphate)
Cytokines	TNF-α, IL-4, IL-15
Chemokines	RANTES (CCL5), eotaxin, IL-8, MCP-1
Growth Factors	TGF-β, bFGF-2, VEGF
Others	Eosinophil Major Basic Protein (MBP)
Neo-formed and neo-synthesized mediators	
Phospolipid Metabolites	Prostaglandin D2, E2, Leukotrienes B4, C4, and Platelet Activating Factor
Cytokines	IL-33, IL-10, IL-12, IL-17, IL-5, IL-13, IL-1, IL-2, IL-3, IL-4, IL-6, IL-8, IL-9, IL-16, Type I and Type II IFN, TNF-α
Growth Factors	SCF, GM-CSF, β-FGF, NGF, PDGF, TGF-β, VEGF
Reactive Oxygen Species	Nitric Oxide

MAST CELLS ACTIVATION

The activation of mast cells is induced by several intrinsic or extrinsic factors, able to stimulate their surface receptors. Among these, the most investigated and deciphered activation pathway for the mast cells is the one mediated by Fc-RI high affinity receptors, which acts in allergic states (28). Fc-RI is a heterotetramer of the immunoglobulins superfamily, consisting

of $\alpha\beta\gamma_2$ subunits. Subunit α has an extracellular domain able to recognize the Fc segment of IgE, while subunits β and γ are intracytoplasmic (22). After the stimulation of Fc-RI, a cascade of successive protein phosphorylations is initiated in the cell, followed by the synthesis of inositol triphosphate and diacylglycerol, which will induce an inflow of intracytoplasmic calcium and the activation of protein kinase C (PKC), all of these finalized with the release of the granules contents, and the activation of neomediators synthesis (29, 30).

In the late phases of mast cells activation serines and threonine kinases, belonging to PKC and MAPK families, intervene decisively. The inflow of intracytoplasmic calcium will produce the stimulation of PI3K, followed by the activation of phospholipase D, PLA2 and of the isoforms β and - of calcium-dependent PKC (29), the latter regulating the production of Fos and Jun factors and indirectly the fabrication of cytokines (31). Also, the molecule ERK1/2 intercedes in the regulation of PLA2 activation and eicosanoids production by Fc-RI mechanism (32), through the MAPKs, PKC, and PI3K pathways, and the enrollment of the intracellular calcium (33).

However, the mast cells activation is not strictly limited to the Fc-RI pathway. The recognition of antigens is possible also through the intervention of other mast cells receptors such as TLRs1-7 and 9, nod-like receptors (NLRs) and retinoic acid-inducible gene 1 (RIG-1)-like receptors (RLRs). The stimulation of TLR is followed by the association of the adaptor protein MyD88 to its ligand, MyD88 adaptor-like/Toll interleukin-1 receptor (MAL/TIRAP), which will determine the activation of a specific kinase – IKB kinase (IKK), able to promote the transcription of the genes responsible for cytokine synthesis (34). On the other hand, the activation of mast cells stimulating factors is counterbalanced by other membranous receptors, whose stimulation modulates the synthesis and release of specific mediators (35), such as: IgG multimeric receptors (FcγR) (36), c-Kit receptor (CD117) (37), C-C Chemokine Receptor type 1 (CCR1), corticotropin-releasing hormone receptor (CRHR), and the beta-adrenoceptor (30).

MAST CELL FUNCTIONS

Through their origin and location, the mast cell is currently viewed as an immune cell, which mediates not only nonspecific defense processes, but also several other complex biologic events, such as tissue repair, angiogenesis or carcinogenesis (38).

Mast cells and tissue repair

Through the synthesis of numerous growth factors, such as PDGF, VEGF, and FGF-2, the mast cells play an important role in the maintenance of tissue integrity (39), for they are involved in all stages of tissue repair. Even from the early phases of inflammation, through the synthesis and release of platelet activating factor (PAF) associated with leukotrienes and IL-1 and IL-8 they determine platelet activation. These reactions are balanced simultaneously by the fibrinolytic effect of heparin and tryptase, also produced by the mast cells (40). The mast cells involvement continues with the production of factors that promote the migration of immune cells in the damaged territories, and the proliferation of endothelial cells or fibroblasts (41). In the late phases of tissue repair, other released proteolytic factors mediate the control of newly synthesized extracellular matrix deposits and, in association with IL-1, IL-4 and IL-6, induce the stimulation of the

myofibroblasts, which ensure local tissue remodeling (42).

Mast cells and nervous tissue

A possible relationship between mast cells and the nervous tissue is suggested by the preferential location of these cells in the vicinity of nerve ends. Moreover, the existence of a synapse-like communication between the mast cells and neurons by several molecules (i.e. N-cadherin or synaptic cell adhesion molecule (SynCAM)) is proved (43). Supplementary evidences sustains that at intestinal level the interaction between mast cells – nervous structures regulates the ion transport, vascular permeability, glandular secretion and contraction of smooth muscle, with result in local homeostasis maintenance (44).

Mast cell and allergic reactions

Classically, the mast cell is acknowledged as the main effector of the pathogenic mechanism involved in the allergic reaction, including the severe form – anaphylactic shock, through its numerous IgE – type receptors. The first contact of the immune system with an allergen induces, by antigen-presenting cells, the stimulation of T helper 2 lymphocytes which determine the activation of B lymphocytes followed by IgE synthesis (45). Therefore, mast cells have a twofold role in the allergic reaction, due to the ability to process and present the antigens in MHCI or MHCII context and to the well-represented expression of IgE – type surface receptors.

In the early phases of allergic reaction (very well studied in asthma and its allergic form), the binding of the allergen to the Fc-RI of the mast cells brutally induces the discharge of their preformed mediators, but also the stimulation of neoformed mediators synthesis responsible for the entire assembly of specific conditions (erythema, edema, increase of vascular permeability, contraction of smooth muscles and mucus hypersecretion) (46, 47).

In the late stage of allergic reaction the mast cell intervention is restricted to favoring the recruitment of other immune cells (eosinophils, basophils and T lymphocytes). Finally, in the chronic stage, mast cells act against the persistent inflammation supporting the tissue remodeling and development of local fibrosis (47).

Mast cells and immune tolerance

The idea of mast cell's intervention in the manifestation of immune tolerance dates back a decade ago (48). Towards this end, most of the researches centered on the role of these cells in the cutaneous territory, where it was noticed that the mast cells exert numerous local influences through the pre- or neoformed mediators, while concomitantly are able to modulate the immune response (24, 49).

Through the secretion of mainly IL-10 and TGF-β, already known as factors with immunosuppressive potential, the mast cells control the amplitude of the local inflammatory reaction, including the control of Fc-RI autoexpression, involved in mast cell degranulation (50). TGF-β together with IL-2 significantly influences the development and differentiation of antigen-specific regulatory T cells – T^{reg} (expressing $CD4^+$, $CD25^+$ and $FoxP3^+$) after primary lymphopoiesis in the thymus. This subtype of lymphocytes is capable of inducing the suppression of proliferation of effector T lymphocytes (51). It seems the mast cell – T^{reg} interaction is one of the defining elements in the appearance of local immunotolerance in atopic dermatitis or heart transplant (48, 52). Also, the mast cells proteases, by their specific activity, enable the occurrence of antigen immunotolerance through the decrease

of leukocyte recruitment, mediated by cytokines or direct antigen cleavage, in inflammatory foci (53).

Mast cells and angiogenesis

The angiogenesis process, defined as development and growth of preexistent or new formed blood vessels, can appear not only in physiological conditions similar to those occurring during embryogenesis, but in pathologic circumstances (as chronic inflammation or carcinogenesis) as well. Histamine and heparin were among the first factors with proven angiogenic effect, for they stimulate the formation of new vascular structures on experimental research performed on laboratory animals (54).

Nowadays, mast cell's intervention in angiogenesis is documented by the secretion angiopoietin-1, FGF-2, VEGF, IL-8, TGF-β, TNF-α, tryptase and chymase (55) – angiogenic factors that intervene in various stages of angiogenesis through the control of migration and proliferation of endothelial cells, synthesis of extracellular matrix components or mobilization of pericytes (24).

Mast cells and cardiovascular disease

Cardiac mast cells seem to play a role in the pathology of coronary heart diseases characterized by the damage of the vascular wall structure with results in the reduction of the cardiac muscle cells blood supply. Experimental research showed the presence of mast cells in the adventitia of coronary arteries during their spasms (56) or in the vicinity of atherosclerotic plaques (57). The released chymases are able to activate the conversion enzyme and the secondary synthesis of angiotensin II, a powerful coronary vasoconstrictor, or to induce proteolytic cleavages of the high-density lipoprotein cholesterol, thus favoring the flow of lipids towards the macrophages present in the vascular wall and the development of atheroma plaques (58).

Mast cells and carcinogenesis

The relationship mast cell – inflammation – cancer currently raises a major interest, proven by the numerous researches aiming to decipher the nature of the mast cell's involvement in the control of carcinogenesis and tumor progression. Recent reports in this field start from the classic histologic study, which revealed the concentration of mast cells around tumor areas (24, 59). In the tumor microenvironment, the local recruitment of the mast cells is achieved under the direct influence of several factors synthesized by the tumor cells, such as SCF (60). The mast cells activity assumes the release of pro-inflammatory, immunosuppressive or angiogenic mediators, or of mitogenic factors (61, 62). The mast cell histamine is capable of stimulating the tumor proliferation rate through the interaction with H1 histamine receptors which induce the inhibition of anti-tumoral activity of the immune cells, an effect secondary modulated also by other mast cell mediators – such as IL-10 or TNF-α (59).

However, the pro-angiogenic effect is the fundamental event where the mast cell intercedes in the support of tumor progression, for it is coordinated through a multitude of factors (such as angiopoetin-1, TNF, FGF-2, VEGF and IL-18) released from the mast cells granules, which stimulate the endothelial and vascular proliferation (63, 64).

Current research also revealed the possibility of mast cell involvement in the early stages of tumor growth through the activity of the secreted proteases such as MMP-2 and MMP-9, an effect which would later be actually completed by the modulator angiogenic role exerted through vascular stimulat-

ing factors (65). It seems that these effects are counterbalanced by the activity of other mast cells factors (TNF-α, IL-1, and IL-6), which inhibit tumor growth through a pro-apoptotic mechanism, such as it was recorded in malignant melanoma (64). Consequently, the complex interrelations established in the tumor microenvironment between the mast cells and tumor cells are still only partially elucidated. Nevertheless, the results of most studies support the multifaceted intervention of the mast cells in the peritumoral immune inflammatory profile, with a dominant effect on the development of neoangiogenesis, resulting in the local or distant invasion of malignant cells (62, 66, 67).

FINAL REMARKS

Although known for over one hundred years, the mast cell is currently viewed as a multifunctional immune cell, for it mediates several physiological processes such as tissue growth and repair, but also pathologic, such as allergic reactions, inflammation and, recently, tumor angiogenesis, tumor development and progression. Distributed evenly in the human body, with perivascular, perimuscular and periglandular concentration in the connective territories located at the interface with the exterior environment, the mast cell acts as a "guardian of local immune processes", as it controls the activity amplitude of other immune cells. The mast cells presence in the tumor microenvironment opens today a new perspective regarding the influence in carcinogenesis, through the possible therapeutic control of the neoangiogenesis.

NEWS

ASPIRIN USE AND COLORECTAL CANCER

Colorectal cancer (CRC) is the second most frequent type of cancer in Europe, with higher incidence for men after 50 years of age. Aspirin has anticancer effects. The aspirin use reduced the colorectal adenomas risk and the distant metastasis for patients with CRC. A recent meta-analysis summarized the results of eleven studies and showed that aspirin therapy after CRC diagnosis improved survival particular among patients with positive prostaglandin endoperoxide synthase 2 (PTGS2) expression and mutated PIK3CA tumors. PTGS2 is an enzyme involved in prostaglandin synthesis which promote inflammation and cell proliferation. Phosphatidylinositol 3-kinase (PI3K) has an important role in carcinogenesis. Also, the meta-analysis highlighted no association between aspirin use before diagnosis and CRC mortality. Future research is needed in order to establish the optimal doses and duration of aspirin adjuvant therapy in CRC (Peiwei Li; Han Wu; Honghe Zhang; Yu Shi; Jinming Xu; Yao Ye; Dajing Xia; Jun Yang; Jianting Cai; Yihua Wu. Aspirin use after diagnosis but not pre-diagnosis improves established colorectal cancer survival. *Gut* 2015;64(9):1419-1425).

RELATIONSHIP BETWEEN THE PROANGIOGENIC ROLE OF EG-VEGF, CLINICO-PATHOLOGICAL CHARACTERISTICS AND SURVIVAL IN TUMORAL OVARY (Abstract) **Aim:** To prove the presence of EG-VEGF in tumor ovary and to analyze its involvement in the ovarian carcinogenesis, as promoter of angiogenesis, in relationship with the clinicopathological prognostic factors and survival. **Methods:** The study group comprises tumor tissue specimens from 50 cases of surgically treated ovarian cancer that were immunohistochemically investigated. A scoring system based on the percentage of positive cells and the intensity of staining was applied for the semiquantitative assessment of EG-VEGF, as negative or positive. Statistics involved χ^2 test, and Kaplan-Meier and log-rank test. **Results:** EG-VEGF was positive in 35 cases (70%) and negative in 15 cases (30%). Our data confirmed the predominance of EG-VEGF positivity in the serous subtype as compared to endometrioid and clear cell subtypes, and its absence in mucinous subtype. Moreover, we demonstrated that EG-VEGF is overexpressed mainly in high-grade ovarian carcinomas (type II) than in low-grade ones. Significant differences were registered between the EG-VEGF positive or negative expression and tumor stage and histological subtypes, respectively. Survival analysis showed no differences in patient's survival and EG-VEGF positive and negative cases. **Conclusions:** The analysis of EG-VEGF expression in ovarian tumors points out the relationship between the enhanced potential for tumor angiogenesis and the tumor aggressivity. **Keywords**: OVARIAN CANCER, EG-VEGF, TUMOR ANGIOGENESIS, IMMUNOHISTOCHEMISTRY.

Although the existence of organ-specific angiogenic factors was hypothesized in the early '80s (1), the presence of such a factor has been later confirmed (2). Its specificity results from the expression characteristics, concretely by its identification and isolation in endocrine organs, as: testis, adrenal gland, ovary, and placenta (2). Consequently, it has been named endocrine gland - derived vascular endothelial growth factor (EG-VEGF). EG-VEGF action is restricted to endothelial cells be-

longing to the steroidal endocrine organs, without known potential on other types of endothelial cells. EG-VEGF has a complex role as regulator of the angiogenic processes including cell proliferation, migration, and survival, pseudovascular and spheroidal organization, permeability and paracellular transport (3).

Besides the above mentioned organs, a low expression of EG-VEGF has been noticed in brain, colon, skeletal muscle, small intestine, spleen, thymus, uterus, and liver, whereas it is absent in non-lactating breast and skin (2). The EG-VEGF overexpression is reported in colorectal (4), pancreatic (5) and ovarian carcinoma (6-9).

The ovarian site offers a generous model for angiogenesis research, both in physiological status characterized by a cyclic evolution and in pathological conditions that includes a large heterogeneity of morphological changes. However, data concerning the EG-VEGF involvement in the ovarian carcinogenesis are limited.

Within this context, our study aimed to analyze the relationship between the EG-VEGF ovarian expression and clinicopathological prognostic factors and survival.

MATERIAL AND METHODS

The study group consisted of 50 cases with epithelial ovarian carcinoma, aged 41 to 77 years, diagnosed in "Cuza Voda" Obstetrics and Gynecology University Hospital from Iasi, Romania, during 2009-2012 intervals.

According to tumor stage, 15 cases (30%) have been classified as stage I, 12 cases (24%) as stage II, and 23 cases (46%) as stage III. Five cases (10%) have been graded as G1, 21 cases (42%) as G2, and 24 cases (48%) as G3, respectively. Epithelial ovarian carcinomas have been included in the following histological subtypes: 33 cases (66%) as serous, 10 cases (20%) as endometrioid, 4 cases (8%) as mucinous, and 3 cases (6%) as clear cell subtype; 14 cases (28%) have been classified as type I category (low-grade) and 36 cases (72%) as type II category (high-grade).

Serial sections have been cut at 4 μm thickness from the tumor specimens, in order to perform routine histological technique, followed by immunohistochemical (IHC) staining with anti-EG-VEGF antibody (Santa Cruz, Biotechnology Inc., Santa Cruz, USA) using the automated system Dako Autostainer Plus (Dako Cytomation, Glostrup, Denmark). A semiquantitative method has been used (8) to quantify the results, each slide receiving a score for the percent of immunoreactive tumoral cells and a score for the tumor tissue staining intensity from the same microscopic field. The sum of the two scores determined the final score, ranging between 0 and 6. A final score less than 2 has been considered negative, while ≥3 score has been considered as positive for the evaluated marker.

Statistical analysis has been performed using the commercially available GraphPad Prism software. We have applied χ^2 test for correlation with clinicopathological characteristics, and Kaplan-Meier curves and log-rank test for survival analysis.

RESULTS

Our study had shown a positive expression of EG-VEGF in 35 cases (70%) and a negative expression in 15 cases (30%). The distribution of EG-VEGF expression within tumor stages has shown the following pattern: 9 cases were positive and 6 cases were negative in stage I, 10 cases were positive and 2 cases were negative in stage II, and 7 cases were positive and 16 cases

were negative in stage III. The correlation of EG-VEGF expression with the tumor grade has been the following: 2 positive cases and 3 negative cases in G1, 14 positive cases and 7 negative cases in G2, and 19 positive cases and 5 negative cases in G3. Expression of EG-VEGF has been more common among the serous subtype (fig. 1), represented by 26 cases followed by endometrioid subtypes, represented by 6 positive cases (fig. 2), and clear cell subtype – 3 cases (fig. 3). EG-VEGF has been undetected in 15 cases (7 case of serous, 4 cases of endometrioid, and 4 cases of mucinous type, respectively). Regarding the tumor type, EG-VEGF expression has been overexpressed in 28 cases of type II, comparative to 7 cases of type I tumors.

The statistical analysis had revealed significant differences between the EG-VEGF expression (positive versus negative) and tumor stage (p=0.009) and histological subtypes (p=0.017), respectively (tab. I). No differences in patient's survival and EG-VEGF positive and negative cases had been registered (p=0.218) (fig. 4).

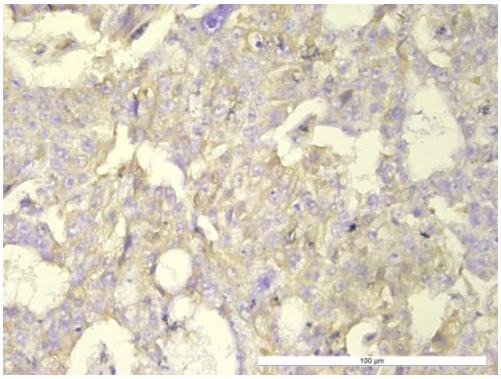

Fig. 1. EG-VEGF positive reaction in serous ovarian carcinoma (IHC, anti-EG-VEGF, x 40).

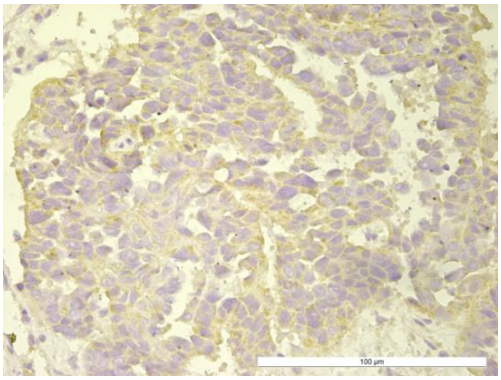

Fig. 2. EG-VEGF positive reaction in endometrioid ovarian carcinoma (IHC, anti-EG-VEGF, x 40).

Type II	36	72	28	77.78	8	22.22	

DISCUSSION

The first data concerning EG-VEGF involvement in the angiogenic processes in steroidal organs have been published 3 decades ago (2). EG-VEGF belongs to a class of proteins that includes Bv8 (7, 10). Although EG-VEGF accomplishes comparable functions as VEGF, its structure is completely different (10).

As a difference from its physiological functions, the EG-VEGF role in tumor environment is to induce endothelial cells proliferation and fenestration in tumor vascular capillaries, by different growth factors activation, as a consequence of hypoxia and action of proinflammatory cytokines (4). The binding of EG-VEGF to its specific receptors (PKR1 and PKR2) determines angiogenic effects (mediated by PKR1) and cellular permeability (mediated by PKR2) (7, 10). As a consequence, EG-VEGF/EG-VEGF-R system represents a paracrine system, the ligand being produced by non-endothelial cells, while the receptors are selectively expressed in vascular endothelium present in the steroidal tissues (7, 10). These facts justify its specificity for the endocrine organs characterized by steroid hormones secretion (8).

Few data concerning EG-VEGF in ovarian carcinoma have been reported in the mainstream publications (6, 8, 9) and its involvement in regulating tumoral cells growth and survival is yet unclear.

As reference in the research in this field, the study conducted by Zhang et al. (6) had analyzed EG-VEGF and VEGF comparative expression at mRNA level (using real-time quantitative RT-PCR) in 50 cases of human ovarian tumors, suggesting that EG-VEGF is not directly expressed by ovarian tumor cells, but more likely it is the result of leukocyte inflammatory activity or of stromal cell intervention. The authors have demonstrated EG-VEGF mARN higher expression in benign and borderline ovarian tumors, and also in tumor stage I (early stage) compared with stage III. VEGF expression had been opposite to that of EG-VEGF, VEGF exhibiting a predominant expression in advanced cases, compared to early stages. Moreover, the investigation of the inflammatory extracellular matrix role related to EG-VEGF expression had identified a higher EG-VEGF mRNA in peritumoral stroma compared to tumoral one; reported to inflammatory peritumoral cells (lymphocytes CD3, CD19, CD45, and NK), EG-VEGF had been overexpressed in CD3 lymphocytes supporting the inflammation role in EG-VEGF liberation.

Later on, an attempt to determine the potential prognostic value of EG-VEGF in ovarian carcinoma had been accomplished by Bălu et el. (9) who analyzed EG-VEGF expression in 30 patients with ovarian tumors, aiming the correlation of EG-VEGF expression related to classical parameters. The obtained results have shown statistically significant differences between EG-VEGF and tumor stage, tumor grade and histological subtypes.

Therefore we consider our research is worthwhile in supplementing data on the EG-VEGF characterization in relationship with the behavior of ovarian tumors. The novelty of our study, based on our previous interest on the role of this molecule in ovarian carcinogenesis (11), is sustained not only through the correlation with the clinicopathological characteristics, but also by those with patients' survival – to the best of our knowledge not yet reported in the literature.

In accordance with the published papers (6, 9), our data revealed statistically significant differences related to tumor stage and histological subtypes. The EG-VEGF decline in advanced stages of ovarian carcinoma may be attributed to a negative action of the steroidal stroma on tumor growth. This observation opens perspectives for considering EG-VEGF as a therapeutic agent in early phases of ovarian carcinogenesis. Within the framework of the histological heterogeneity of ovarian carcinoma, we confirmed the predominance of EG-VEGF positivity in the serous subtype as compared to endometrioid and clear cell subtypes, and its absence in mucinous subtype. Moreover, we demonstrated that EG-VEGF is overexpressed mainly in high-grade ovarian carcinomas (type II) than in low-grade ones. These statements can be interpreted as evidences for a direct relationship between the enhanced potential for tumor angiogenesis and the tumor aggressivity.

The EG-VEGF prognostic role for survival was not proved, but this negative result may be attributed to the relatively reduced number of cases included in the study – a more extensive research being necessary to clarify this issue.

CONCLUSIONS

The analysis of EG-VEGF expression in ovarian tumors, founded on the peculiar

morphology of endocrine organs characterized by steroid hormones secretion, offers complementary data for a better understanding of the angiogenesis role in carcinogenic mechanisms.

EMPHYSEMATOUS CYSTITIS: AN UNREPORTED COMPLICATION AFTER PANCREATICODUODENECTOMY (Abstract): Pancreaticoduodenectomy was associated with an increased morbidity, and septic complications are the primary cause of death in these patients. However, severe sepsis, caused by a postoperative urinary tract infection, is uncommon. It is presented the case of a 72 years old man, with a pylorus-preserving pancreaticoduodenectomy for an ampullary adenocarcinoma. Postoperatively, the patient developed a chyle leak, and a severe urinary tract infection (i.e., emphysematous cystitis), with septic shock. The diagnosis, management and outcome are discussed. In conclusion, emphysematous cystitis is a potentially life-threatening complication, which may occur due to the postoperative immunodepression after pancreaticoduodenectomy. **Keywords**: PANCREATECTOMY, COMPLICATION, CHYLE LEAK, IMMUNODEPRESSION, EMPHYSEMATOUS CYSTITIS.

Emphysematous cystitis is an acute infection, characterized by the presence of the gas into the walls of the urinary bladder (1). Pancreaticoduodenectomy is a complicated surgical procedure, which is associated with increased morbidity (2). Infectious complications after pancreatectomies are encountered in around 30% of the patients (3). Septic complications represent the primary cause of death after pancreaticoduodenectomy, and in most of the cases are consequences of a postoperative pancreatic fistula (3). Urinary tract infections after pancreatico-duodenectomy are encountered in 7% of the patients, but extremely rarely may lead to septic complications (3).

CASE REPORT

A 72 years old man, with no significant medical history, underwent a pylorus-preserving pancreaticoduodenectomy, with standard lymph nodes dissection(2), for an ampullary tumor. The pathology report showed an ampullary adenocarcinoma, pT1, pN0 (17 lymph nodes retrieved). The postoperative outcome was complicated with a chyle leak, which occurred two days (postoperative day 4) after starting the enteral feeding on the naso-jejunal tube, which was intraoperatively mounted. The triglycerides level in the abdominal drainage fluid was 253 mg/ dL, with normal levels for amylase and lipase. Postoperatively, the patient had spontaneous normal

glycaemia levels. Total parenteral nutrition was initiated, along with fasting and octreotide administration, with apparently favorable outcome (decrease of the daily drainage from 7 liters/day to 1 liter/day). On postoperative day 36 fevers appeared, along with chills.

Laboratory tests showed increased leucocytes count (21,000/ mm^3); no other abnormalities were observed, including the serum urea and creatinine levels. The computed tomography identified the presence of gas within the wall of the urinary bladder (fig. 1, white arrow). On notice, the patient did not present any urinary symptoms or signs, and he had a daily urinary output volume within the normal ranges. A urinary catheter was inserted, and broad-spectrum antibiotics and antifungal treatment were started. The evolution was rapidly progressive to septic shock, multiple organ dysfunctions, and death within 48 h after diagnosis. Hem cultures were positive for *Candida*.

Fig. 1. An axial computed tomography showing the aspects of emphysematous cystitis (presence of the gas within urinary bladder walls – white arrows).

DISCUSSION

A chyle leak is defined as a milky white fluid enriched in triglycerides (>110 mg/ dL) (4), and it is considered a rare complication after pancreaticoduodenectomy, with a reported prevalence ranging from 1.8% to 16% (4-10).

The cause of a chyle leak after pancreatectomy is a lymphatic disruption (4, 9). Manipulation of the para-aortic region (8), retroperitoneal invasion (8), the number of harvested lymph nodes (≥ 18) (6) or an extended lymph nodes dissection (5), vascular resection (6), portal vein/ superior mesenteric vein thrombosis (5), chronic pancreatitis (10) and early postoperative feeding (7, 8) are considered independent risk factors for development of a chyle leak after pancreaticoduodenectomy. Furthermore, a chyle leak is also more frequently encountered after pancreaticoduodenectomy for a malignant pathology (8), in males (6), in patients with lymph nodes metastases(5;8), early T stages tumor (≤ T2) (7), advanced ages (≥ 66 years) (7), soft pancreas texture (7), and without postoperative pancreatic fistulae (7).

Although an early enteral nutrition was associated with high risk for chyle leak in some studies (7, 8), it is worth to mention

that the early enteral nutrition reduces the postoperative infectious complications after pancreaticoduodenectomies (11). Nevertheless, some studies did not identify an early enteral intake as a risk factor for a chyle leak development after pancreatectomies (9).

Postoperative enteral nutrition brings an intake of fats, and fatty meals increase the flow in the lymphatics (4). This is the reason a postoperative chyle leak can be clinically diagnosed after the enteral nutrition is restored. A drain output volume > 335 ml on postoperative day four after pancreatectomies was correlated with a high suspicion for a chyle leak diagnosis in some studies, particularly in the absence of a postoperative pancreatic fistula(7). A grading system for chyle leak after pancreatectomies was proposed in a study(10). The data from the literature have shown that the occurrence of a chyle leak after pancreatectomy is usually observed in the postoperative day 5- 8 (4-7).

In the reported case, male gender, advanced age, soft pancreas texture, a malignant early stage tumor (i.e., T1) and early enteral nutrition might be speculated as risk factors for postoperative chyle leak.

A persistent chyle leak may potentially induce malnutrition, immunodeficiency and sepsis because of the depletion for immunoglobulin, lymphocytes and long-chain triglycerides (6, 8); it is also associated with increased mortality (6). Peritonitis or other forms of sepsis were observed in about 20% of patients with pancreatectomies and a postoperative chyle leak or chylous ascites (6).

Total parenteral nutrition, octreotide (a somatostatin analogue) and medium-chain triglycerides are recommended for the treatment of a chyle leak, and most of the patients have a favorable outcome (5, 8). An intraoperative milk test was suggested to identify a lymphatic leakage after pancreatectomies (4).

Emphysematous cystitis is a severe, life-threatening complication that occurs mainly in diabetic or immunodepressed patients (1). Escherichia coli represent the most frequent causative bacteria for emphysematous cystitis, while *Candida* remains an uncommon finding (1).

In the reported case, the infectious complication was most likely due to the persistent high output volume chyle leak, with substantial malnutrition and immunodeficiency, that couldn't be compensated by the parenteral nutrition.

The clinical symptoms of emphysematous cystitis are not particular, and the imaging investigations are the most important tool for diagnosis (12). Although a plain abdominal radiograph may diagnose the presence of the gas within the urinary bladder walls, computed tomography is considered the gold standard for the imaging diagnosis in patients with emphysematous cystitis, because it may exclude other causes of presence of the gas into the bladder, such as colo-vesical fistulae etc (12). Moreover, computed tomography may also detect the associated pyelonephritis (12).

In the reported case, there were no clinical or bioumoral signs to suggest a urinary disease. Furthermore, the diagnosis was established at computer tomography examination. An uncommon finding for the reported case of emphysematous cystitis was the *Candida* etiology.

The mortality rate in patients with emphysematous cystitis is 7% (1, 13), but may increase to over 50% in cases with associated pyelonephritis (1). Only an early diagnosis and an immediate aggressive treatment may save the patient from a fatal

outcome (1, 13).

In the reported case, although the diagnosis of emphysematous cystitis appears to be made in the early setting, however, the evolution was rapidly progressive to a fatal outcome. This unfavorable evolution might be explained by the *Candida* etiology in a severely immunodepressed patient.

In conclusion, emphysematous cystitis is an uncommon, but severe complication that may occur due to the postoperative immunodepression.

HIGHLIGHTING CONSIDERATIONS ABOUT PREDISPOSING FACTORS IN THE DYNAMICS OF ETHANOLIC DEPENDENCE SYNDROME (Abstract): **Aims:** This research aims to highlight the involvement of behavioral disorders as predisposing vulnerable factors in the pathology of patients with ethane deficiency, compared to healthy subjects. **Material and methods:** For 120 patients included in the study a statistical and mathematical representation of the factors of personality and temperament was made: impulsivity, socialization, social desirability, somatic anxiety, social-cognitive anxiety and muscle tension, in relation to the dynamics of the ethanolic challenge syndrome. **Results:** The "Karolinska Scales of Personality - KPS" was used to evaluate the representation. For the statistical analysis was used *SPSS version 17.0* and for the charts and tables was used Microsoft Excel. **Conclusions:** Blood tests were performed (OGT, PGT, TG-gamma) to determine the degree of severity and the predisposition to develop subsequent ethanolic complications. **Keywords**: PREDISPOSING FACTORS, ETHANOL DEPENDENCE SYNDROME, STATISTICAL AND MATHEMATICAL REPRESENTATION.

The term to alcoholism was first medical developed by Magnus Huss (1849) and considered by the WHO (1967) "the fourth public health problem" as a set of physical and mental disorders caused by the consumption of alcoholic beverages" (1) with somatic and psychological effects and serious consequences on work capacity and interpersonal relationships.

Chronic alcoholism and psychiatric complications represent 5.5% of the psychiatric pathology in the country's population and have major consequences, causing: temporary inability to work, accidents at work and significant financial costs for medical care (2).

According to Sher and Trull, (3) in the sense of Deshaies and in developmental theories and vulnerability to the onset of alcoholism (4), personality factors, especially those of temperament, are classified as vulnerability and risk factors.

MATERIAL AND METHODS

The study included a group of 60 subjects selected by age, gender, social status, professional training and domicile, between 30 and 65 years of age, assisted in the Department of Occupational Medicine of the Arad County Emergency Hospital in 2016

and 2017, diagnosed with alcoholic addiction syndrome.

In comparison, the study uses 60 homogeneous control batch consisting of healthy subjects as a first batch and another batch, identical, but without alcoholic addiction syndrome over a two-year period.

The "Karolinska Scales of Personality - KSP" questionnaire (6), which contains 135 items in 15 scales, grouped in 5 categories, was used to evaluate the representation. Item capitalization was done on the Likert scale with 4 anchors (1-4) (7).

For the statistical analysis we used *SPSS version 17.0* and for the charts and tables we used *Microsoft Excel*.

Blood test were performed (OGT, PGT, TG-gamma) to determine the degree of severity and the predisposition to develop subsequent ethanolic complications.

RESULTS

The main idea of this study was to establish is there are any significant differences between our two groups. For this we run a Wilcoxon sum - rank test to compare and quantify the responses given by our patients in all 135 questions. We obtained that in most of our questions 132 (97.7 %) out of 135 there are extremely significant differences ($p < 0.001$). The only three exceptions are question number 25, 36 and 69, here there are no significant differences between our groups ($p > 0.05$). In each case the healthy sample had significantly better results (tab. I, II, fig. 1, 2):

TABLE I

Comparative analysis between pathologies diagnosed in the study groups

Pathological disorders	Healthy group (N1=60) (%)	Diseased group (N2=60) (%)
Depression	15%	90%
Somatic anxiety	22%	93%
Impulsivity	27%	60%
Psychopathic personality	5%	74%
Avoiding monotony	41%	87%
Nervousness and suffering	19%	89%
Muscular tension	8%	76%
Social cognitive anxiety	21%	67%
Psychic anxiety	12%	81%
Psychic asthenia	4%	56%
Inhibiting aggressiveness	82%	24%

TABLE II

The distribution of level of OGT, PGT and TG-gamma in 120 subjects

OGT-less than 50mg./dL = I		OGT over 50mg./dL = 2	
No	42	No	78
%	35	%	65
PGT-less than 50mg./dL = I		PGT over 50mg./dL = 2	
No	26	No	94
%	22	%	78
TG-gamma = I		TG-gamma = 2	
No	36	No	84
%	30	%	70

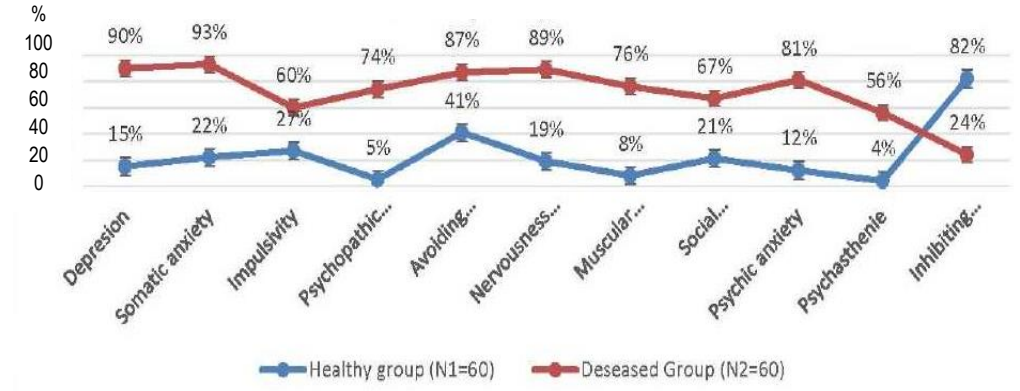

Fig. 1. Predisposing factors

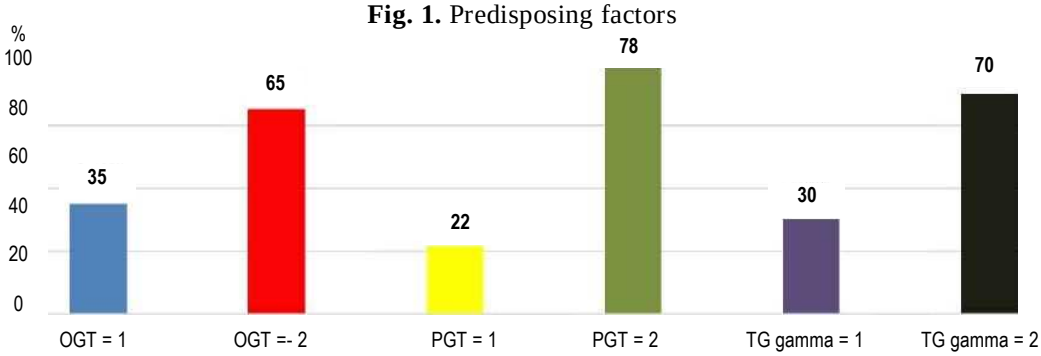

Fig. 2. The distribution of the subjects according to their medical tests

DISCUSSION

Psychopathic personality of patients with ethanolic dependence is recognized with the healthy group through a significant difference (1, 2, 3). Many study highlights the high percentage of factors involved in the occurrence of ethanolic addiction syndrome: low work potential, low skills, low power of attention and concentration, increased impulsivity, low socialization, nervous and muscular tension, social-cognitive anxiety, indirect aggression and irritability (8, 9, 10).

Alcoholism is multifactorial disorder both environmental and biologic factors contribute (10, 11).

Because many drinkers occasionally imbibe to excess, temporary alcohol-related pathology is common in nonalcoholic.

The period of heaviest drinking is usually in late teens to the late twenties. This is also a time of high risk for temporary alcohol-related social, occupational or driving difficulties.

The phenomena are often isolated events or self-limited, but when repeated problems in multiple life areas develop, the person is likely to meet criteria for alcohol abuse or dependence (12, 13).

In the absence of alcohol dependence, an individual can be given a diagnosis of alcohol abuse if he or she demonstrates repetitive problems with alcohol in any one of four life areas: an inability to fulfill major obligations, use in hazardous situa-

tions such as driving, legal problems, or use despite social or interpersonal difficulties (14, 15, 16).

CONCLUSIONS

In our study was demonstrated like the subjects selected for the study show an increased level of neuroticism, a lower degree of socialization, and a tendency of increased impulsivity in interpersonal relationships, compared to those subjects in the healthy group.

AORTOCORONARY BYPASS GRAFT PATENCY ASSESSED BY CORONARY COMPUTED TOMOGRAPHY ANGIOGRAPHY – UNICENTRIC STUDY (Abstract): Coronary artery bypass graft (CABG) surgery is used to revascularize ischemic myocardium affected by coronary artery obstruction. Conventional coronary angiography (CCA) is an invasive method used for graft evaluation. Nowadays, in post CABG patients grafts can be assessed noninvasively by using coronary computed tomography angiography (CCTA). **Aim**: To determine the late patency rate in coronary bypass grafts using CCTA. **Methods**: To assess graft patency, sixty post CABG patients (51/60 males and 9/60 females) were evaluated using dual source computed tomography (DSCT) angiography. All patients underwent a primary isolated CABG surgery between January 2000 and December 2004, performed by a single surgeon, at the Department of Cardiovascular Surgery, "Prof. Dr. George I. M. Georgescu" Institute for Cardiovascular Diseases, Iaşi, Romania. The grafts were classified as patent, occluded and stenotic (stenosis >50%). **Results**: The mean age of patients was 68.05±7.59 years and the mean time after graft implantation was 129.53±16.74 months. The number of assessed grafts was 200, including 146 saphenous vein grafts (SVG) and 54 in situ left internal mammary artery (LIMA) grafts. A total number of 105/146 (71.92%) venous grafts and 52/54 (96.3%) arterial grafts were patent. **Conclusion**: Nowadays, computed tomography angiography is a modern noninvasive imaging modality used to evaluate the aortocoronary graft patency in early and late postoperative settings. In our study, the late saphenous graft patency rate was superior to that found in earlier angiographic studies. **Keywords:** CORONARY COMPUTED TOMOGRAPHY ANGIOGRAPHY, CORONARY ARTERY BYPASS GRAFT, SAPHENOUS VEIN GRAFT, LEFT INTERNAL MAMMARY ARTERY GRAFT

Coronary artery bypass graft (CABG) surgery represents the standard of care in the treatment of advanced coronary artery disease in order to restore myocardial perfusion. Triple vessel disease, one or two vessel disease involving the proximal left anterior descending artery (LAD), left main artery stenosis and left ventricular failure are the main clinical indications for CABG (1). The long-term prognosis after myocardial revascularization depends on bypass graft patency and progression of native coronary artery disease (2). Conventional coronary angiography (CCA) is the gold

standard in evaluating the patency of CABG, but it is a two-dimensional projection method that allows evaluation of the vessel lumen, not of the vessel walls, and is characterized by important limitations (invasiveness, high cost, need for hospitalization, low patient compliance). The development of electrocardiographically (ECG) gated multidetector computed tomography angiography has allowed accurate visualization of graft patency noninvasively, to detect or exclude significant stenosis in bypass grafts (3). The superior temporal resolution of dual source computed tomography (DSCT) has substantially improved coronary imaging. Weustink *et al*., using DSCT angiography, reported a diagnostic accuracy of 100% in the evaluation of graft stenosis on a segment basis. Coronary computed tomography angiography (CCTA) is now used more widely in postoperative settings and in preoperative planning for repeat CABG surgery (2). While asymptomatic CABG patients are not routinely followed by CCA, DSCT represents an opportunity for graft follow up in such as patients, as well as in symptomatic post CABG patients. The aim of this study was to assess graft patency noninvasively using DSCT.

MATERIAL AND METHODS

We performed a single center study that included 60 post-CABG patients, 51 (85%) males and 9 (15%) females, who underwent a primary isolated CABG surgery in the interval January 2000 - December 2004, performed by a single experienced surgeon, at the Department of Cardiovascular Surgery, "Prof. Dr. George I. M. Georgescu" Institute for Cardiovascular Diseases, Iași. All patients underwent CTCA after a written informed consent was obtained. Exclusion criteria were allergy to iodine contrast agents, renal failure and inability to hold breath. The number and types of grafts and the native recipient vessels were extracted from each patient surgical record. An 18G cannula was placed in an anticubital vein for the administration of the iodinated contrast. All patients received nitroglycerin spray 0.8 mg within 5 minutes of scan acquisition.

All CCTA examinations were performed on a second-generation 128-slice DSCT scanner (Somatom Definition Flash; Siemens Healthcare, Forchheim, Germany). Scanning parameters were 100 or 120 kV tube voltage, tube current modulation with Care Dose 4D (reference 320mAs), 128 x 0.6 mm collimation, gantry rotation time 280ms. Peak arterial enhancement time was determined by the bolus tracking method. The contrast was injected by a power injector at 6 ml/sec, followed by 50ml saline flush. Images were reconstructed with a slice thickness of 0.75 mm, using a soft-tissue convolution kernel (B26f) and a sharp-tissue convolution kernel (B46) for vessel wall calcifications, to compensate blooming artifacts. Three-dimensional volume-rendered reconstructions were used to obtain general information about the status and anatomy of the grafts and native coronary arteries. Axial slices were examined for the presence of significant narrowing by determining the presence of ≥50% reduction in luminal diameter and vessel occlusion. The analysis was assisted by curved multiplanar reconstructions of all vessels.

The patients mean age was 68.05 years (range 48 to 82 years), and the mean interval between CABG surgery and CTA was 129.08±16.64 months. Mean body mass index (BMI) was 28.3±3.76 (range 20.53 to 40.57) kg/m^2. Arterial hypertension was the most common risk factor followed by dyslipidemia and diabetes mellitus (tab. I).

TABLE I
Patient characteristics

Variable		
Continuous	**Mean**	**SD**
Age, years	68.05	7.59
Follow-up interval, months	129.53	16.74
BMI, kg/m^2	28.27	3.88
Total cholesterol	187.28	45.88
HDL	48.93	13.06
LDL	107.33	40.82
Triglycerides	157.71	81.83
Category	**N**	**%**
Ever smoked	26	43.33
Male gender	51	85.00
Family history CAD	18	30.00
Dyslipidemia	51	85.00
Diabetes mellitus	26	43.33
Hypertension	56	93.33

Abbreviations: BMI, body mass index; HDL, high-density lipoprotein cholesterol; LDL, low-density lipoprotein cholesterol; CAD, coronary artery disease.

RESULTS

The maximum number of grafts per patient was 5 (one patient) and the minimum number was one (three patients), with a mean number of 3.33 grafts per patient. Six patients had only saphenous vein grafts (SVGs); three of them had only one venous graft on the right coronary artery (RCA), one patient had two venous grafts (on RCA and diagonal arteries), and two patients had three venous grafts (on RCA, diagonal and obtuse marginal arteries).

The grafts were classified as patent if there was continuous lumen visualization at origin, in the body and at its distal anastomosis with native recipient vessels; occluded when only their stumps were seen; stenotic if there was ≥50% diameter narrowing.

The total number of assessed grafts was 200, including 146 SVGs and 54 arterial grafts of in situ LIMA. A total of 105/146 (71.92%) SVGs and 52/54 (96.3%) LIMA grafts were patent; 41 venous grafts and 2 arterial grafts were occluded. The patients with a single SVG/RCA graft were two males (both SVG/RCA were patent) and one female (occluded SVG/RCA).

Thirty-one of the 60 patients (51.67%) had all grafts patent, 17/60 (28.33%) patients had just one occluded graft, 10/60 (16.67%) patients had two occluded grafts, whereas only two patients had three occluded grafts (43/200 occluded grafts and 157/200 patent grafts).

The third segment of RCA was grafted in 40 patients (20% females and 80% males), while posterior descending artery (PDA) was grafted in 20 patients (5% females and 95% males); all patients were right dominant (fig. 1). Left anterior descending (LAD) artery was the most grafted vessel (54 grafts, 7 in females and 47 in males), followed by diagonal branch, 45 grafts in 42 patients, 7 females and 38 males (3 males

with two grafted diagonal branches). Obtuse marginal branch (OM) was grafted in 40 patients (10% females, 90% males) with 41 grafts, one male with two grafted obtuse marginal branches (fig. 2).

A number of 54 patients had a LIMA graft to LAD. LIMA graft was not developed in 2 patients.

Fig. 1. Patient M.V. 71-years-old, 12 years after CABG surgery (2001-2013), has 4 grafts (SVG/PDA, LIMA/LAD, SVG/D1, SVG/OM1), all of them permeable

Fig. 2. Patient P.V. 72-years-old, 13 years after CABG surgery (2000-2013), has 5 grafts (SVG/RCA, LIMA/LAD, SVG/D1, SVG/D2, SVG/OM), all of them permeable, except SVG/RCA

The diagonal branch was the second most grafted artery. 45 diagonal branches were grafted in 42 patients, of which 34 (75.56%) patent and 11 (24.44%) occluded venous grafts were visualized. There was one stenotic (stenosis of ≥50%) graft to the diagonal branch.

OM was grafted in 40 patients. There were 41 venous grafts to OM, 32 (78.05%) patent and 9 (21.95%) occluded. Four patent SVGs to OM were stenotic grafts.

On right coronary artery, there were 60 venous grafts, of which 39 were patent (65%), with a worse patency in females. In males, 36/51 SVGs to the RCA (70.59%) were patent, while in females 3 of 9 (33.33%) SVGs to RCA were patent. According to their distal anastomoses, 40 venous grafts anastomosed distally to RCA, proximal to the *crux cordis* (8 females and 32 males), while 20 SVGs had distal anastomoses to PDA (one female and 19 males). Patent grafts to RCA proximal to the crux had been found in 25/40 (62.5%) patients and 15/40 (37.5%) patients had SVGs to RCA occluded, with a much worse outcome for females 6/8 (75% occluded) than males 9/32 (28.12% occluded). Two patients had stenotic graft to RCA (≥50% stenosis). 14/20 (70%) grafts anastomosed distally to the crux, to PDA, were patent, while 6/20 (30%) were occluded, with a better outcome for female (100%) than for male (68.42%) (fig. 3).

	LIMA/LAD	SVG/RCA	SVG/D	SVG/OM	SVG
FPG%	100,00	33,33	85,71	75,00	60,00
MGP%	95,74	70,59	73,68	78,38	73,81
GPG%	96,30	65,00	75,56	78,05	71,92

Fig. 3. Distribution of graft patency rate by distal anastomoses and sex (FPG, graft patency in females; MPG, graft patency in males; GPG, general graft patency)

The overall patency rates for arterial LIMA and venous grafts in this patient population were 96.3% and 71.92% respectively. There were 67.12% (98/146) saphenous venous good quality grafts, without any stenosis at origin, in the body or at their insertion with native vessel (7 SVGs were stenotic grafts).

DISCUSSION

Conventional coronary angiography (CCA) is the standard investigation for the evaluation of native coronary arteries and bypass grafts in post CABG patients (4). CCA is an invasive procedure, which has a significant risk in post CABG patient, associated with stroke, cardiac arrhythmia,

contrast allergy, nephrotoxicity, high cost, and radiation exposure (5). CCTA is a noninvasive method used for the assessment of coronary arteries and bypass grafts, which has been improved with the advent of DSCT scanners and has shown a high degree of accuracy for the detection of significantly lesions (6). Nonselective injection of contrast on CCTA abolishes such serious risks as arrhythmia, graft dissection, myocardial infarction or embolic events as compared to the selective injection of contrast agents in bypass graft on CCA. The current CCTA technology is able to evaluate a higher number of grafts as compared to the earlier CCTA technology, with a sensitivity of 100% for detecting significant lesions and a NPV of 100% (7). High sensitivity and high NPV indicate that negative CCTA results exclude significant graft lesions and the need for diagnostic CCA. Moreover, CCTA graft imaging can be done prior to planned CCA for graft visualization or in redo CABG for preoperative planning (8).

In contrast to arterial grafts, SVGs usually appear larger on CCTA images and fewer streak artifacts from surgical clips are seen. The proximal anastomosis of a graft is typically better visualized than its distal part on CCTA. Distal anastomoses that are not well visualized are considered patent when contrast is present within the graft conduit lumen.

All right-sided grafts in this study were SVGs, whereas left-sided grafts were represented by in situ LIMA graft on LAD and SVGs on diagonal branches or obtuse marginal arteries.

The advantages of LIMA graft conduit include decreased postoperatively mortality and improved cardiac event-free survival rates. The LIMA grafts are more resistant to atherosclerosis and have a long-term patency rates superior to those of SVGs (9). The wall of the arterial conduit is better suited to a high-pressure system and high flow velocity after CABG surgery. LIMA is used most often to revascularize the LAD or its branch territory. In situ LIMA grafts are commonly used to target the LAD (10). Sequential distal grafting is sometimes performed proximal side-to-side anastomosis to diagonal branches and distal end-to-side anastomosis to LAD or both to LAD (11). In our study, all LIMA were in situ grafts, with end-to-side anastomosis to LAD, without sequential anastomosis performed. On CTA, the LIMA graft is usually seen as a vessel along the left anterior mediastinum and may be difficult to visualize distally because of its size and artifacts. Long-term patency rate of the LIMA grafts, over 90% at 10 years after the surgery, was demonstrated by several studies.

Using SVGs for coronary arteries revascularization offers many advantages such as availability, accessibility, ease of harvest, resistance to spasm, but SVG occlusion in the later stages, due to plaque formation in the bed of fibrointimal hyperplasia and development of atherosclerosis, represent the main limitations. SVGs patency rate have increased due to continued improvements in surgical techniques, combined with antiplatelet or anticoagulant agents and lipid lowering drug therapy. The use of no-touch techniques to haverst the saphenous vein (SV) has been reported to significantly improve long term graft patency. Souza *et al.* (12) reported that the harvesting of SV with surrounding tissue provides high short- and long-term patency rates comparable to the LIMA (angiography at 8.5 years showed a patency rate for the conventional group of 76% and 90% for the no-touch group). Hata *et al.* (13) reported a SVG patency rate of 64.7% at 8 years.

Campbell *et al*. reported 66.7% patency rate of SVG at 7.3 years, while Naveed *et al*. (14) reported 66.1% venous grafts as patent at a mean follow up of 8.01 years.

CONCLUSIONS

In our study, patency rate for SVGs at 129 month was 71.92%, which is higher than in the previous reports. The secondary prevention methods, statins, antiplatelet agents, lipid lowering therapy, and lifestyle factor modification, contributed to improvement of SVG patency rate thus, venous graft occlusion had developed at a slower rate than found in earlier angiographic studies. While the association of arterial hypertension with the other risk factors related to the metabolic syndrome in elderly patients makes them more prone to the development of cardiovascular diseases (15, 16), further studies are required to determine whether a more aggressive pharmacological therapy could favorably modulate patency in venous conduits.

CYTOLOGICAL ANALYSIS OF THE PERIODONTAL POCKET IN PATIENTS WITH AGGRESSIVE PERIODONTITIS AND CHRONIC PERIODONTITIS

Oral exfoliative cytology includes the study and interpretation of the features cells exfoliated from the oral mucosa. The aim of a study realized by a group of argentinian researchers was to analyze cytological changes in the periodontal pocket of patients with different clinical stages of aggressive periodontitis and chronic periodontitis. Patients, aged between 24-54 years, of whom 41 were diagnosed with aggressive periodontitis, 40 with chronic periodontitis, sub-classified as mild, moderate and severe periodontitis, and 40 healthy individuals who were the control group. For the cytological study were taken samples of the epithelium of the periodontal pocket. Superficial and intermediate cell values were significantly greater in patients with aggressive periodontitis than in patients with chronic periodontitis or the control group. Histiocyte number was higher in patients with chronic periodontitis than in those with aggressive periodontitis, and differed significantly in both types of periodontitis compared to the control group. There were significant differences in polymorphonuclear neutrophil leukocytes when both types of periodontitis were compared to the control group. Microbial flora was statistically higher in patients with chronic periodontitis, and there were differences between patients with periodontitis and the control group. The cytological study demonstrated that patients with aggressive periodontitis had greater tissue damage, shown by the increase in intermediate and superficial cells of the epithelium of the periodontal pocket compared to the group of healthy subjects and to a lesser extent, to patients with chronic periodontitis. Only superficial cells made it possible to differentiate the sub-stages of the disease (Cecilia EC, Myriam AK, María EL. Cytological analysis of the periodontal pocket in patients with aggressive periodontitis and chronic periodontitis. *Contemp Clin Dent*, 2014; 5 (4) : 495-500).

THE HIV-POSITIVE PATIENT IN INTENSIVE CARE – PSYCHOLOGICAL PROFILE (ABSTRACT). **Aim:** This paper aims to outline the profile of HIV-positive patients in intensive care, in terms of psycho-emotional and vital parameters. **Material and methods:** We evaluated the HIV-positive patients that required intensive care (IC), from January 2011 to December 2013, in the HIV/AIDS Regional of the „Sf. Parascheva" Infectious Diseases Clinical Hospital Iaşi. **Results:** From January 2011 to December 2013, the HIV/AIDS Regional Centre in Iaşi recorded 2649 hospitalizations, of which 0.67 % (18 cases) required intensive medical care. Of these 10 were males and 8 females, aged between 0 and 65 years with a median of 24 years. There were 29 deaths (1.09 % of all hospitalizations), 11 of which in intensive therapy (38 % of all deaths) - 7 men and 4 women. CD4 counts in persons requiring IC care were between 1 and 112/mm^3, and most naïve patients who died were late-presenters. The main diseases diagnosed were pulmonary tuberculosis and pneumocystosis, the main cause of death being multiple organ failure. The duration of hospitalization ranged between 4.5 and 30 days. Treatment success rate was correlated with the CD4 and biological status: liver and renal failure, respiratory failure, meningeal coma, hypoproteinemia, diselectrolitemia. From a psychological perspective, patients that arrived in the intensive care showed a history of non-compliance and non-adherence, a personality structure often marked by a lack of respect for them, indifference or ignorance regarding the factors that generate well-being. **Conclusions:** HIV-positive patients in the position of requiring intensive care showed a marked immunological collapse due to abandonment of therapy or late detection. **Keywords**: HIV/AIDS, INTENSIVE CARE, ADHERENCE, ANTIRETROVIRAL THERAPY, PSYCHOLOGICAL PROFILE

The HIV infection is currently considered a worldwide pandemic. Some of the main problems concerning HIV patients are epidemiological, regarding the means of transmission, confections with hepatitis B, C and D, HIV outspread in vulnerable populations (intra-venous drug abusers), viral resistance to antiretroviral therapy (ART), choosing the most adequate ART treatment. At the same time, the medical world is confronting with numerous cases of HIV patients in extreme health conditions, which require intensive care assistance (1).

A patient's survival essentially depends on the characteristics of the infectant HIV clade (resistance to ART), on establishing an optimal therapeutic regimen and also on the patient's co morbidities (renal, cardiac,

diabetes) (2).

Given this general context, we consider the multidisciplinary collaboration between doctors to be essential in order to prevent the adverse events and also to keep track of drug interactions.

In Romania, the "pediatric cohort", represented by the young people born in 1986-1989 and infected in the hospital, is still the main part of all HIV infected people. However, we have observed in the past years a shift in patients' morbidity, from the adolescent age to adults and older.

From a psychological point of view, young people living with HIV/AIDS experience a series of particular emotional states: "therapeutic exhaustment" from having grown up with multiple ART regimens, abandonment of therapy, denying HIV status. This has an impact on the overall health status, making patients vulnerable to opportunistic infections that have an increased effect on the weakened immune system (3, 4).

Another situation to be considered is that of patients living with HIV/AIDS that are unaware of their diagnosis, slow-progressers (with a slow increase in viral load and a slow decrease in immunity throughout a long period of time) and late-presenters (HIV-infected patients with a very low immunity, CD4 cell count under 200/mm^3) (5). They represent the majority of HIV patients assisted in a medical intensive care (IC) unit.

This paper aims to describe the clinical-biological and psycho-emotional profile of the HIV patient requiring intensive care assistance.

MATERIAL AND METHODS

We realized a retrospective study for a period of 36 months, from January 2011 to December 2013, evaluating HIV positive patients in intensive care. In the mentioned time span, the Infectious Diseases Hospital Iasi reported 28.773 admissions, of which 2649 were HIV infected patients. Of these, 18 HIV positive patients required intensive care (0.67%) (fig. 1).

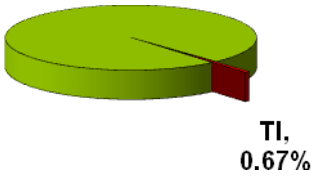

Fig 1. HIV patients admitted to ICU in 36 months

We evaluated the viro-imunological parameters at admission, and the clinical and biological status, highlighting organ deficits and failure. We also studied the psychological reports written at admission and at discharge, for patients whose biological status allowed psychological evaluation.

The psychological evaluation consisted mainly in clinical semi-structured interviews that explored the patients' overall emotional status and their emotions towards the HIV diagnosis.

The demographics revealed 10 male patients and 8 female, with a median age of 32.4 (range 24-65 years).

From the total of 18 cases (100%) of HIV in intensive care, 61% (7 male, 4 female), setting the survival rate 39% (fig 2).

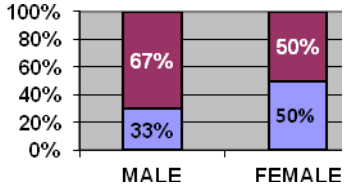

Fig 2. Gender distribution, and survival rate

RESULTS

In our study, we found that patients were admitted to the intensive care unit (ICU) with the following associated pathology, which revealed the HIV-infection:

- pneumocystosis and Kaposi sarcoma – one case;
- generalized tuberculosis and ongoing pregnancy – one case;
- ovary tumor – one case;
- HIV myelitis and encephalopathy – one case;
- cryptococosic meningitis – 2 cases;
- respiratory failure caused by a pneumocystis jirovecii infection – 5 cases;
- generalized tuberculosis with pleural-pulmonary, ganglionary, meningean and gastro-intestinal spread – 7 cases.

From an immunological point of view, CD4 cell count varied between 1 and 112/mm^3. Patients were admitted with severe immunosuppression, mainly with respiratory failure due to pulmonary pneumocystosis or pulmonary tuberculosis.

The number of days of hospital admission varied between 4.5 and 32 days in the ICU.

The initial psychological interview was conducted for 16 of the 18 patients in ICU. In 2 cases the severely deteriorated health status did not allow communication. The 7 survivors were evaluated at discharge from ICU and also monitored long term.

The psychological interview was semi-structured; questions regarded general life aspects, the moment of diagnosis and the progression of the HIV disease, coping with antiretroviral therapy, motivations for taking or refusing the ART, family, personal life, projects and life goals.

After analyzing the interviews, we observed two directions in HIV patients.

One category of patients was represented by those that had "given up" on life, deciding to stop taking the ART in order to end life. This form of "suicide" by not taking medication reveals a profoundly melancholic emotional profile, characterized by moderate to severe depression, a sense of being overwhelmed by life and all that society expects from the individual (financially, marital, maternally, educationally). Patients described a wish to "shut down", to stop existing, and often times to punish those around them (family, friends, and community) for their attitude towards them (rejection, stigma, work exploitation, indifference, and hate).

Another category was represented by the survivors – the patients that found motivation for living and for creating a close to normal existence. This motivation came from different sources – from wanting to take care of their family and children, from getting the support they needed from their parents or their life partner, from wanting to function normally in society, as successful individuals.

Long term psychological monitoring for these survivors revealed an increase in adherence to ART and a change in lifestyle. The motivation found in the ICU acted as psychological support for re-evaluating their life status and for taking the necessary actions to prevent further medical complications.

DISCUSSION

The number of cases in our study – 18 (0.67%) out of 2,649 – could be considered a small sample, when compared to the total number of HIV positive admitted patients. However, the author's motivation for evaluating the psychological status of the HIV patient in ICU was driven by the complexity of the cases, the medical and human costs, and especially the profound psychological implications of this pathology. The

survival rate of almost 40% encourages long term management and is a solid platform for clinical therapy and for the activity of the infectious diseases doctor and the IC specialist.

The HIV positive patient goes through a series of emotional changes, after the diagnosis. These changes are similar to those described in mourning: first there is denial, followed by anger, negotiation and finally acceptance. This acceptance of the positive status leads to a natural behavior of adherence to ART. However, some of the patient remain trapped in one of these states, and don't go through all the emotions necessary in order to reach acceptance. In this case they lack the ability or the intrinsic desire to take medication (6).

The Romanian "pediatric cohort" represents a particularly vulnerable population, due to the fact that it is made up of young adults that have spent their childhood and adolescence taking pills and fighting different co morbidities (7, 8, 9).

Adherence in this population is an ongoing problem due to both the long term therapy that causes "therapeutic exhaustion" and to lack of social support to go through all the emotional stages described above.

From a psychological point of view, practice has revealed two opposite attitudes:

1. denial of the disease and all the aspects concerning it, when meeting a new partner, a new group of friends, or in new social contexts; wanting to be like everybody else by NOT taking pills;

2. acceptance of the disease and coping with every-day social challenging situations, having a functional family, healthy children, a workplace etc.; wanting to be like everybody else WHILE taking pills.

Unfortunately, the first category of patients is the most common in ICU, being admitted with different organ failures and opportunistic infections that require intensive care assistance.

For slow-progressers and adult naive patients, the psychological impact is greatly increased by having to cope with a highly stigmatizing diagnosis while in ICU. They find themselves in the position to either give up or find strength and self-motivation to overcome the physical illness and the psychological trauma. Family support is essential in establishing a "safety net" for the patient, in his attempt to overcome the disease.

Also of crucial importance is the psychological support that is offered throughout hospitalization. The relationship that the patient builds with the psychologist is the stepping stone for future adherence to ART (10, 11).

CONCLUSIONS

In our research, we realized that, in order to fully address the needs of the HIV positive patient, the infectious diseases doctor, along with the ICU specialist must collaborate with the psychologist. This allows a multidisciplinary perspective on the patient, and professional support from all sides. It is of great value to identify the patient's psychological profile and his motivation, thus increasing life expectancy through a high level of ART adherence.

ANTIRETROVIRAL THERAPY AND ACQUIRED RIFAMPICIN RESISTANCE

According World Health Organization (WHO), in 2013, 13% of new cases of tuberculosis (TB) were HIV positive. Antiretroviral therapy (ART) reduced the risk of TB morbidity and mortality among patients HIV+ (1). A group of researchers from the National Institute for Research in Tuberculosis India have evaluated the impact of ART on acquired rifampicin resistance (ARR) in HIV-TB coinfection. The study group included 574 new pulmonary TB cases with and without HIV (246 TB+HIV-, 212 TB+HIV+ART-, 116 TB+HIV+ART+), receiving a TB treatment regimen which comprised thrice-weekly rifampicin for 6 months. The results showed that the relative risk for ARR was 21.1 (95%CI 2.6-184), $p<0.001$ for patients TB+HIV+ART- and 8.2 (95%CI 0.6-104), $p=0.07$ for patients TB+HIV+ART+, compared to patients TB+HIV-. ART reduced the relative risk for ARR among the patients TB+HIV+ by threefold (2).This study sustain the WHO recommendation for ART initiation in all cases HIV+TB+, irrespective of CD4 cell level (1) (World Health Organization. Global tuberculosis report 2013. www.who.int/tb/publications/global_report/en/ ; Narendran G, Menon PA, Venkatesan P et al. RESEARCH ON PLASMA AND SALIVA LEVELS OF SOME BIVALENT CATIONS IN PATIENTS WITH CHRONIC PERIODONTITIS (SALIVARY CATIONS IN CHRONIC PERIODONTITIS)

A. Manea[1*], M. Nechifor[2]
University of Medicine and Pharmacy "Grigore T. Popa"-Iaşi

2. Department of Pharmacology
[*]Corresponding author. E-mail alextril95@gmail.com

RESEARCH ON PLASMA AND SALIVA LEVELS OF SOME BIVALENT CATIONS IN PATIENTS WITH CHRONIC PERIODONTITIS (Abstract): The purpose of this study was to determine whether chronic periodontitis can stand behind modifications in the salivary and blood concentration of some bivalent cations (Calcium, Magnesium, Zinc and Copper). For this purpose, we formed a group of 30 adult patients with clinically onset chronic periodontitis, and another one of 30 healthy patients as control. Both groups were free from acute oral pathology and general illnesses. The groups were divided again according to the habit of smoking. Total saliva samples were obtained as "first time in the morning", then weighed and processed. Cations were read on Atomic Absorption Spectrophotometer and by Ion Chromatography (Magnesium). The same patients were required to undergo laboratory blood tests for Calcium, Magnesium and Zinc. Data obtained was normalised, then statistically interpreted using two-tailed heteroscedastic *t-Student* tests. Our data confirmed the existence of a connection between salivary calcium, magnesium, zinc and copper, and of blood magnesium, and chronic periodontitis. Salivary calcium and magnesium are affected by smoking.
Keywords: CHRONIC PERIODONTITIS, CALCIUM, MAGNESIUM, ZINC, COPPER.

The meaning of the words "chronic periodontitis" was argued upon for decades. It took a great deal of systematic work (1) to put together all definitions and mechanisms that come under it.

Chronic periodontitis is caused by plaque (2), but disease progression depends on an individual's susceptibility (3, 4, (5). While many factors have been cited as influencing the progression of the disease, there appears to be a fundamental association with the nature of the host response. Therefore, chronic periodontitis is a chronic inflammatory condition that recognizes the influence of local and general factors in its evolution. Identification of the histological characteristics of the development of chronic periodontitis has also influenced treatment philosophies and how clinicians treat individual patients affected by chronic periodontitis.

Bivalent cations take many involvements in acute and chronic inflammatory pathology. The studied cations (calcium, magnesium, zinc and copper) and many others play complex roles in the human organism. They

are found both intracellular and extracellular and are crucial for many normal processes within the normal physiology. From this point of view, the tissues of the oral environment have the unique particularity to be in contact with both blood and saliva. Therefore, bivalent cations' concentration in blood and saliva may have important effects on physiological processes but also on pathogenic mechanisms in the oral environment. Salivary concentrations of bivalent cations vary in certain conditions of the oral cavity and of the head and neck (such as malignant tumours) (6, 7, 8).

There are several conditions (glossopyrosis and oropyrosis) where salivary magnesium is constantly low (9).

Variations in the concentration of salivary cations are sometimes consistent with and some other times different than the serum concentrations of the same cations, under different pathological conditions.

The development of gingivitis and subsequently of the chronic periodontitis lesion has been classically described as progressing through a series of stages, i.e. the initial, early, established and advanced lesions (10). These stages are not always discernible as distinct entities in their own right. The "initial lesion" of chronic periodontitis is a subclinical entity occurring within the first four days of plaque accumulation. The characteristic immune response to bacterial enzymes and metabolic end products is observed as a result of complement activation of the alternative pathway. There is also a release of tumor necrosis factor-a. However, the presence of an organized plaque biofilm induces the neutrophils to release their lysosomal agents, in an act of "abortive phagocytosis". The action of these extremely active agents exacerbates local tissue damage; however, the lesion is not clinically discernible, and only occupies 5–10% of the surrounding connective tissues (10). A number of other factors have been described as being involved in the pathogenesis of chronic periodontitis (11, 12, 13, 14, 15).

The aim of this study was to assess the differences in some bivalent cation concentration (calcium, magnesium, copper and zinc) in the blood and saliva of patients in their initial status (with and without chronic periodontitis).

PATIENTS AND METHODS

The research was aimed at adult patients of both sexes.

The first lot consisted of adult subjects of both sexes, non-smokers and free from any pathological conditions of the oral cavity. The second lot consisted of adult subjects of both sexes, smokers and free from acute pathological conditions of the oral cavity. The third lot consisted of adult subjects of both sexes, non-smokers and with onset chronic periodontitis. The fourth lot consisted of adult subjects of both sexes, smokers and with onset chronic periodontitis. The demographic data of the four lots are described in Table I.

TABLE I

Demographic structure of the lots

Parameter	Lot I Control non-smokers	Lot II Control smokers	Lot III Periodontitis non-smokers	Lot IV Periodontitis smokers
No. of persons	9	21	12	18
Age & Sex				
Age	29±5.66	38±8.29	34.33±8.6	31.75±8.93
Sex distribution M/F	7/2	18/3	11/1	11/7

Lots I and II were built up of adults of both sexes, without acute oral pathology, and who did not feature general illnesses.

Inclusion criteria: Patients included in the study lots needed to:

- be of age;
- feature chronic periodontitis;
- be fully compliant to a treatment scheme.

Exclusion criteria:

- Patients with massive metallic dental restorations, that would hinder proper readings for copper and zinc;
- Patients that would not comply with assuming a proper and constant hygiene technique (brushing, flossing);
- Patients that were afterwards called on duty in other places (therefore, impossible to follow);
- Patients with drug-induced gingivitis or with other forms of periodontitis;
- Patients with chronic ethylism;
- Pregnant and breast-feeding patients;
- Patients with systemic illnesses such as diabetes mellitus, renal insufficiency, liver cirrhosis, malabsorption syndromes;
- Patients who used food supplements that contained bivalent cations;
- Patients with any kind of psychosis.
- Patients who used drugs that could bias cation levels (such as diuretics, cardiac tonics).

The diagnosis criteria for chronic periodontitis were: true loss of gingival-dental attachment; existence of periodontal pockets deeper than 3 mm; radiological loss of interdental septa (horizontal bone loss) or of lamina dura (vertical bone loss); all these for at least six dental-periodontal units per arch (16).

In what smoking was concerned, the lots were divided as follows:

- The first lot consisted of 21 periodontitis-free persons, non-smokers.
- The second lot consisted of 9 periodontitis-free persons, of which 6 smoked less than 10 cigarettes a day, and 3 smoked more than 10 cigarettes a day.
- The third lot consisted of 12 persons with periodontitis who didn't smoke at all.
- The fourth lot consisted of 18 persons with periodontitis, of which 10 smoked more than 10 cigarettes a day, and 8 smoked less than 10 cigarettes a day.

Patients were first subjected to an initial clinical examination and a thorough anamnesis.

The patients were required to have their Orthopantomogram (OPG) taken, or to produce a recent one if available. The x-rays were eventually obtained for each patient clinically diagnosed with chronic periodontitis.

Periodontal probing followed. We used a first-generation calibrated periodontal probe, of the 'O'-type by the University of Michigan, with Williams's markings. Each tooth (meaning a tooth that is not so damaged as to prevent measuring) was subject to six measurements, three on the buccal side and three on the oral side. After performing such measurements, and combining them to the chart head, patients received a clear and final diagnosis.

The structure of oral and general pathology, as well as that of hygiene status and scale deposits may be found in table II.

Saliva sampling

Patients were then instructed to produce a saliva sample in a sterile sealed single-use polyethylene syringe. They would have to do this the morning of the next appointment, just after waking up, before any hy-

giene or intake (eating or drinking) (17). After collecting the saliva sample, patients were asked to bring it to the practice as they would come to the appointment.

The patients were also required to perform a routine blood test, or to bring in any recent tests, if available; the tests included total blood calcium, magnesium and zinc, blood cell count and distribution, PCV, Hb and several other parameters. The blood samples and tests were performed at patient chosen locations.

The saliva samples were tare-weighed in ceramic and platinum crucibles on an analytical scale (*Balanţa*, Sibiu, Romania), then oven-desiccated at 400ºC for 24 hours. The crucibles were identified with numbers written with heat-resistant marker. The residue was taken up with 5 mL nitric acid 5%, then flushed and diluted with distilled water up to 50 mL (working volume for the atomic absorption spectrophotometer (AAS)). The solution obtained was filtered (using filter paper) into sterile dry polypropylene containers. Containers were labeled according to the original sample ID number and then the concentrations of cations were read on an AAS in the Faculty of Pharmacy. For magnesium, the determinations were performed by the Analytical Chemistry department of the Chemistry Faculty in the "Al. I. Cuza" University Iaşi.

Statistic interpretation of the data series was performed using a *t-Student* test, two-tailed and of the heteroscedastic type.

TABLE II

Oral and general pathology, hygiene status and scale deposits

Parameter	Lot I Control non-smokers	Lot II Control smokers	Lot III Periodontitis non-smokers	Lot IV Periodontitis smokers

Chronic medication	0	0	0	0
Oral hygiene (OHI)				
2.33 – 3	0	1	1	12
1.33 – 2	4	6	1	10
0 – 1	5	14	0	5
Scale deposits	4	8	12	16

As far as dental treatments were concerned, for the third and fourth lot, we found the following situation: Patients were found with new onset dental caries (13 in the periodontitis lots, 4 in the control lots), with improper fillings (21 in the periodontitis

lots, 7 in the control lots), with caries under fillings (7 in the periodontitis lots, 2 in the control lots), with gangrenes (6 in the periodontitis lots), root remains (18 in the periodontitis lots, 3 in the control lots). In the periodontitis lots, 26 patients featured more than one crown (4 ceramic, 11 metal – acrylic, 3 metal – diacrylic and 7 metallic), while in the control lots we only found 15 people with crowns or bridgework (5 ceramic, 3 metal–acrylic, and 7 metallic). Cervical margins of crowns were thoroughly checked, and found inappropriate in 24 patients of the periodontitis lots and 3 patients in the control lots (tab. II).

The study was performed according to the EU norms for clinical studies, and after the issue of the endorsement of the Research Ethics Committee of the University of Medicine and Pharmacy "Grigore T. Popa", Iaşi.

RESULTS

In saliva samples, there were several significant differences. We tried to allocate such differences to known or alleged phenomena in chronic periodontitis.

Salivary calcium was lower in non-smoker patients with periodontitis. That is, in control groups salivary calcium had an average of 84.24±0.87 mg/L (lot I) / 86.88±3.11 mg/L (lot II), while in the periodontitis lots, salivary calcium had an average of 53.37±6.57 mg/L (lot III) / 56.12±8.45 mg/L (lot IV), $p<0.05$ for periodontitis, $p<0.05$ for periodontitis and smoking (fig. 1).

Blood calcium did not feature any significant differences ($p=0.5894$) (Fig. 1).

Contrary, salivary magnesium increased in patients with periodontitis. The control group featured an average of $0.81 \pm 8.5 \times 10^{-3}$ mg/L salivary magnesium, while in periodontal patients, it reached 1.07 ± 0.18 mg/L, $p<0.05$ (fig. 2).

Blood magnesium decreased in patients with periodontitis. We found in the control group an average blood magnesium of 2.05 ± 0.08 mg/L, compared to an average of 1.87 ± 0.12 mg/L in patients with periodontitis, $p<0.05$ (fig. 2).

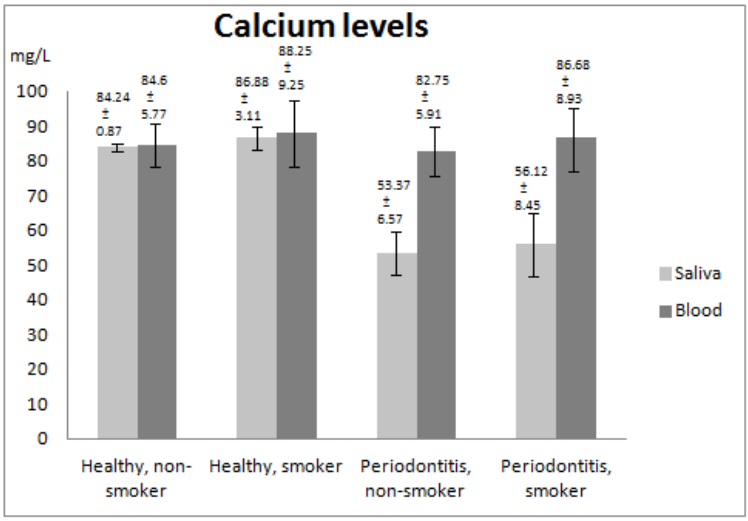

Fig. 1. Differences in calcium levels

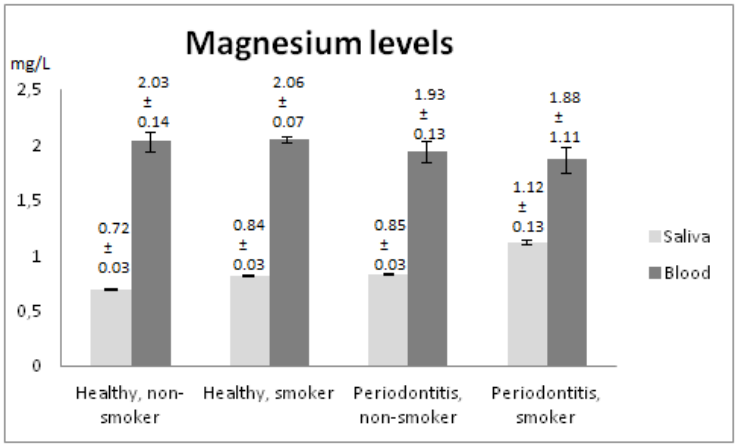

Fig. 2. Differences in magnesium levels

Smoking severely affected the salivary magnesium level in patients with periodontitis. Lot III had 0.82±0.03 mg/L, while lot IV had 1.12±0.13 mg/L, $p<0.05$. Salivary magnesium was also affected by smoking in healthy patients, lot I having 0.72±0.03 mg/L and lot II having 0.84±0.02 mg/L, but the statistical significance was not enough to state a clear difference, $p=0.05$.

Salivary copper increased in periodontitis (healthy average of 0.83 ± 0.18 mg/L, compared to 1.2 ± 0.2 mg/L in the periodontal patients), but this was not so evident ($p<0.05$) (fig. 3). Smoking had a positive effect on salivary copper in healthy subjects (lot I having a "basal" 0.66±0.01 mg/L while lot II had 0.92±0.16 mg/L, $p<0.05$) as well as in those with chronic periodontitis (lot III had 0.99±0.21 mg/L while lot IV had 1.18±0.15 mg/L, $p<0.05$).

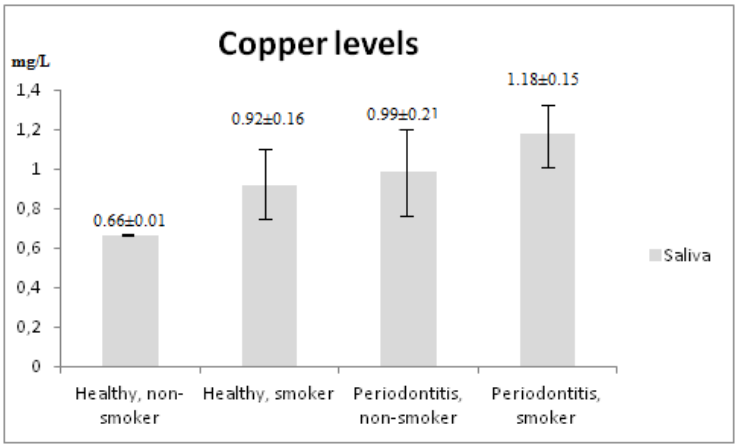

Fig. 3. Differences in salivary copper levels

Salivary zinc was not that accurately distributed among patients with periodontitis (lot III with 0.37 ± 0.01 mg/L, and lot IV with 0.21 ± 0.12 mg/L), but was defi-

nitely higher in healthy subjects (lot I with 0.48 ± 0.05 mg/L and lot II with 0.53 ± 0.18 mg/L). The difference was statistically significant ($p<0.05$) (fig.4).

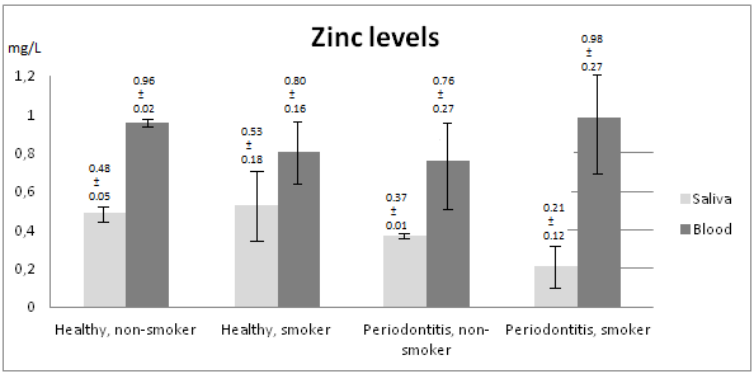

Fig. 4. Differences in zinc levels

DISCUSSION

Bivalent cations have various involvements in acute and chronic inflammatory mechanisms. Extracellular calcium triggers NLRP3 inflammasome which enables inflammatory monocyte and macrophage to release high levels of interleukin 1β (18). Some elements of the molecular mechanism of inflammation depend on the calcium release from intracellular structures, or on the entrance of calcium ions from the extracellular area into the cells (19). Human macrophages' activity is calcium-dependant (20).

In periodontitis, Kuraner (21) identified an increase in serum calcium and a diminishment of plasma zinc. In parotid saliva, calcium had a lower concentration than in normal subjects.

Lowering of salivary calcium may be charged to the deposition of scale that occurs by precipitation of soluble calcium from the saliva, therefore decreasing calcium concentration. This mechanism could also explain the relative uniformity of figures in the working lot ($\sigma=7.65$, that is 14.06%) compared to the control lot ($\sigma=34.3$, that is 29.7%), probably by reaching a saturation threshold of the precipitation phenomenon.

Magnesium is an essential bivalent metal for the activity of over 300 enzymes. It features an anti-oxidant activity since it reduces the forming of peroxide radicals. It is involved in the modulation of vascular permeability, and in the endothelial function. Magnesium reduces the synthesis of cytokines (22). Administration of magnesium suppressed some inflammatory responses in various tissues (23).

In rats with experimental magnesium deficiency, an inflammatory syndrome was discovered, characterized by the increase of the release of inflammatory cytokines, and by leukocyte activation. The synthesis of acute phase proteins increases (24).

The relative uniformity of the salivary magnesium values in the control lot is probably caused by a strict tuning of salivary secretion in periodontitis.

In our research the serum level of calcium and magnesium does not feature significant differences in patients with chronic periodontitis (either smoker or non-smoker)

compared to the control lots.

The salivary concentration of calcium is significantly lower though in patients with periodontitis. Smoking did not affect, either in the periodontitis lot or in the control lot, the level of salivary calcium.

The salivary concentration of magnesium is significantly higher in the periodontitis lot compared to the control lot, and higher in the smokers with periodontitis than in the non-smokers, also with periodontitis. Thus, in the case where the salivary Magnesium / salivary Calcium ratio is obviously higher in patients with this periodontal condition, magnesium is suspected to reduce the bacterial LPS-induced inflammation (25), and an increased salivary magnesium level could contribute to the put-off of the periodontal inflammation, mostly caused by bacteria. Respectively, a reduced level of magnesium increases phagocytosis and the yield of reactive oxygen species in the neutrophils (26).

An increased magnesium level could diminish apoptosis and also sustain tissue regeneration (27). A higher salivary magnesium level could have a diminishing action on the destruction of some pro-inflammatory cytokines such as TNF-α and IL-6 (22). Magnesium deficiency supports the development of inflammatory conditions (28).

The increase of copper is not very obvious, and it can be charged to other causes, such as contamination from present or prior bronze bridgework, and smoking (Figure 4).

Zinc is an essential element for the activity of the immune system. In case of zinc deficiency, the oxidative stress exacerbates (29). Administration of zinc diminishes the oxidative stress hence inhibiting the development of certain inflammatory processes (30). The ratio of copper / zinc concentrations is important for the intensity of the oxidative stress. Thus, an increase of the copper / zinc ratio is correlated to an increase of the level of the oxidative stress (31). There is no assertion of what an increased zinc level could mean. Probably it is due to a very host-dependent immune mechanism involving salivary IgA and complement, as a reaction to the presence and multiplication of periodontal bacteria.

The salivary level of copper is significantly increased in patients with chronic periodontitis, compared to their respective control lot. The accentuated decrease in the salivary zinc level in patients with periodontitis has an alleged connection with smoking, since in the control lot there is no significant difference in salivary zinc concentration between smokers and non-smokers.

The existing data on the variation of salivary and blood concentrations of the above-mentioned bivalent cations in relation to chronic periodontitis are still contradictory. By analyzing the salivary concentrations of calcium in patients with periodontitis (both chronic and aggressive periodontitis), adult smoker and non-smoker, Kiss (32) found that the level of salivary calcium in smokers is significantly higher than in non-smoker periodontitis patients (57.76 ± 18.8 mg/L *vs.* 44,6 ± 7.8 mg/L). The higher calcium level was associated to an increased bone loss and probing pocket depth.

By analyzing salivary calcium concentration in patients with periodontitis, smokers and non-smokers, Sutei (33) found no significant differences.

Kolte and his team analyzed in 2012 the saliva in smokers compared to non-smokers and found that total proteins, calcium, magnesium, and zinc are significantly reduced in smokers *vs.* non-smokers (34).

The same diminishment of calcium and magnesium concentration in the smokers' saliva was also found by Zuabi et al (35).

CONCLUSIONS

In our research we were unable to depict significant differences in salivary calcium from patients with chronic periodontitis, that is in smokers *vs.* non-smokers, but in both cases these concentrations were significantly lower than the concentrations in the saliva of healthy subjects, both smokers and non-smokers, but in both situations these concentrations were significantly lower than those in the saliva of periodontally healthy patients, either smoker or non-smoker.

In our study, the level of salivary magnesium in smokers with chronic periodontitis is significantly higher compared to both healthy smokers and non-smokers with chronic periodontitis.

The heterogeneity of the data in the literature is rather difficult to explain. Our results show a clear increase of the salivary copper / zinc ratio and the diminishment of salivary and blood zinc in patients with chronic periodontitis, compared to the healthy ones. We reckon that the lower zinc level may cause a slower and weaker immune activity, thus supporting the development of bacteria involved in the pathogenity of chronic periodontitis.

Thus, testing the salivary concentrations of bivalent cations may be useful for the assessment of patients with periodontitis, smokers or non-smokers.

ACKNOWLEDGEMENTS

This research was funded by the EU under the POSDRU 2007–2013 program, #88/1.5/S/58965, of which the researcher was beneficiary subsequent to a selection process.

NEWS

RECEPTOR-MEDIATED RECOGNITION OF MYCOBACTERIAL PATHOGENS

Mycobacterium is a genus of Actinobacteria that includes more than 50 different species, ranging in virulence from the non-pathogenic *M. smegmatis* to the causative agent of tuberculosis (TB) in humans, *M. tuberculosis.*Infection with mycobacteria most commonly occurs through inhalation or ingestion of bacilli. The bacilli are phagocytosed by host macrophages and dendritic cells (DCs) at the site of infection, for example by alveolar macrophages in *M. tuberculosis*-infected lungs or by intestinal macrophages in animals infected with *M. avium* subsp. *paratuberculosis* (MAP). Mycobacteria have evolved a range of mechanisms to circumvent phagosome maturation, preventing lysosomal degradation, and are therefore able to both survive and replicate inside the host phagosome. In order for mycobacteria to be phagocytosed by macrophages and DCs, the pathogen is first recognized by pattern recognition receptors (PRRs) on the host cell. This is achieved through the recognition of highly conserved molecular structures found on the surface of pathogens, often critical for microbial survival, termed *pathogen associated molecular patterns* (PAMPs) Several families of PRRs exist, all of which are capable of recognizing a different repertoire of PAMPs; including plasma membrane-bound and intracellular Tolllike receptors (TLRs) and cytosolic NOD-like receptors (NLRs) and RIG-I like receptors (RLRs). Future studies targeting different combinations of receptors may lead to a better appreciation of the complex interactions between phagocyte and mycobacterium. Ultimately, increasing our understanding of innate immune recognition of mycobacterial pathogens will aid in our abilty to treat and prevent mycobacterial diseases. (Kate E. Killick, Clíona Ní Cheallaigh, Cliona O'Farrelly, et al. Receptor-mediated recognition of mycobacterial pathogens. *Cellular Microbiology* (2013) 15(9): 1484–1495)

CLOSTRIDIUM DIFFICILE EPIDEMIC OUTBREAK IN AN ONCOLOGY UNIT (Abstract): **Aims:** Contributions to the knowledge of some peculiarities of *C. difficile* involvement in human pathology, nosocomial infections (NI) included. **Material and methods**: This clinico-epidemiological and laboratory study included 14 patients admitted to the Medical Clinic of the Iasi Regional Cancer Institute with the diagnosis *of C. difficile* NI based on detection of toxins A and B in stool samples. The data were assessed and interpreted using an algorithm which revealed the peculiarities of *C. difficile* NI outbreak occurrence and evolution. **Results:** Of the 14 cases included in the study, 5 (35.8 %) had community-onset infections and 9 (64.3 %) oncology unit-onset infections. The average hospital stay was 22 days. Immunocompromised condition and the use of antibiotics in the ciprofloxacin, colistin and cefotaxime group for 4 - 10 days were the main risk factors. **Conclusions**: This epidemic *C. difficile* NI outbreak which affected immunocompromised patients with high susceptibility to infection, common finding in oncology care was brought under control by active preventive measures associated with concomitant antimicrobial therapy effective in *C. difficile* infections. **Keywords**: *CLOSTRIDIUM DIFFICILE*, NOSOCOMIAL INFECTION, ONCOLOGY, EPIDEMIC OUTBREAK.

Similar to other species of the 200 described, *Clostridium difficile* can induce invasive phenomena and toxigenic processes through the mediation of some histotoxins (enterotoxins, haemolysins, proteases) that destroy the soft tissues, especially in immunocompromised patients treated with antibiotics who may develop colitis, sometimes severe, and invasive infections, such as bacteraemia (1, 2).

Although the role of clostridia in human pathology was reported before 1870, in the era of antibiotics *C. difficile* is still an important causative agent of human diseases, and the most common cause of nosocomial infections (IN), producing toxin-mediated diarrhea, pseudo membranous enterocolitis and toxic mega colon (3, 4, 5).

Recent clinico-epidemiological observations have demonstrated the involvement of highly virulent *C. difficile* strains in the occurrence of epidemic outbreaks in various health care units, requiring effective diagnostic, treatment and prevention inteventions (6, 7).

The possible involvement of *C. difficile*

in intestinal infections has been suggested ever since 1935, but, in the absence of accessible methods of investigation, these infections were thought to be caused by *Staphylococcus aureus*, recognized as the main causative agent of NI at the onset of antibiotic era (6, 7, 8).

The identification in 1978 of *Clostridium difficile* as a Gram positive sporulated bacillus allowed its inclusion among the etiologic agents of antibiotic-associated diarrhea, proving its widely emerging tendency with various clinico-epidemiological manifestations (9, 10, 11).

The spread and aggressiveness of *C. difficile* strains may be favored by: the use of antibiotics (even in a single dose) and cytostatics, digestive tract surgery, severe chronic diseases, administration of proton pump inhibitors, immunosuppression from various causes; frequent hospitalizations, age over 65 years (12, 13, 14).

The risk of *C. difficile* infections is maintained by the healthy carriers in the general population, with a prevalence of 2 - 5%, with the possible involvement of other risk groups including children, women after delivery, and tissue and organ recipients, stem cells included.

MATERIAL AND METHODS

The clinico-epidemiological study was conducted in the interval January-October, 2013, using the data in the observation sheets and laboratory results.

The study group included 14 patients with a mean age of 56.4 years, admitted to the Medical Clinic of the Regional Cancer Institute for *C. difficile* NI diagnosed by the presence of toxins A and B in stool samples.

The data were assessed and interpreted by using an algorithm which revealed the peculiarities of *C. difficile* NI outbreak occurrence and evolution (fig. 1).

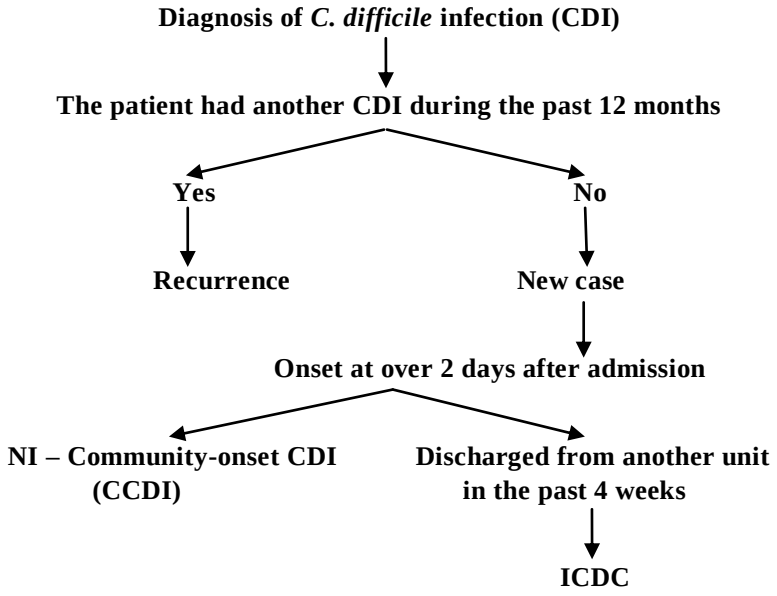

Fig. 1 The scheme of the structural algorithm for *C. difficile* infection outbreak

RESULTS

Community-onset C. difficile NI (CCDI). The assessments, based on the clinico-epidemiologic algorithm, showed that of the 14 cases included in the study, 5 (35.8%) were considered community-onset NI. The 5 patients were aged between 30 and 72 years, 4 were females and 4 from urban areas, with onset on average 72 hours before admission, multiple previous hospitalizations, no surgeries, and clinical symptoms started on average 2 days after admission (tab. I).

Clinical symptoms occurred 3 to 9 days after prior hospitalization (mean: 2 - 6.4 days) with fever state, abdominal pain and accelerated intestinal transit (3-20 stools/ day).

TABLE I

Some characteristics of the patients with community-onset *C. difficile* infection and clinical onset during hospital stay

No. case	Age	Sex	Area	Diagnosis upon admission	Co morbidities	Antibiotic therapy	
						Type	No. days
1.	72	M	urban	Acute myeloid leukemia Pseudo membranous colitis	Renal failure Heart failure Viral hepatitis C	Cefotaxime Ciprinol	7
2.	61	F	urban	Multiple myeloma Secondary immune deficit	Respiratory failure Cardiac failure	Ciprinol	8
3.	52	F	rural	Myeloproliferative syndrome	Myocardial infarction Breast cancer	Cefotaxime Ciprinol	7
4.	39	F	urban	Myeloproliferative syndrome Prolonged febrile syndrome	No	Augmentin	7
5.	30	F	urban	Diffuse non-Hodgkin's lymphoma	No	Vancomycin Metronidazole	3

Despite cancer-induced immunosuppression, of the 5 patients with CCDI only 1 case (20%) presented a severe evolution.

Oncology unit-onset C. difficile NI: 9 cases (64.3%), mean age of 60.5 years, onset 9- 35 days (average 22 days) after admission, characterized by abdominal pain (50%) accelerated intestinal transit (> 5 stools/day) (100%), fever (> 38.5 °C) (66.6%), and a mild clinical course (77.7 %).

In these patients, the clinico-epidemiological investigation showed that the risk factors involved in the occurrence of CDNI were the use of antibiotics in the ciprofloxacin, colistin, cefotaxime group for 4-10 days in 4 cases (44, 4%); cefotax-

ime and a dose of cytostatics in 2 patients (22.2%), chemotherapy and radiotherapy alone in 3 patients (33.3%).

The most commonly recorded co morbidities were: hepatitis C virus, arterial hypertension and anemia (tab. II).

TABLE II

Some characteristics of the patients with oncology unit -onset *C. difficile* infection

No. case	Age	Sex	Area	Diagnosis upon admission	Co morbidities	Surgery	Antibiotic therapy	
							Type	No. days
1.	67	F	urban	Malignant biliary tract tumor	Anemia Malnutrition AHT	yes	no	no
2.	68	F	urban	Lymphoid leukemia	AHT	no	Vancomycin	3
3.	67	M	urban	Malignant rectal tumor	Viral hepatitis C	yes	Cefuroxime	3
4.	70	M	urban	Malignant rectal tumor	AHT	yes	Cefotaxime	3
5.	76	F	urban	Malignant sigmoid colon tumor	Viral hepatitis C	yes	no	no
6.	30	F	urban	Diffuse non-Hodgkin's lymphoma	-	no	Vancomyicn Metronidazole	3
7.	73	F	rural	Diffuse non-Hodgkin's lymphoma	Anemia Osteoporosis AHT	no	Vancomycin Metronidazole	3
8	78	F	urban	Malignant ovarian tumor	-	yes	Cefotaxime Cytostatics	3
9.	67	M	urban	Malignant rectal tumor	AHT Nephropathy	yes	Cefotaxime	3

DISCUSSION

C. difficile - associated diseases cause polymorphic clinical manifestations dominated by diarrhea of varying severity and possible severe course in the case of pseudo membranous enterocolitis or toxic mega colon.

Both isolated cases, as well as those involved in nosocomial outbreaks have as characteristic feature the association of antibiotic and immunocompromised status.

The use of the classes of antibiotics, including penicillins, cephalosporins, macrolides, aminoglycosides, and lincosamides, can be associated with the induction of human *C. difficile* infections.

The onset of *C. difficile* infection is associated with the use of antibiotics that disrupt the equilibrium of intestinal flora. The virulence of the pathogenic agent strains is dependent, in principle, on the production of two enteric cytotoxins (Ted A and Ted B), and the outbreaks of *C. difficile* infection, particularly those with

severe symptoms, are related to the presence of ribotype O_{27}/NAP_1 (1, 2, 5, 6, 9).

The clinico-epidemiological diagnosis may benefit from laboratory investigations, which include detection of toxins in the stool samples of patients with suspected *C. difficile* infection.

The use of culture media for the isolation of this pathogen is not recommended as approximately 2-5% of the general adult population may be intestinal carriers.

Cell cultures are exposed to stool filtrate for 24-48 and a specific cytopathic effect is observed followed by a confirmation test with neutralizing antibodies, the results being available in 48-72 hours.

Rapid and highly specific results for both *C. difficile* toxins can be obtained using some variants of the immunoenzymatic test (12, 13, 14).

C. difficile selective agar is a medium that allows the isolation of *C. difficile* strains from stool samples, and colony characteristics allow the differentiation from other clostridia possible causes of antibiotic-associated diarrhea.

As to the cultures grown on blood agar media the colonies can be easily identified by the odor due to the production of cresol 12, 13, 16).

Roberts et al. (17) and Byrne et al. (18) analyzing the results of clinico-epidemiological researches on the incidence of *C. difficile* infections in various geographical areas have concluded that due to the emerging trend, the medical and socioeconomic implications these infections are a major population health issue.

Redelings et al. (11) reported that in the USA, in 2005-2006, hospitalizations for *C. difficile* infections increased by 117% with a corresponding increase in hospital costs and death compared to a decade earlier. Wysowski (15) showed that in the USA *C. difficile*-related mortality rate increased by 35%, from 5.7 per million population in 1999 to 23.7 per million population in 2004, the same being true for England.

Since 1990, the first-line therapy of non-severe *C. difficile* infections is metronidazole while vancomycin is recommended in severe infections, given the fact that there is a relatively low level of persisting spores at risk to germinate after reducing the concentration of antibiotics (5, 6).

Onderdonk and Garrett (5), and Vonberg (10) found that the spread of *C. difficile NI* can be controlled by consistently applied common hygiene-sanitary and epidemiological measures, directed to patients, suspects, health care workers and ambient environment. It is envisaged that *C. difficile* spores can live for long periods on surfaces, objects, food, and can be spread through aerosols especially in rural hospital without being destroyed by the usual methods of decontamination, which are effective only for the strains in vegetative form.

CONCLUSIONS

The nosocomial infection outbreak presented in this study although occurring in a group of immunocompromised patients and thus high susceptibility to infection, common situation in an oncology unit was brought under control by active preventive measures including daily screening, patient isolation, disinfection chemicals, including sporicidal agents, and the standard precautions of the health care professionals and support staff. Concomitantly, the antimicrobial therapy effective in *Clostridium difficile* infections was initiated, monitored by laboratory tests and customized in patients with certain co morbidities.

STATISTICAL STUDY ON THE INCIDENCE OF ALLERGIC DISEASES TREATED WITH DESLORATADINE AND LEVOCETIRIZINE AT "ATOPIA" ALLERGOLOGY MEDICAL CENTER, IAŞI, ROMANIA (Abstract): Allergies and allergic manifestations are a major health problem in our country and around the world. Epidemiological data have reported an increased incidence of allergic diseases up to 10-30% over the past decades. **Aim:** To evaluate the incidence of the most common allergic diseases treated with desloratadine or levocetirizine, second-generation antihistamines. **Material and methods:** For diagnosis and assessment of treatment with the two antihistamines the following tests were performed: allergy skin testing, immunoglobulin E blood levels, evaluation of target organ for allergic reaction (lung function tests, nasal and conjunctival examination, assessment of bronchial inflammation). **Results:** We conducted a retrospective study that included 365 patients (64% women and 36% men) diagnosed with different types of allergy in the *"Atopia" Allergology Medical Center* at Iaşi during the interval August 2012 – August 2013. Patients were aged 2 to 90 years (mean age group 35.98 years; 39.55 years for women, and 29.74 years for men). **Conclusions:** The majority of patients were from urban areas (82%). The most common allergic diseases in the study group were: urticaria (21%), allergic rhinoconjunctivitis (14%), allergic bronchitis (14%) and allergic asthma (12%). **Keywords:** DESLORATADINE, LEVOCETIRIZINE, URTICARIA, ALLERGIC ASTHMA, RHINOCONJUNCTIVITIS

According to the latest statistics, today, one of four people is affected by an allergic disease (1). Allergy is the immune response to common elements in the environment, which usually do not cause any reaction. An allergic reaction is triggered by substances called allergens and they are frequently represented by pollens, molds, dust mites, pet dander, specific foods, and chemicals (isocyanates, anhydrides, formaldehyde, some metals - chromium, nickel) (2).

Hereditary predisposition is a major risk factor; if one parent is allergic, the estimated risk of the child to be allergic is 48% and increases to 70% if both parents are allergic.

A growing number of studies have shown that allergies are becoming more complex and persistent, patients being now sensitized to more and more trigger factors, facing increasingly severe and persistent

symptoms.

Despite great progress achieved in the last 10 years in the research of treatment and causes regarding allergic disorders, there are still many issues to be solved towards achieving the objectives of more effective therapies, even a possible prevention (3, 4).

Desloratadine and levocetirizine, the most commonly prescribed antihistamines in the world nowadays, have a better efficiency and safety compared with first-generation antihistamines and a long latency period.

Desloratadine and levocetirizine are very efficient in the treatment of allergic diseases, including seasonal allergies, such as perennial allergic rhinitis, urticaria, and allergic conjunctivitis.

Although they are among the most frequently prescribed drugs, second-generation antihistamines are not without side effects. The most important potential side effects include effects on the nervous and cardiovascular system and drug interactions (5).

MATERIAL AND METHODS

We conducted a clinical and pharmacotoxicological retrospective study on a series of 365 patients diagnosed and treated at the Iasi "Atopia" Allergology Medical Center during a one-year interval (2012-2013). The diagnosis of allergic disorder was made on history and some allergy tests: allergy skin testing, immunoglobulin E blood levels, lung function tests, nasal and conjunctival examination, assessment of bronchial inflammation.

Patients diagnosed with allergic disorders received either desloratadine or levocetirizine alone, or association of these two along with other drugs such as antileukotriene agents, steroids (inhaled or topical), immunomodulatory agents.

Of the study patients, 64% were females and 36% males (fig. 1). Patients came from urban areas (82%) and rural areas (18%) (fig. 2). Patients were aged between 2 years and 90 years; the average age was 35.98 years (39.55 years for women, and for men 29.74 years) (fig. 3).

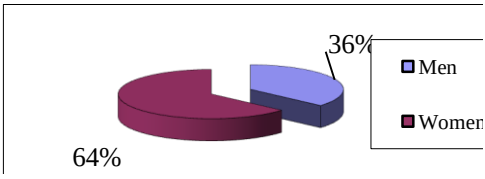

Fig. 1. Gender distribution of patients

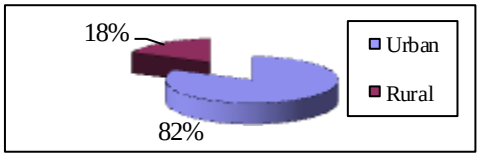

Fig. 2. Environmental distribution of patients

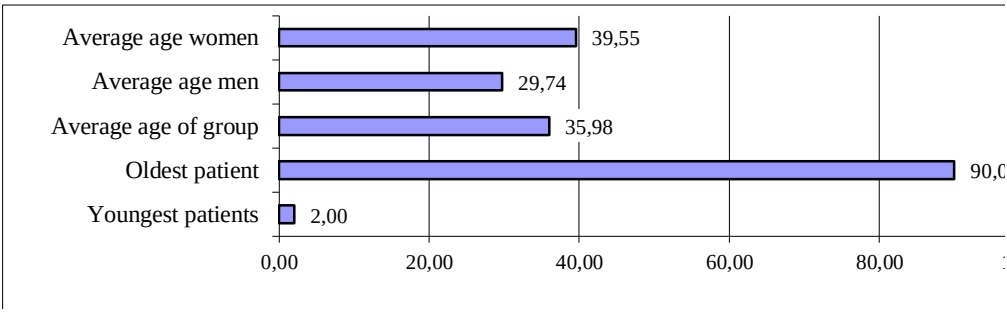

Fig. 3. Age distribution of study patients

From allergy observation sheets we collected data regarding the incidence of allergic clinical manifestations of patients treated with desloratadine or levocetirizine, and data on side effects caused by these drugs to the study patients.

Data were statistically analyzed using *MS Excel* software, interpreted, and corroborated with references in the literature.

RESULTS AND DISCUSSION

Distribution of allergic diseases in the studied group is presented in figure 4.

We mention that each patient presented one to three allergic diseases and the total number of diseases was 756, corresponding to an average of 2.07 diseases / patient.

The most common allergic diseases in the study group were: urticaria, allergic bronchial asthma, allergic bronchitis, allergic rhino conjunctivitis and other allergic manifestations, such as: allergic rhinitis, allergic dermatitis, angioedema, allergic conjunctivitis and allergic laryngitis.

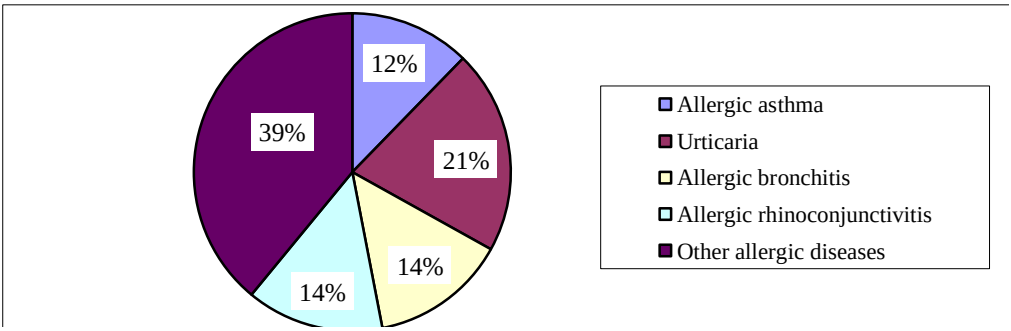

Fig. 4. Distribution of allergic diseases in the study group

In table I and figure 5 are shown the demographic data of patients (gender, average age and environment), as well as the incidence of major diseases.

Analysis of allergic diseases in the studied series showed predominance of urticaria (67.52%) and allergic rhino conjunctivitis (66.04%) in women, and allergic asthma (41.94%) and allergic bronchitis (35.24%) in male.

TABLE I

The structure of the study group

Allergic diseases	Gender		Average age (years)	Environment		Total diagnoses
	M (%)	F (%)		R (%)	U (%)	
Allergic asthma	41.94	58.06	35.34	17.20	82.80	93
Urticaria	32.48	67.52	36.80	19.75	80.25	157
Allergic bronchitis	35.24	64.76	36.22	22.86	77.14	105
Allergic rhino conjunctivitis	33.96	66.04	34.40	18.87	81.13	106
Other allergic manifestations	36.61	63.39	34.67	18.64	81.36	295

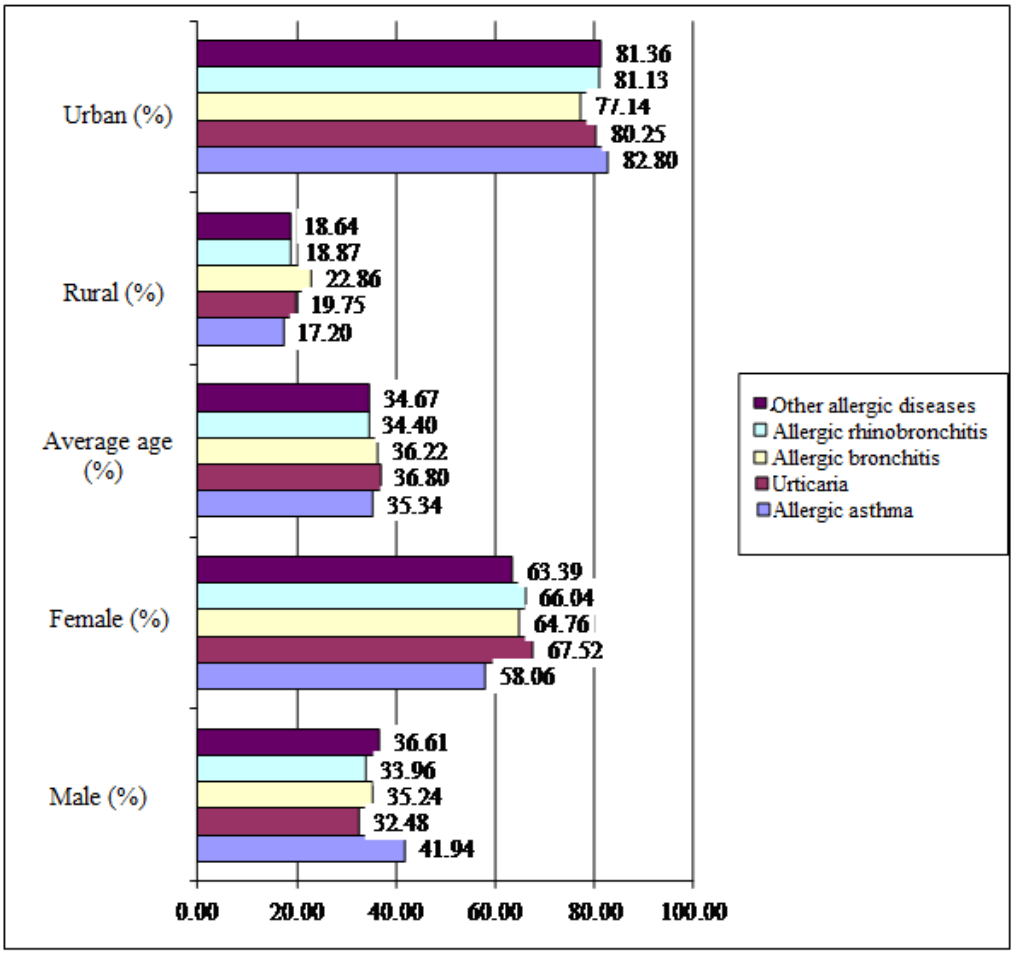

Fig. 5. Demographic data of the groups of allergic patients included in the study

The study group included a two-year-old patient with urticaria by sensitization to anti-inflammatory syrup (ibuprofen), and a 90-year-old patient with chronic urticaria by sensitization to antibiotics.

Table II presents the number of atopic cases and cases with predominant allergic diseases in the study group, respiratory and cutaneous type. Figures 6 and 7 show that 8% of the cases were atopic and 41% had skin allergies, this type of allergy being the most common in the atopic patients. Associated pathologies were present in 21.4% of the patients.

Therefore, 8% of the patients had hereditary predisposition to develop allergy, a much lower percentage than in the literature (6, 7).

The most common allergens involved in sensitization of the patients, responsible for producing allergic manifestations, were: mites, house dust, pollen, mold, animal dander, food (especially fish); these allergenic agents can be found in similar studies (7). Overall, the prevalence of sensitization to indoor allergens was increased in patients

with cutaneous manifestations, while the prevalence of sensitization to outdoor allergens was linked to respiratory manifestations. The presence of concomitant polysensitization to multiple allergens was frequent in patients with cutaneous disorders. Also, patients who simultaneously show sensitization to more than one allergen manifest a greater allergic poly symptomatology than those with mono sensitization.

TABLE II

Atopy, allergic diseases and associated pathology of patients

Indicator	Number of cases	Percentage distribution (%)
Family history		
Cases with no atopy	8	2
Cases with atopy	29	8
Undefined cases	328	90
Total	**365**	**100**
Allergic diseases		
Allergic asthma	86	24
Urticaria	150	41
Other allergic diseases	129	35
Total	**365**	**100**
Associated pathology		
Cases with associated pathology	78	21.4
Cases with no associated pathology	287	78.6
Total	**365**	**100**

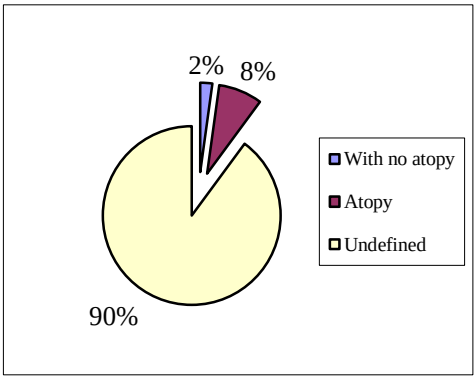

Fig. 6. Distribution of cases according to atopic structure

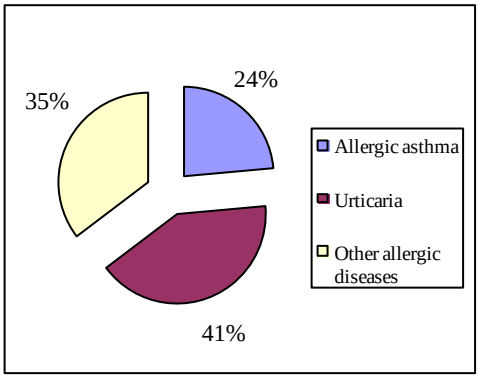

Fig. 7. Incidence of allergic diseases

We studied the incidence of the most significant side effects noted in specialized studies (8, 9).

Of all patients (365) treated with desloratadine or levocetirizine (5 mg/day), 2.74% experienced side effects (xerostomia, headache, fatigue, drowsiness, exhaustion and myalgias). At 61 years-old female patient, from an urban area, diagnosed with bronchitis and allergic rhino conjunctivitis, treated with desloratadine (5mg/day), the following side effects were recorded: asthenia, headache, myalgias.

Of the two study substances levocetirizine has greater potency, as confirmed by *in vivo* studies, in humans.

Levocetirizine may cause drowsiness in sensitive individuals.

Although desloratadine is less efficient, it has the advantage of a longer half life. Its most important side effect is drowsiness.

Desloratadine has a safety profile similar to levocetirizine, does not cross the blood-brain barrier, and has a very low sedation rate, which gives increased safety and tolerability (10). According to the literature, desloratadine and levocetirizine are "non-sedating" antihistamines, but the best would be to describe them as having minimal sedative effects, at therapeutic doses (11, 12).

The efficacy and safety of second-generation antihistamines, supported in the literature, is also confirmed by our study by the diminution of allergic symptoms and decreased incidence of treatment-emergent adverse events in our study patients.

CONCLUSIONS

We conducted a statistical study (August 2012 - August 2013) on the incidence of allergic diseases in 365 patients treated with desloratadine or levocetirizine in the *"Atopia" Allergology Medical Center* at Iaşi. We followed the adverse drug reactions during treatment.

Data were collected from allergy observation sheets and statistical analysis was performed using *MS Excel* software.

In the study group (365 patients), the incidence of allergic diseases was: urticaria (21%), allergic bronchitis (14%), allergic rhino conjunctivitis (14%), allergic asthma (12%), and other allergic manifestations (19%).

Of all the patients treated with desloratadine or levocetirizine (5 mg/day), 2.74% experienced side effects: xerostomia, headache, fatigue, drowsiness, and muscle aches.

NEWS

CAESAREAN SECTION INCREASED RISK OF ALLERGIES

Intestinal microbiota stimulates the development and maturation of the immune system early in life. At birth the child's gut is colonized by bacteria from the mother's vaginal microbiota, included *Bacteroidetes* phylum which is linked to protection against allergies. The caesarean section (CS) reduces microbial exposure and the immune system reacts excessively against innocuous antigens in its surrounding. Using DNA sequencing and computer analysis methods Jakobsson and colleges showed that infants born through CS were less colonized with the *Bacteroidetes* phylum, and have lower blood levels of the Th1-associated chemokines for inhibit allergic immune responses. The researchers concluded that CS induced a "lower total microbial diversity, delayed colonization of the Bacteroidetes phylum and reduced Th1 responses". These results explain the higher frequency of allergies in babies born by cesarean section than in those born vaginally (Jakobsson HE, Abrahamsson TR, Jenmalm MC, Harris K, Quince C, Jernberg C et al. Decreased gut microbiota diversity, delayed Bacteroidetes colonisation and reduced Th1 responses in infants delivered by Caesarean section. *Gut*, 2013; DOI: 10.1136/gutjnl-2012-303249).

ASSESSMENT OF NUTRITIONAL HABITS ON A GROUP OF PUPILS FROM A COUNTRYSIDE ELEMENTARY SCHOOL IN ROMANIA (Abstract): Food is a major contributor to healthy children and youth. The study of this factor must be complex, considering the dietary habits of the population. **Material and methods**: 65 pupils from rural area were surveyed weekly about eating chicken, fish, fruits, bread and cereal by-products. A special attention was given to daily consumption of fruits (to those who recognize this contribution). **Results and discussion**: chicken appears in menus mostly 2-3 times a week (40.0%) or 4-7 times (27.7%). Fish is particularly present in menus one time (47.6%) or 2-3 times (26.2%). Fruits are provided in 75.4% cases 4-7 times a week. The dominant consumption of bread is of 4-7 times (90.8%) and of cereal by-products is of 2-3 times (58.5%) or even of 4-7 times (27.7%) a week. Self body weight is considered to be appropriate by 63.1% teenagers and in 23.1% cases they considered their body weight is too high. **Conclusions**: The implementation of national dietary programs can change the nutritional habits of children if they are based on a real assessment, achieved only with the help of surveys conducted by questionnaire method. **Keywords**: CONSUMPTION FREQUENCY QUESTIONNAIRE, INTAKE OF CHICKEN, FISH, FRUITS, BREAD, CEREAL BY-PRODUCTS.

Food is an external factor that plays an essential role in maintaining the health of children and youth. Currently, there are many issues related to diet, due to the current difficult economic situation in most families, especially in those from rural areas. Economic problems are difficult in rural areas where the income is assured only by household items. Products obtained must assure the family needs and also designated for sale, to obtain funds used to ensure future crops. In this context the study of rural youth nutrition is very important (1, 2).

The study is particularly important, as today there are more questions about national dietary programs, intended to change the nutritional habits of the population. For example it is ongoing a program that gives fruit to the pupils in the school. We must know the exact situation because providing fruits to a population that already consumes fruits is a useless action.

MATERIAL AND METHODS

The investigation was conducted on a

group of 65 pupils who live in rural areas and learn at the School grades I-VIII of Băceşti countryside area, Vaslui County. Sex distribution of cases is relatively balanced, as assessed 36 boys (55.4%) and 29 girls (44.6%). To these young people was applied frequency questionnaire of food consumption. (3.4) is a weekly frequency questionnaire contributions (the fruit is estimated daily consumption) questionnaire was completed by pupils in the study group. We insist on weekly consumption of chicken, fish and seafood, fruits, bread and cereal by-products.

Statistical processing of results was done with Pearson Chi-Square test.

RESULTS AND DISCUSSION

The study was conducted on a sample of 65 pupils in eighth grade, aged between 13 and 14 years. We insisted on the frequency of eating chicken, fish, fruits, bread and cereal by-products in their menus.

1. Chicken meat is specific to rural area as baby grows quickly, so the presence of this meat in meals is not a problem. We must insist on this point because buying food in rural areas may be disrupted by lack of money. Population eats mostly products obtained in their household. Dominant contribution is 2-3 times per week (40.0%), followed by 4-7 times (27.7%). 18.5% of all pupils consume chicken meat only one time a week, while other 13.8% pupils do not consume at all (Fig. 1).

The situation is serious in 30% of families where the chicken is missing or is a very rare presence. Hygiene specialist and GP should know these issues to try to remedy the situation.

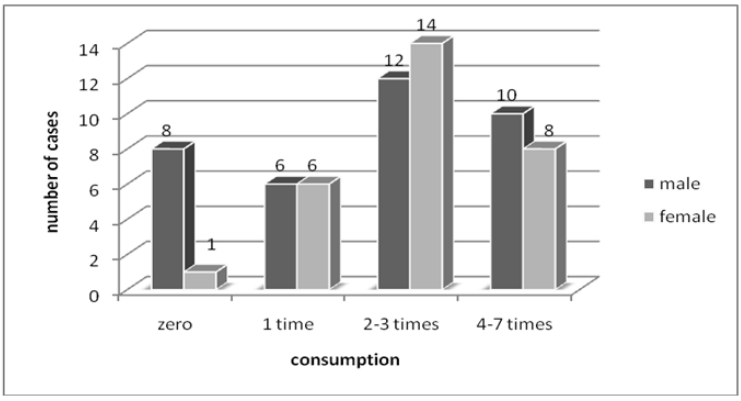

Fig. 1. Weekly intake of chicken meat at studied pupils

It is important to make assessments also on gender. At males, there are 22.0% pupils who do not eat chicken, while at females only 2.7%. Dominant contribution is 2-3 times both in boys (33.4%) and girls (48.8%). Pearson Chi-Square shows statistically significant differences ($\chi^2 = 5.126$, df = 3, p = 0.163) that directs to a traditional chicken diet.

These aspects are very important because any attempt to change the diet is likely to fail, if we start from the reality represented by a given population anchoring in tradition. Advices from television like "drink to your health daily…" have little chance of success.

2. Fish consumption is not a great option for our questioned pupils. It is not consumed especially in rural areas, where is not purchased. Throughout the group, the dominant contribution is one time (47.6%) or 2-3 times (26.2%). There are only 3.1% of families consuming fish 4-7 times, and 23.1% of families who do not eat at all (Fig. 2).

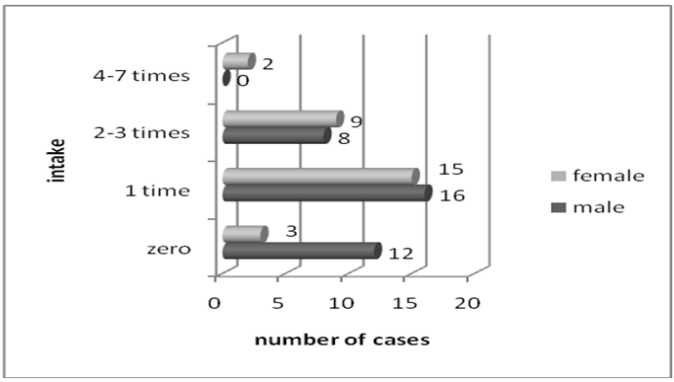

Fig. 2. The frequency of fish in the meals of studied pupils

At present menus the boys eat fish 2-3 times in 44.7% cases and 51.7% girls. In these situations there are no statistically significant differences ($\chi^2 = 6.816$, df = 3, p = 0.078).

3. Fruits are consumed fresh to give to the body an adequate intake of vitamin C. You should pay particular attention to the results due to the insistence of national programs to achieve this. A population consuming fruits in large quantities does not require supplementation by such programs. People who do not need supplements can consume, but they should be carefully provided.

We have found that 75.4% from all consumers eat fruits 4-7 times per week and other 23.07% consume fruits only 2-3 times (Fig. 3).

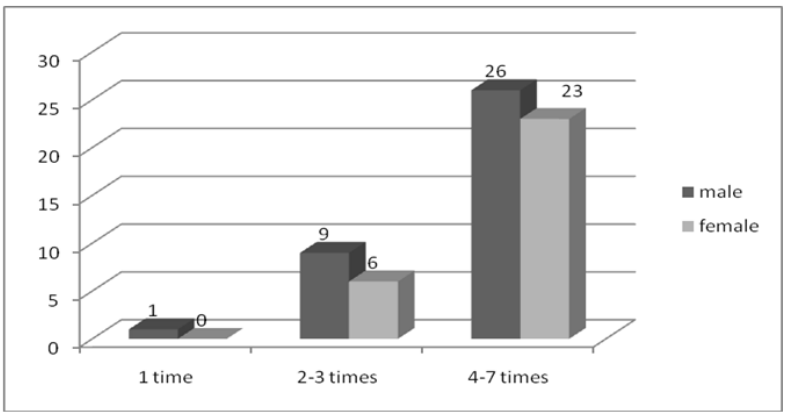

Fig. 3. The frequency of fruits in the meals of studied pupils

Basically surveyed pupils consume sufficient fruits; the intake was mostly 4-7 times a week. To this group is not necessary to make a further contribution. Food corrections are necessary, but not to fruits. To give fruits to these children is a futile gesture that has no educational value. Being tired of fruits that are offered, pupils become irritated, without a positive result.

In fact, you expect to get positive results from a large population which is consuming fruits. National programs should be oriented to feature food consumption of the population and not the opinion of one or another who does not know the reality and does not want to know.

On gender, the study is less important because boys are eating 4-7 times a week appear in 72.3% cases and in 76.3% cases for girls. The statistically significant differences obtained between genders ($\chi^2 = 1.042$, df= 3, p = 0.594) are logical and expected.

Fruits consumption is normal in rural areas where in every yard there are at least 2-3 trees. Keeping them for winter is not a problem as apples, pears, quinces are less perishable. Providing to these children fruits is a serious tactical mistake.

We must study here daily frequency of fruit consumed where 40 young people (61.5%) stated the presence of fresh fruit in daily menus (tab. I).

TABLE I

Daily intake of fruits

Daily consumption	One time	Two times	Three times	Four times	Many times
Male	0	5	5	2	8
Female	3	3	6	1	7
Total number	3	8	11	3	15
Percentage (%)	7.6	20.1	27.6	7.1	37.6

A fruit presence in the menu 1-2 times a day is not a problem. 7.6% pupils observe a contribution of one time and 20.1% observe an input of 2 times. If you eat fruits every day, one or two fruits are sufficient to provide the necessary nutrients. From an intake to 3 times per day and higher start too high values. We remark that 7.1% pupils are eating fruits 4 times a day and 37.6% who eat them several times a day. Practically 40% of surveyed pupils are eating fruits daily.

Fruits are needed by the body only in recommended quantities of rational consumption norms. They are low in protein and fat, have significant amounts of low molecular weight carbohydrates, but are important sources of vitamins and minerals. Their caloric intake is less than 100 kcal per 100 g, so it is very small (5, 6).

Providing these products in an excessive amount does not have a beneficial effect on consumers' health. Mass media programs provide only partial information on the role of vegetables and fruit in the diet without disadvantages offered and insisting on excessive consumption. Professionals must properly inform consumers about the importance of each product, with its nutritional value. Any such exaggeration is related to fruits has a negative impact over population. We do not need national programs offering fruits to a population which already consume them in large quantities.

Money allocated could be spent more effectively if it is done an accurate and extensive food survey.

4. Bread and cereal by-products. A balanced diet must include animal and vegetable products. Bread and cereal by-products are an important source of vegetable proteins and carbohydrates, giving the body an increased calorie intake. On the entire group, the dominant bread consumption is of 4-7 times (90.8%). There are 1.5% responses of absent or one time consumption. Otherwise bread is consumed very frequently. It is a traditional consumption for our population, especially for the wheat one which is widely grown in Moldavia (Fig. 4).

Of course it is also important the distribution of responses according to the pupils' gender. The consumption of 4-7 times appears in 91.6% cases at males, and in 89,7% cases at females, the calculated differences being statistically insignificant (χ^2 = 2.101, df = 3, p = 0.552). On the study group the consumption of bread doesn't raise special problems, being well represented.

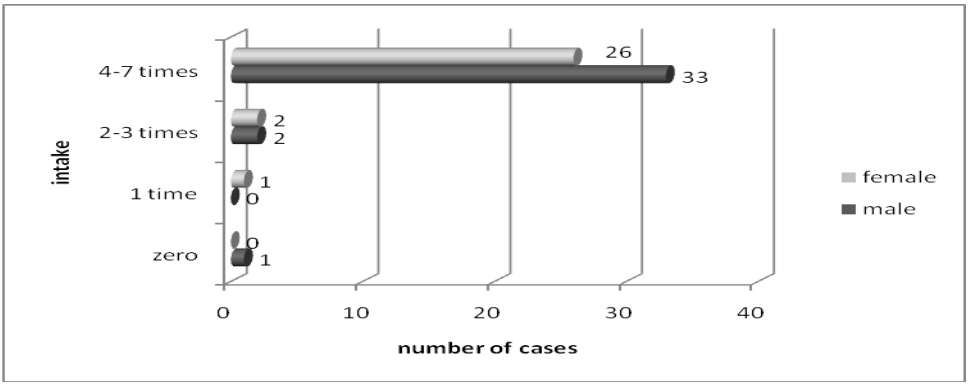

Fig. 4. Presence of bread in the questioned pupils' menus

The consumption of cereal by-products is a new issue, with no relation to tradition. The elders didn't usually consume rice, pasta or croup. These products have evolved simultaneously with the industrialization of nourishment. The dominant consumption of cereal by-products is of 2-3 times (58.5%) or even of 4-7 times (27.7%). There are also 10.8% responses of one time and even 3.1% negative responses. The small or absent consumption is not a major problem because this is food that provides mostly a quantitative intake, and not a qualitative one. The balanced intake of 2-3 times a week appears both at boys and girls, Pearson Chi-Square showing no statistically significant differences (χ^2 = 1.086, df = 3, p = 0.780). Even with these new products introduced in the menus the nourishment appears similar.

5. Assessment of body weight

To approach this aspect we will first discuss children's view regarding the role of nourishment in maintaining their health. Proper nourishment helps maintaining health – it is an assertion sustained by 81.5% pupils. There draw attention a percentage of 14.5% of negative responses of some pupils who can't make the connection between balanced nourishment and ensuring a normal growth and development of the body.

Body weight is closely connected to the quantity and quality of food given to teen-

agers. Their opinion about their own body weight is very important because it can change some food habits. Children who think they are too fat can start worrying about this aspect and try to lose weight (Fig. 5).

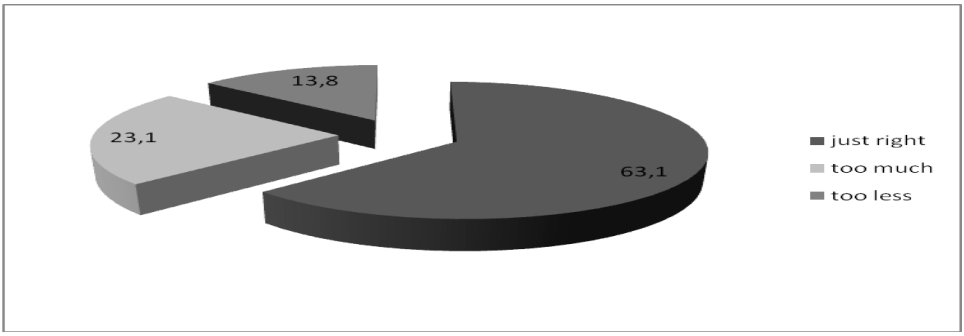

Fig. 5. Pupils' opinion about their own body weight

On the entire group, appear only 63.1% responses of just right weight, which is quite low for 13-14 years old pupils. Too much weight is stated in 23.1% cases which should be objectified by weighing.

On gender, too much weight is stated by 22.7% boys and 24.1% girls, and too less by 8.3% boys and 20.7% girls. The calculated differences are statistically insignificant ($\chi^2 = 2.281$, df =2, $p>0.05$) and reveals a similar perception of self body weight.

The study is very important because it provides an overview of eating habits of pupils in this group and allows a close observation of the mistakes that appear. The noticed mistakes are not those stated on TV, related to an insufficient fruit intake. Food changing programs must be carefully made, after a thorough study about the actual eating habits of the target population. On a population so rooted in traditions as the one in the study group, any attempt of forcing consumption in a certain direction has little chance of success.

CONCLUSIONS

Chicken is present especially 2-3 times (40.0%) in the menus, followed by 4-7 times in consumer cases (27.7%) and also there are cases of absence (13.8%).

Fish is a food with a great nutritional value, but is not widely used in our country. In most of the cases (47.6%) it is on the table only one time a week or 2-3 times (26.2%) a week.

Fruits appear to be consumed in this group by 75.4% of pupils for 4-7 times a week, and by 23.07%, 2-3 times a week. Particularly should be noted the existence of non-response to zero and only 1.5% of responses for one time.

The dominant consumption of bread is of 4-7 times (90.8%) and of cereal by-products is of 2-3 times (58.5%) or even of 4-7 times (27.7%) a week.

Self body weight is considered to be appropriate by 63.1% teenagers. There are 23.1% cases in which body weight is considered too high, but these teenagers should be weighted to get the objectivity of the statement.

Any national dietary program geared towards changing nutritional habits of a population group should be based on the actual assessment of targeted populations. Otherwise the results are less encouraging.

NEWS

POLYSPECIES BIOFILM FORMATION ON IMPLANT SURFACES WITH DIFFERENT SURFACE CHARACTERISTICS

Rough implant, while being beneficial for initial bone formation and osseointegration, have been generally considered to enhance initial adhesion and the subsequent colonization of oral bacteria. The aim of this study was to investigate the microbial adherence and colonization of a polyspecies biofilm on 7 differently processed titanium surfaces. Six-species biofilms were formed anaerobically on 5-mm-diameter sterilized, saliva-preconditioned titanium discs. Material surfaces used were either machined, stained, acid-etched or sandblasted/acid-etched. Samples of the latter two materials were also provided in a chemically modified form, with increased wettability characteristics. Surface roughness and contact angles of all materials were determined. The discs were then incubated anaerobically for up to 16.5 h. Initial microbial adherence was evaluated after 20 min incubation and further colonization after 2, 4, 8, and 16.5 h using non-selective and selective culture techniques. Results at different time points were compared using ANOVA and Scheffé post hoc analysis. The mean differences in microorganisms colonizing after the first 20 min were in a very narrow range (4.5 to 4.8 log CFU). At up to 16.5 h, the modified sandblasted/acid-etched surface exhibited the highest values for colonization (6.9±0.2 log CFU, $p<0.05$) but increasing growth was observed on all test surfaces over time. Discrepancies among bacterial strains on the differently crafted titanium surfaces were very similar to those described for total log CFU. Fusobacterium nucleatum was below the detection limit on all surfaces after 4 h. Within the limitations of this in vitro study, surface roughness had a moderate influence on biofilm formation, while wettability did not seem to influence biofilm formation under the experimental conditions described. The modified sandblasted/acid-etched surface showed the highest trend for bacterial colonization. From a clinical point of view related to hygienic requirements, the choice of implant surface characteristics may be salient to the long-term health of any implant placed [Schmidlin PR, Müller P, Attin T, Wieland M, Hofer D, Guggenheim B. Polyspecies biofilm formation on implant surfaces with different surface characteristics. (*J Appl Oral Sci* 2013; 21(1): 48-55).

THE SEROPREVALENCE OF HEPATITIS C VIRUS INFECTION AMONG BLOOD DONORS IN THE NORTH WEST REGION OF ROMANIA (Abstract): The infection with hepatitis C virus (HCV) known also as a blood-borne infection can be life-threatening by delayed consequences of persistent infection. This study aimed to estimate the hepatitis C infection prevalence, its epidemiological mode of manifestation and its recent evolution among blood donors from North West region of Romania. We made a chronological study using the HCV seropositive confirmed results to serological blood donors screening, provided by two Blood Transfusion Centres, chosen for their quality of provided data: Cluj and Satu Mare. The statistics were descriptive and the time series modelling used the polynomial regression. In both counties, about three fourth of donors were male and in Satu Mare, female donors (29.2%; $p<0.001$) have been significantly more represented than in Cluj (24.6%). Hepatitis C virus seroprevalence was significantly ($p<0.01$) higher in Satu Mare ($279.8/10^5$ donors, CI: $241.7\text{-}317.9/10^5$ donors) than in Cluj ($212.6/10^5$ donors, CI: $187.4\text{-}237.8/10^5$ donors). The mode of manifestation was endemic in different patterns, one with wave and a stable one with a particular high value of $1.091.1/10^5$ female donors (CI: $674\text{-}1508.2/10^5$ donors) seroprevalence, in 2008, in Satu Mare. The variation of the prevalence value was higher for women and particularly (coefficient of variation: 91.9%) for those from Satu Mare. The hepatitis C virus seroprevalence among blood donors reflected a stable, endemic manifestation with particular variation and high transmission in female populational subgroups. **Keywords**: HEPATITIS C VIRUS, BLOOD DONORS SEROPREVALENCE, TIME SERIES.

Hepatitis C virus (HCV) infection is a serious public health concern because of the high risk for persistent infection (75-85% of infections) and delayed consequences as chronic hepatitis, cirrhosis and hepatocellular carcinoma (1, 2).

In the epidemiology of hepatitis C infection there are many differences between countries (even within the same country) related to risk factors, health care practices and socioeconomic issues. In the countries of Eastern Europe and also in Romania, there were many changes in population condition of life, habits, movements, socioeconomic situation and as well in the reforms of healthcare system. These factors

may significantly influence the populational manifestation of hepatitis C and in consequence, the selection of donors.

In developed countries, blood transfusion or plasma-derived products used to be the main route of HCV transmission, but after the systematic selection and screening of donors, the residual risk of transfusion-transmitted HCV, now is very low (3, 4).

In Romania, EU Directives and WHO recommendations for tissues and cells donations were adopted in the legal documents and are applied, except blood donors, which receive compensation (three days free time, tickets for bus and restaurant) for each donation. Blood donation and transfusion safety are centralized, in the Ministry of Health coordination and administration trough the National Institute of Blood Transfusion (NIBT). Across the country, there is one Blood Transfusion Centres (BTC) in each county, which use the same regulation and the quality assessment, particularly for screening of the transfusion transmissible infections (5). The donors are selected from the population aged between 18 and 62 years, documented as being free of chronic diseases, disabilities, acute infections or the belonging to some risk groups, in order to select individuals with low probability of the presence of HCV infection. Since 1995, the routine serological screening for HCV infection has been introduced in all Romanian BTCs.

To our knowledge, the HCV seroprevalence among blood donors in Romania has not been previously studied. Only few papers related to patients or specific high or low risk groups for the HCV infection, in some Romanian areas, have been published (6, 7, 8).

The aim of this study was to estimate the HCV infection prevalence, the mode of epidemiological manifestation and its recent evolution among blood donor population of the North West region of Romania. This study is part of a larger objective that we have established in our activity, which aims to identify and use objective sources of data in order to accurately describe the epidemiology of C hepatitis in our region.

MATERIAL AND METHODS

To estimate the HCV infection prevalence and its populational manifestation among blood donors we have made a chronological (longitudinal ecologic) study, including the confirmed positive results to the routine serological screening tests, for HCV antibodies. A confirmed positive result was considered the donor with positive results to all serological tests made in the local laboratory of BTC and in the National references laboratory for transfusion transmitted virus (NRLTTV) of the NIBT. The usual serological screening consisted in two simultaneous enzyme-linked immunosorbent assays (ELISA) tests, made in local laboratory of BTC and for the positive results, other different two ELISA tests and a Western Blot test, made at NRLTTV. For the indeterminate results, all tests were repeated from a new blood sample, at 3-6 weeks interval from the first determination.

Between departmental BTCs of the North West region of Romania, we have chosen two collaborative centres in our academic training: Cluj and Satu Mare, known for a good quality of provided data. Data source were the laboratory registers of the two selected BTCs, where were recorded the results of tests made in both BTC

laboratory and NRLTTV. Were collected summed anonymous data about the year of donation, gender and positive confirmed screening results for the presence of HCV antibodies. Data validation was made by the person in charge with the management of the laboratory register.

Collected data were recorded in an Excel worksheet, Office for Windows 2007 and the statistics were performed in the same software. The descriptive statistics was made by using proportions, confidence intervals, z test for statistical significance (comparison of proportions), the chi-square significance test for trend, the variance coefficients and the modelling for chronological analysis used the polynomial regression (9).

RESULTS

The period for which were found confirmed and valid results, for both Cluj and Satu Mare counties, was 2003 to 2010. In the 8 years period, in Cluj BTC were laboratory screened for HCV antibodies, 128,398 persons, with a yearly average of 16,050 persons and a variation from 15,177 to 17,365 donors (tab. I). In Satu Mare BTC were screened 73,969 persons, among which in average were about 9,264 person per year, and a variation from 7,487 to 10,808 persons in each year. All screened donors were aged between 18 and 62 years, the legal age for blood donation.

In both counties, about three fourths (75.4% for Cluj, 70.8% for Satu Mare) of donors were male (tab. I). For the entire period, the proportion of women donors was significantly higher ($p<0.001$) in Satu Mare County (29.2%) than in Cluj County (24.6%) and for each year it was the same situation, except the year 2008 and 2009.

From 2003 to 2010, among Cluj County donors, 273 ($212.6/10^5$ donors, confidence intervals CI: $187.4\text{-}237.8/10^5$ donors) were found positives to HCV antibodies and for Satu Mare County donors, 207 ($279.8/10^5$ donors, CI: $241.7\text{-}317.9/10^5$ donors) were positives, the prevalence being significantly ($p<0.01$) different in the two geographical areas.

In Cluj County, according to gender, the frequency of seropositive female donors, varied between the highest value of $375.7/10^5$ donors (CI: $192\text{-}559.4/10^5$ donors) in 2004 to the lowest of $72.5/10^5$ donors (CI: $9.5\text{-}154.5/10^5$ donors) in 2010. determining a range of $303.2/10^5$ donors, but without a significant (chi test for trend -0.2857) decreasing trend in evolution (tab. III). For male, the minimum value was $103.9/10^5$ donors (CI: $45.1\text{-}162.6/10^5$ donors) in 2009. the maximal of $331.1/10^5$ donors (CI: $227.4\text{-}434.8/10^5$ donors) in 2007, the range was $227.1/10^5$ donors and with a insignificant (chi test for trend -0.6667) decreasing in time. For entire Cluj County donors, the trend of evolution in the time interval was stable with insignificant (chi test for trend -0.5952) variation of seroprevalence between the highest level of $360.6/10^5$ donors (CI: $266.3\text{-}454.9/10^5$ donors) in 2007 and the lowest of $108.5/10^5$ donors (CI: $56.9\text{-}160.1/10^5$ donors) in 2009. There were no statistically significant differences between male versus female, yearly seroprevalence rates, except in 2003, when was a significant ($p<0.002$) higher prevalence among males.

In Satu Mare area, the seroprevalence in female donors had variations between $130.8/10^5$ donors (CI: $2.7\text{-}258.9/10^5$ donors) in 2005 and a particularly very high value of $1.091.1/10^5$ donors (CI: 674-

1508.2/10^5 donors) in 2008, but without a significant (chi test for trend 0.71429) trend evolution (tab. IV). In male donors of the same county, the seroprevalence had variation with the highest value of 343.5/10^5 donors (CI: 206.3-480.7/10^5 donors) in 2008, the lowest of 87.2/10^5 donors (CI: 22.6-151.8/10^5 donors) in 2009, but without significant (chi test for trend -0.1667) decline in the trend evolution. The range of the prevalence rate was of 960.3/10^5 donors, for female and of 256.3/10^5 donors, for male donors. Differences statistically significant ($p<0.05$) of the specific seroprevalence by gender was in 2005 with higher level in males and a particularly higher value for females in 2008 ($p<0.01$) and in 2009.

TABLE I

The number and the distribution by gender of blood donors serologically screened for hepatitis C virus antibody, in Cluj and Satu Mare Blood Transfusion Centre, in the 2003-2010 periods.

Years	Donors from Cluj County			Donors from Satu Mare County			p value[£]
	All	Female (%)*	Male (%)*	All	Female (%)*	Male (%)*	
2003	15,177	3,425 (22.6)	11,752 (77.4)	7.487	2,495 (33.3)	4,992 (66.6)	<0.01
2004	17,365	4,259 (24.5)	13,106 (75.5)	8.055	2,685 (33.3)	5,370 (66.6)	<0.01
2005	16,491	4,064 (24.6)	12,427 (75.4)	9.174	3,058 (33.3)	6,116 (66.6)	<0.01
2006	16,248	3,879 (23.9)	12,369 (76.1)	9.425	3,141 (33.3)	6,284 (66.6)	<0.01
2007	15,530	3,751 (24.2)	11,779 (75.8)	9,250	2,545 (27.5)	6,705 (72.5)	<0.01
2008	15,598	3,998 (25.6)	11,600 (74.4)	9,370	2,383 (25.4)	6,987 (74.6)	NS

The graphical representation of HCV antibody prevalence among blood donors reveals different patterns of evolution in the two counties: some wavy evolution for Cluj and more stable, but with an accidental transmission for 2008 In Satu Mare (fig. 1).

The models of polynomial regression denote a time stability of the endemic manifestation, without significant variation in time. For Cluj, in the graphical model there are (for both male and female donors) two peaks at 3 years interval, reflecting a probable high HCV transmission in certain particular population, but for both gender the modelling of the time-series show a stable evolution over time (fig. 2).

In Satu Mare for the first 5 years, the graphic curves, for both genders are in slowly increase and then they are divergent, with a high peak for female in 2008 and a sharp decline for male's curve, in 2009 (fig. 3).

The modelling of time-series show for men a slight decrease of prevalence in time (the coefficient of determination: 51.3%) and for female a stable evolution in time.

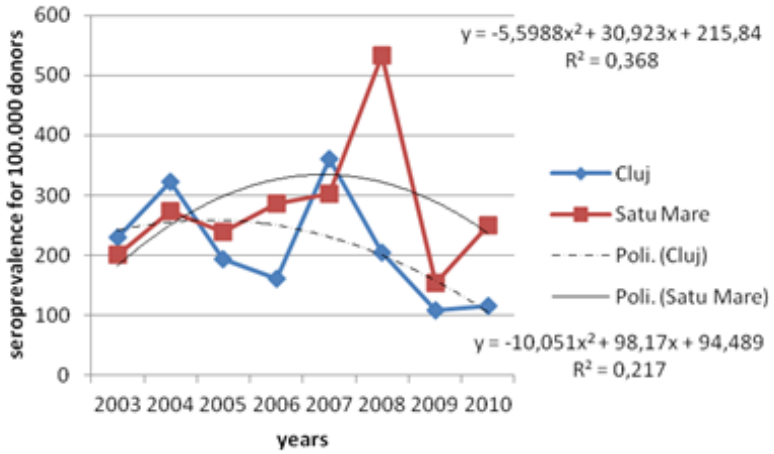

Fig. 1. The annual prevalence of seropositive persons for hepatitis C virus antibody, among blood donors from Cluj and Satu Mare County, in the 2003-2010 period and the time series modelling by polynomial regression.

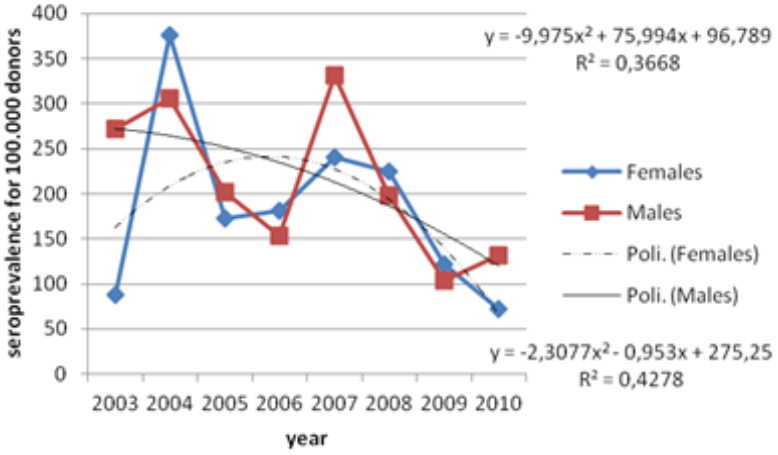

Fig. 2.The annual prevalence of seropositive persons for hepatitis C virus antibody, among males and females blood donors from Cluj County, in the 2003-2010 periods and the time series modelling by polynomial regression.

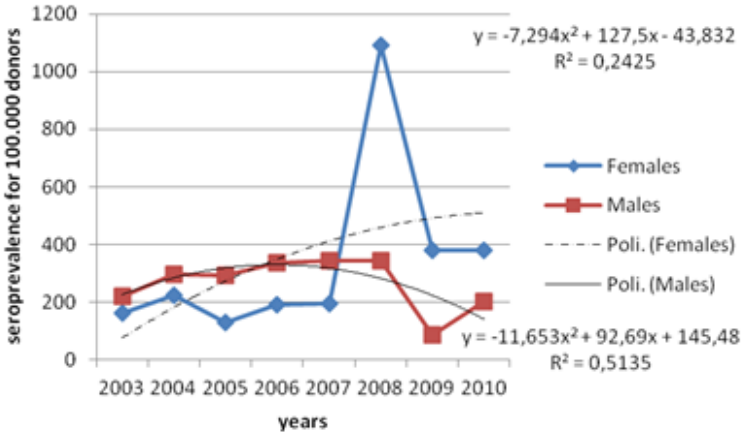

Fig. 3. The annual prevalence of seropositive persons for hepatitis C virus antibody, among males and females blood donors from Satu Mare County, in the 2003-2010 periods and the time series modelling by polynomial regression.

TABLE IV

The coefficients of variation for the hepatitis C virus antibody prevalence, among Cluj and Satu Mare blood donors, in the 2003 – 2010 period.

County	Female (%)	Male (%)	Total (%)
Cluj	53.2	39.2	42.7
Satu Mare	91.9	33.9	40.4

The variability of seroprevalence rates, evaluated through the coefficient of variation was higher in Cluj (42.7%) than in Satu Mare (40.4%) and among the female blood donors, both in Cluj (53.2%) but mainly in Satu Mare for whom the coefficient (91.9%) was the highest (tab. IV).

DISCUSSION

Keeping the risk of HCV contamination for blood products as low as possible is an important issue of patient security. In this sense, improvements in the selection of blood donors depend on the knowledge about infection prevalence in general population and detailed epidemiological data, particularly about transmission.

The present study provides some epidemiological aspects based on high quality and exhaustive data, for two counties of the North West region of the country, using the same standardized and centralized selection method for blood donors.

In the region the different attitude of people towards blood donation (difference by gender), may reflect the educational campaigns for blood donation, sometimes made under the pressure of the urgent practical needs for blood products. On the other side the behaviour to donate blood, may be associate with some personal characteristics and may represent persons with high HCV infection prevalence (risk groups). These aspects show the importance and the needs for implementation and improvement of programs for educate and prepare people to donate.

In comparison with European countries, the observed blood donors HCV seroprevalence in the presented study, is higher than in blood donors from developed countries

($0.35/10^5$ in France, $1.5/10^5$ in Switzerland), but similar with other or bordering countries like Turkey ($380/10^5$ donors), Hungary ($426/10^5$ donors) or Kosovo ($300/10^5$ donors) (10. 16). However, comparisons with other studies have to be carefully discussed, because discrepancies may be explained by the study periods, the included populations, and by the performances of serological tests used in the study (10, 11, 12, 14, 16). In addition, the HCV seropositivity varies between new and repeated donors ($41.07/10^5$ for new donors, against $1.55/10^5$ for repeated donation in United Kingdom; $97.4/10^5$ respectively $1.5/10^5$ in Germany), which were not distinguished in our study (13. 15). Besides the methodological reasons mentioned above, this difference observed with similar tests, could be explained by the higher prevalence of HCV infection in Romania, level never measured on representative sample, only estimated or evaluated in some risk groups (6. 7. 8). In addition, the effectiveness of low risk blood donor's selection in Romania has not been assessed. These differences are barriers for achieving a homogeneous blood safety in Europe: they therefore warrant investigation and maybe other specific preventive and/or control measures.

In the presented study were found in some years, significant differences in HCV seroprevalence distribution by gender and an accidentally high rate in 2008 for female blood donors from Satu Mare County. This higher prevalence in women, in our study, could reflect a similar phenomenon as in the general population, or could be the result from a less effective screening in female donors. Recent results on different population subgroups in south-western Romania, are in favour of the first hypothesis (men 3.4% versus women 5.5%; p = 0.002) (8). This higher prevalence in women, if confirmed by other studies, should be related to an obstetrical transmission, among other assumptions (16). Differences between genders were founded in other published study and in those from developed country, the higher prevalence in young men were associated with intravenous drug use (10, 16, 17, 18). There are also some studies made in development countries, who founded an important impact of medical invasive practice for the increasing prevalence of HCV infection in community and especially for elevated values in women (16. 19).

In evolution the stable endemic manifestation of HCV infection in the blood donors population of the two analysed county of north west region, even with apparently high transmission in some subgroups of population are contrary to the constantly decrease in HCV seroprevalence for blood donors, observed in other studies (12. 13. 14. 15). These issues should encourage the study of HCV infection epidemiology in the region and stimulate the evaluations for improvements of the blood donors' selection methods.

In this study the comparisons seems to be reliable because were used homogenous data from two large donor populations selected with the same methods. In addition were included only confirmed HCV positive subjects registered in the same manner. Under these circumstances, the results are worrying and should lead to further investigations. The weaknesses of the study are the short analyzed period of only eight years, not enough to assess the long evolution in time and the number of only two BTC included affecting the representativeness for the North West region of country.

CONCLUSIONS

In the studied blood donor's populations of the North West region of the country, the populational manifestation was endemic and stable in time. The pattern of populational manifestation was different, reflecting on one side a stable transmission and of the other part a transmission in wave and a particular very high accidental among female candidate blood donors. For the analysed period the highest variability denoting heterogeneity of the prevalence was among female blood donors. The individual differences on the attitude toward blood donation may favour the selection of persons at increased risk for the HCV infection. These aspects should lead to further investigation for identifying the particular risk factors for transmission in the regional population and then to improving the donor's selection.

ACKNOWLEDGEMENTS:

The authors wish to thanks the team working in the Blood Transfusion Centre in Cluj and Satu Mare and in particular the laboratory workers.

NEWS

NEW PROPOSALS ON CLASSIFICATION OF LUNG CARCINOMA

The World Health Organization (WHO; Geneva, Switzerland), in conjunction with the International Association for the Study of Lung Cancer (Aurora, Colorado), published its last official classification in 2004, and this book has served well as a benchmark for classification of lung tumors since then. Since 2004, lung cancer pathology has seen an enormous growth in data on the molecular pathology of lung cancer and the way that influences both the development of the disease and how it should be treated. These advances have had major repercussions for pathologists dealing with lung cancer, not only on our core morphologic diagnoses but also on the need for molecular data to inform therapeutic decisions. All the updates culminated in proposals for a revised classification of adenocarcinoma, driven by William D. Travis et al and sponsored by the International Association for the Study of Lung Cancer, the European Respiratory Society, and the American Thoracic Society. In Muller-Hermelink HK opinion, there is both a clinical need and an academic desire to integrate molecular data into the classification of lung cancer. There is already good evidence that doing so enhances the clinical relevance of the classification, makes it more biologically meaningful, and, in some circumstances, makes it more accurate. Fundamentally, the classification remains a morphologic one, which may, when appropriate, be enhanced or qualified by IHC and/or molecular pathologic findings. There is no need or indication to replace the morphologic classification with a molecular classification, even if such a thing existed. In today's lung cancer clinic, neither the morphologic nor the molecular approach, in isolation, serves patients adequately; in combination, they provide significant improvements in the way patients with lung cancer can be treated. TRUTH OR LIE – SOME ETHICAL DILEMMAS IN THE COMMUNICATION OF A SEVERE DIAGNOSIS (Abstract): Informing the patient about his disease is a very important issue in the medical practice, thus communication becomes imperative in healthcare services. Communicating the diagnosis of a pathology that doesn't bear any imminent risk for life is a common procedure for physicians. However, the situation changes drastically in the case of a severe diagnosis or a hopeless prognosis, with terminally ill patients. **Aim:** In this article the authors proceed to a critical analysis of the dilemma of communication or non-communication of a severe diagnosis. **Material and Methods:** The problem of communicating a severe diagnosis is described from a philosophical perspective (in terms of three fundamental ethical theories: Aristotle's theory of virtue, Kant's ethical theory and Bentham and Mill's moral theories). At the same time, certain physiological and medical approaches are presented. **Results and conclusions:** In order to avoid any communication conflict, especially considering the particular situation of the seriously ill patient in the context of the contemporary medical activities, the authors propose the debating of two opposing approaches: "the sacred lie principle" and "the justified medical truth" in the physician - patient relation. **Keywords:** SEVERE DIAGNOSIS COMMUNICATION, MEDICAL ETHICS, INFORMED CONSENT.

Communication is a personal ability that cannot be separated from the human being. It is the process used by individuals to exchange information, using a common and adequate system of signs, symbols and actions that allow both the adjustment of own behavior and the understanding of other people's behavior (1).

In the physician – patient relation the communication is essential, and its necessity for the communication between the patient and the physician / medical team is widely recognized and proved by researches. Due to its high importance in the medical activity and to the fact that the ability to communicate is not innate, but learned, the study of this topic is more and more frequently included in the medical curricula (2). This approach allows the future physicians to develop themselves globally, combining the professional technical aspects with the communication and rational interpersonal skills that form a "measurable and changeable set of behavior features that can further evolve" (3).

Over the years medicine has considera-

bly increased its complexity and intricacy, imposing over-specialization, through which the areas of expertise of the medical specializations were narrowed and deepened in order to improve performance. The doctor-patient relationship, in turn, has met a number of important changes, becoming much more complex, involving more professionals. On the other hand, the time dedicated to medical consultations has decreased considerably, raising the gap between patient and physician. The commercial character that society imposed on the doctor-patient relationship has also contributed to this, turning the doctor into a service provider under the risk of malpractice accusation in case of breaking the contractual relationship established between him and his patient.

Thus modern medicine has moved the doctor away from his patient, reducing the interpersonal interaction and communication between them, while the technical aspects of the medical profession have become increasingly conspicuous. The emphasis on the scientific and technical side of the modern medical profession in the higher education system has greatly contributed to this state.

Considering the increasing pace of industrialization and bitter preoccupation to heal at any price, placing in the forefront the disease to be treated rather than the patient as a human being, in the recent years, the adequate and effective communication has become increasingly important. There are a certain number of researches proving the importance and the role of social and psychological aspects in the evolution of pathology. The 2004 report of the Institute of Medicine (IOM) in the United States shows that about half of the causes of mortality and morbidity in this country are related to social and behavioral factors which led to the conclusion that the medical standards should incorporate psychological and social knowledge and communication skills in order to create an efficient therapeutic relationship between the physician and his patient, ensuring patient compliance and improving treatment outcomes (4).

Parallel to the technical progress of medicine, doctor-patient relationship has undergone a major transformation by moving from paternalistic model when the doctor makes all the decisions concerning the treatment, towards the relationship of partnership, which promotes patient autonomy, in which doctor and patient work together to identify the best therapeutic solutions. In this type of relationship, the physician invests medical expertise, considering the "best interests" of the patient from the perspective of the given medical data. The patients, in turn, invest their own set of values and life principles as a filter for all the information received. Such doctor-patient relationship, which aims to develop a medical decision by articulating the medical information provided by the physician to the patient's life principles, can be functional only by means of establishing efficient communication between the two parts (5).

THE INFORMED CONSENT OF THE PATIENT

The patient’s informed consent has become a reality of the Romanian clinical activity in the last decade. Although it is often regarded as a formal procedure of the patient signing a "document" (in fact, its meaning remains unclear to the patient), which authorizes the necessary medical intervention, according to the national and

international regulations; however, the informed consent tends to overcome the excessive formalization by practically displaying its moral, legal and social advantages (4).

The moral benefits may be limited to the patient's awareness of his/her own moral value and the right to be treated respectfully by the doctor, as well as the doctor`s moral satisfaction, gained by refraining from unconscious tendencies to dominate, encouraged by his advantageous professional position over the patient's vulnerability and dependence.

The legal advantage of the informed consent, if properly conducted, becomes relevant when used as a means of protection in case of legal action initiated by the patient against the physician.

The social benefit derives from the fact that getting an informed consent can be considered an education process with informative features, since a certain sequence of the medical science development is revealed to the subject that enhances his knowledge, and at the same time requires him to take the responsibility for his own actions within the therapeutic program, which consolidates the core of personal autonomy. This advantage of the informed consent takes higher importance especially for countries that overcame totalitarian political regimes that inhibited both the individual autonomy and the cultural pattern or collective spirit. The doctors assuming the role of "educator" of the patient supposes an implicit acknowledgment of the ideals of the human rights consigned within the Declaration of Human Rights (1947), but also their contribution to the maintaining and strengthening of these relatively recent acquisitions of the human civilization.

CONTEMPORARY CIRCUMSTANCES

Besides the advantages detailed above, informing the patient remains a highly debated problem, both in the academic and clinical terms, when it's a matter of a life-threatening diagnosis. In Western countries, the practice of direct revealing of the lethal diagnosis is consistently implemented since the second half of the twentieth century. This practice is based on the principle of patients' autonomy, under which he has the right and full power of deliberation – decision concerning his own life regardless of the existential context, justified by clinical need of the patient`s compliance to the therapy (6).

In the Romanian clinical environment, in spite of the globalization trends to create common standards of activity in various fields, including that of medical practice, a denial of adequate or complete information about a patient's diagnosis persists, especially a serious one and it occurs without there being the patient's prior refusal to be informed, as required by national and international legal practice (for example, the Oviedo Declaration of the European Council in 1996, on the right of "not knowing" stipulates that the information may be waived only if the patient wishes not to be informed).

Sometimes the patient reveals certain ambivalence toward "truth", an uncertain desire to know his diagnosis, which requires the specification of the information that the patient really wants to receive. The patient is frequently not able to understand at once what he is informed about, including the full spectrum of consequences of his disease. At each stage of the disease, we can observe apparent reactions of escape, of denial or avoidance, which should

not be taken as a resignation, but reflect the patient's resentment and his way to react, which must be accepted and respected. The interweaving of the patient's responsibility regarding his decision with the support provided by the physician enables the efficient collaboration between the two and excludes the possible conflicts between the "principle of the sacred lie" and "the legitimate medical truth".

In literature there are frequent descriptions of disputes different opinions whether a serious diagnosis should be communicated or not, ranging from total rejection and assessing it as inhuman and accepting it as fundamental right of the patient (7, 8), the doctor often facing the dilemma of informing the patient or not of the serious or terminal stage of the illness.

On one hand, in Romania the legislation forces the physician (under the potential threat of punishment) to inform the patient about his medical condition and the patient has the right to file a complaint of malpractice in case the doctor breaks his right to information. On the other hand, non-disclosure of bad news to patient is based on an attempt to protect the patient, under paternalist approach of the doctor-patient relationship, the doctor being authoritarian by competence, and fully responsible in the relation with the patient, whilst the patient is dependent (subject), and fully confident of the good intentions of the physician towards him. In this type of relationship the physician decides either to inform the patient about a lethal diagnosis or not, with the condition that such decision is taken in accordance with the promotion of the patient's benefit. Since the general, most often accepted perception is that the negative information and especially the one about the state of incurability, produces negative effects (consequences), the doctor, desiring to protect and not to damage the patient, tends to avoid the communication of the diagnosis.

PHILOSOPHICAL PERSPECTIVES

The philosophical valences regarding the dilemma of whether to inform patients suffering from a serious illness will be analyzed considering three fundamental ethical perspectives: the teleological perspective (Aristotle's theory of virtue), the deontological perspective (Kant's ethical theory) and the utilitarian one (Bentham and Mill's moral theories).

Aristotle (9) developed an ethical theory of self-realization according to which we, as human beings, hold potential moral virtues that can and are updated only through practice. Only by proceeding correctly do we become righteous or only by offering do we become generous. But we can, for example, offer too little and then we are considered stingy, or we give too much and then can be considered wasteful. In this context, Aristotle defined virtue as a middle state between two vices, one that is born of excess and the other of deficiency. Thus, generosity is the middle way between of avarice (deficiency), and waste (excess) contrarily, courage is born by avoiding cowardice (deficiency) and at the same time fearfulness (excess), and modesty is the middle way between shyness and naughtiness. In order to live morally and virtuously we must find the midpoint between two extremes. In other words, a life lived virtuously is that the moderate way. If we want to be sober we must consider the "golden middle" of our own perspective, in other words, we must know our own measure.

According to the Aristotelian view, the concept of virtue cannot be applied to all

types of activity as for some behavioral acts there is no middle way. For instance, we can eat and drink moderately (to some extent), but we cannot kill, steal or lie moderately, as these actions themselves are labeled as immoral. Under these circumstances, if the doctor wants to be moral, he must be honest at any time, even towards a patient facing a terminal or serious diagnosis. The moral act is done not under the influence of pressing/ stressful circumstances, sometimes rather despite them, but always reasonably. At the same time, according to the Aristotelian view, a virtuous act cannot be committed accidentally, but only as the manifestation of sustainable moral traits of character. Returning to informing the terminal patient, in Aristotelian terms, the appropriate question is not telling the truth or not, but how and when that truth must be told. The answer to this issue, in terms of his theory, is that the truth must be told in a moderate (cautious) way that could mean "the right words in a proper case" avoiding over-information on the one hand and refusal to inform him on the other.

The utilitarian's theory changes perspective in approaching morality: from virtue and self-development towards the considerations about society and law. Morality is not just a personal matter devoted solely to self-realization (self-becoming), as Aristotle sees it, but it also refers to the common good and public order. Establishing a foundation of moral criticism is an indispensable process of building a better society by means of improving the legislative base. From the utilitarian approach of the two significant representatives (Jeremy Bentham and John Stuart Mill), legislation is the crucial element in achieving individual and general social welfare (10).

Both utilitarian philosophers promote the principle of "maximum happiness for the maximum number of people" as the moral basis of an adequate legislation; according to this principle, an action can be judged as morally right if its consequences are as good as possible for a number of people as large as possible. If legislation promotes such actions and consequences, they are considered appropriate.

Returning to the problem of communicating the diagnosis, we can assume that from the utilitarian perspective, the relationship physician – patient must be guided by laws, codes and social conventions based on the principle of the best consequences for the largest number of individuals. Let us assume that the doctor lies to the patient about the diagnosis, with the good intention of not harming them. As a result, the patient will experience a state of satisfaction/ happiness gradually subdued by the persistence or worsening of the illness's symptoms and ultimately replaced by a deep sense of disappointment that can dangerously affect the patient's life and, in a bad way, the physician's life. Therefore, not disclosing the truth cannot be a rule of conduct as it does not maximize the happiness or subdue the pain of a maximum number of individuals. By contrast, utilitarian analysis of consequence shows a new rule of conduct for medical doctors: "the medic must tell the truth to his patients".

From the Kantian perspective, the priority in ethical evaluation moves from the consequences towards the action itself. According to Kant, each time we act voluntarily, we are guided by certain rules, of which, we may or may not be aware at the time of the action, but which we acknowledge, when we have to justify our behavior to others or to ourselves. In order to distinguish the moral behavior norms

from the immoral ones, Kant formulated the categorical imperative, the most well-known formula: *Act only according to that maxim whereby you can, at the same time, will that it should become a universal law* (11). According to this formula, the maxim is moral if, without contradiction, it is required to be a rule of conduct for everyone, without exception. For example the maxima "*Lie in order to get what you want*" cannot be moral for no one, even the most experienced liar, would accept it (or like it) as a universal rule of behavior. If a person chooses to lie in some cases, they should want to be victimized by a liar, crook or cheat. Presumably, nobody wants to be deceived, so no rational thinker, according to Kant, would accept such maxima.

As for the topic of this paper, from the Kantian perspective, in order to stay a moral person, the doctor, like any other human being, must tell the truth under any circumstances. This *must*, coming not from external constraints, but from the holy will (each man's duty) to follow their own moral law (or in other words from the categorical imperative of human beings by virtue of freedom, personal autonomy), is by definition (due to universality) the moral law of all people.

From all of the above, we find out that all three ethical approaches reach the same result by different means, namely: non-disclosure of adequate information about their medical condition to the terminal patient is, theoretically, morally unjustified. It should be noted, however, that within these theoretical reflections, slightly modified by empirical necessity, a moderate opinion may be added, according to which the refusal to provide information is still unacceptable; however, it is morally accepted to limit information in order to safeguard the patient's interest, complying with the requirement of prior critical analysis of the condition, the nature of pathology, the expected evolution and patient's personality. As stated, this view is possible, provided that it is not the case of some limitation of *content* but merely of an apparent one, with a background in the spirit of Aristotelian, utilitarian and Kantian ethics.

MEDICAL PERSPECTIVES

Despite the perspective offered by the philosophical approach, many practitioners argue that providing full and detailed information to the patient with serious diagnosis can lead to the worsening of their state, inducing possible state of depression, anxiety, apathy etc. These assumptions are often rooted in practice (12). On the other hand, communicating serious diagnosis or bad prognosis is one of the most difficult aspects of the doctor-patient communication which, unfortunately, is insufficiently taught during the training of future specialists in our country.

The way of communication and informing the patient is extremely important. How the patient perceives, internalizes and reacts to the information received, strongly depends on the form of communication. Even if the statement is a seriously bad diagnosis, the physician should not try to minimize the importance of information, but tell the truth in an empathic manner, with the aim of actively involving the patient in their recovery. The minimization of the importance of the disease risks to suggest the patient that there is no need to worry or get deeper involved in the therapeutic process, which will lead to a poor therapeutic compliance. Contrarily, the disclosure of reality must be accompanied

by instilling confidence in the physician as well as hope for the better (13).

The act of information in medicine should be individualized while the way of communication must vary from case to case. In order to avoid the negative effects of information, the doctor should get more information about the patient, especially on his values and cultural context from which he comes before disclosing a diagnosis of serious illness or a poor prognosis. A patient may need additional information which requires that the relationship between the doctor and the patient be based on trust and hope. After a longer contact with the patient, the doctor may find important data on the patient`s character and their emotional status that allows him to choose the correct way of providing information about the disease and its prognosis.

In the communication process, patience is essential. The patient's satisfaction is higher when the duration of the meeting with his doctor is in line with his expectations, especially when the doctor proves to be a real communication partner. Unfortunately, it was found that doctors would listen, on average, just 23 seconds before stopping the patient from the story of his complaints and turn the discussion into another direction. Allocating enough time for discussion allows the patient to better understand the information that must be provided in accessible terms, according to his degree of education and age (14).

There are several studies showing that effective communication in medicine has positive therapeutic effects on short and long term, both at the psychic and somatic level (15).

On short term, good communication creates a state of satisfaction with the interaction with the physician and the medical care received, and promotes adherence to the prescribed treatment and recommendation.

In the long run, good communication is likely to improve the patient's health condition and quality of life, proved by the resolution of symptoms, especially pain relief and improvement of physiological parameters such as blood pressure and blood sugar level. In addition, it leads to anxiety reduction that has positive effects on the health of the patient.

The efficiency of the communication between doctor and patient is reflected in meeting its goals, among which the most important is to create a therapeutic relationship. Only throughout efficient communication can a doctor withdraw useful information from the patient, based on which the physician can make the best decision together with the patient and his family and launch the therapeutic procedure. In this sense the patient will adopt the appropriate behavior related to his disease and treatment. In order to comply with the medical prescriptions, the potential benefits and risks, the patient must understand and accept the medical diagnosis (16).

Taking into account the results of several studies on the importance and beneficial role of communication in medicine, WHO insisted in recent years on the need to promote the ethical values within medical communication, stating that "information is a basic right for all as health is a priority for the whole world" (3).

An important aspect of the effective communication in medicine is reducing the risk of malpractice claims. An example of this is provided by the Netherlands, a country where about 40% of health care services are provided by family doctors, who go along patients for long periods and estab-

lish with them and their families long term relationships based on trust; this makes patients less likely to act legally against their doctors even if they are mistaken. This last fact is based on the premise that physicians have the best intentions in relation to their patients (18).

PSYCHOLOGICAL PERSPECTIVES

In the communication process the doctor and the patient should be placed on equal positions, a condition necessary for providing a partnership, focused on patient autonomy (17).

In his interaction with the patient, the physician should adopt a cognitive empathetic approach that might allow the doctor to get closer to the patient and gain his confidence. It is necessary for the doctor to avoid excessive emotional involvement because it could affect the diagnosis and therapeutic behavior. The "compassionate detachment" helps the doctor to better understand emotions, inner experiences and the patient's perspective on the disease; it is beneficial for the latter as he does not need pity from his doctor, but understanding and support. The studies show that the empathic communication between the doctor and his patient determines the satisfaction of the latter, the adherence to the treatment and perception of his interaction with the physician as being of good quality. Other studies indicate a lower risk of malpractice claims and obvious improvement of health status of the patient if a relationship is based on empathy (19).

In the process of communication the physician must be prepared for any reaction from the patient, especially when communicating a diagnosis of seriously bad or incurable illness. The patients' reactions to bad news may be very different and can be placed on a range from stoically facing reality to hysterical manifestation, crying, anger or denial. No matter where he is placed in this continuum, the patient has the right express his emotions in reaction to the diagnosis and prognosis of their disease, and the doctor must allow and even encourage this (14).

Some oncology professionals suggest some ways of dealing with patients with no hope for cure (20). It is proposed to avoid communication of the diagnosis to those patients that never suspected the pathology and are in a good state for the moment. The information can be cautiously suggested to those with a strong character who value truth more than tragic subjectivity, as well as to those who already feel the sad diagnosis and refused a treatment or intervention. In this perspective, the physician's careful deliberation based on psycho-medical criteria becomes essential, also taking into account the socio-professional and family environment of the incurable patient.

THE ROLE OF THE FAMILY IN THE DOCTOR - TERMINALLY ILL PATIENTS COMMUNICATION

In establishing an ethical and collaborative relationship between doctor and terminal patient it is also important to highlight two aspects: vulnerability and limited autonomy of the dying patient and the importance of relationships and family roles.

The current Romanian legislation, connected to Western values and ethical principles, promotes individual patient information and making decisions based on his autonomy. Nevertheless, in some cases these patterns of behavior cannot be achieved in the interaction with some patients. The medical practice and legislation

in many European countries, including ours , provide the possibility that – in case of patients with diminished or absent capacity of decision – the closest kin should take part in the medical decision according to what the patient would want in that situation (21).

Often, the patients' family members want to get as much information as possible about their relatives in serious condition. At times, they might be the ones to hold the most information about the patients. This knowledge could entail greater clinical approach of the latter (22).

We must also consider the situations when the patients, although accompanied by family members, do not feel comfortable being examined in their presence. It can be seen as a violation of their dignity or privacy. Such conflict situations are not rare and an inadequate solution to difficult ethical dilemmas is an additional source of stress (23-25).

Confidence is extremely important in interacting with the medical personnel, both for the patient and his relatives. The lack of information or the inadequate communication can lead to loss of confidence and limitation of the patient in his decision making ability. For the medical staff the situation becomes even more delicate when interacting with patients from particular ethnic groups with cultural values different from those of the majority of population. Some studies on communication between medical staff and patients from certain ethnic groups (Chinese and Asian population in the U.S.) showed that the latter may have less trust in physicians (26, 27) or have a distant attitude towards health care workers.

Such studies show that familiarizing the medical personnel with the behaviors and beliefs of the patients is essential for a good relationship and communication, allowing the identification and resolution of potential conflicts of values (28-31).

CONCLUSIONS

Along with the progress of medical science, communication is nowadays thought to be essential in establishing a therapeutic relationship between doctor / healthcare professional and patient. However, communicating the serious diagnosis and prognosis remains a real challenge for the physician, who is often "caught" inside the dilemma of the "principle of sacred lie" and the "legitimate medical truth".

Thus, the solution of this difficult issue of disclosing the serious diagnosis and prognosis is supported both by theoretical, philosophical arguments, and by the results of studies and clinical practice. All these arguments support and promote disclosure of the diagnosis to the patient, no matter how serious, emphasizing the great importance of the way to communicate and the doctor's ability to morally support the patient, instilling them the confidence they need.

The necessity and importance of communication in medicine result from the essence of the medical profession itself which comprises of a blend between the Asclepian tradition promoting the importance of technical knowledge and critical current practice and the Samaritan tradition that promotes the doctor's compassion towards his patients the good relationship between physician and patient outlining the humanistic character of medicine.

TRANSARTERIAL CHEMOEMBOLIZATION FOR HEPATOCELLULAR CARCINOMA

Transarterial chemoembolization (TACE) is used as treatment for hepatocellular carcinoma. Cytolysis, caused by necrosis of tumour or of non-tumoral parenchyma, may occur days after the procedure and can influence tumour response and liver function. A study by Marquez *et al*. evaluated the impact of cytolysis on tumour response, hepatobiliary complications and survival of patients with liver disease who underwent treatments for hepatocellular carcinoma. The researchers analyzed the associations between cytolysis and radiologic tumor response, as well as adverse hepatobiliary events. Also, they compared the survival rate at 18 months after chemoembolization between the groups with and without cytolysis. The study found that cytolysis was associated with a favourable radiological response, but had no impact on the occurrence of short-term adverse hepatobiliary events or survival at 18 months. **(**Marquez V, Sylvestre MP, Wartelle-Bladou C, Bouchard L, Perrault P, Grégoire P, Pomier-Layrargues G. Impact of cytolysis following transarterial chemoembolization for hepatocellular carcinoma. *J Gastrointest Oncol*. 2013;4(1):45-52. doi: 10.3978/j.issn.2078-6891. 2012.061).

STRATEGY OF SURGICAL TREATMENT OF GIANT PRESACRAL TUMOR - A CASE REPORT (Abstract): Presacral tumors are uncommon lesions that can be difficult to diagnose because of their nonspecific presenting signs and symptoms. Surgery is the mainstay of treatment as it establishes the diagnosis and prevents the adverse consequences associated with malignant degeneration and secondary bacterial infection. Large, highly vascularised pelvic tumors may pose intraoperative difficulties as bleeding and intraoperative tumor perforation. Cross-sectional imaging is essential in evaluating these lesions to determine the optimal surgical approach and the extent of resection. We emphasize a multidisciplinary expert individualized approach. We report a case of a presacral giant gastrointestinal tumor initially considered as unresectable but further on successfully managed by preoperative vascular embolization followed by resection via abdomino-perineal approach. **Keywords**: PRESACRAL TUMOR, ANGIOEMBOLIZATION, RESECTION, PRESACRAL SPACE.

Presacral or retrorectal tumors represent a spectrum of heterogeneous lesions ranging from simple benign cysts to complex malignant masses invading surrounding pelvic structures. The incidence of presacral tumors in the general population is not known, as the majority of reports on these lesions are from tertiary referral centers and thus do not represent the true incidence of these tumors (1).

Despite their infrequent occurrence, a basic comprehension of the etiology, presentation, diagnostic evaluation and management of these lesions is important as incorrect diagnosis or inappropriate management can result in significant morbidity and adverse outcome (1).The only large series not from a referral center was published almost 30 years ago by Uhlig and Johnson and found an average incidence of two presacral tumors per year in the metropolitan Portland area (2).

The benefit of percutaneous or laparoscopic biopsies in the presacral region has not been presented thoroughly in the literature since this region known to have unique anatomic and oncologic properties (3). The standard treatment for the most giant presacral tumors remains the complete surgical resection, with the aim to obtain negative microscopic margins over the organ origin. However, because of the anatomic site and

tumor size, complete resection is either not feasible or possible only through extensive aggressive procedures with expected major functional morbidity (4).

Angioembolization can be used for many types of malignant tumors to achieve good surgical results. It may be employed either preoperative or palliative to alleviate symptoms and reduce further dissemination as well as increasing the response to other treatment modalities by occlusion of the feeding vessels in order to cut off the growing of the tumor using different substances (5).

CASE REPORT

A 38 years old man, with no previous medical history, was admitted for a palpable right abdomino-pelvic mass, lower abdominal pain with difficulty in voiding and passing motion for two weeks associated with history of chronic constipation on laxatives and poor appetite. There was no history of fever, vomiting, hematemesis, melena and hematuria. No neurological symptoms were recorded. A weight loss of 5 kg was recorded in 6 months. The patient was initially diagnosed in his country two years ago when only an excision biopsy was performed via laparotomy because of the large volume and high vascularisation of tumor. The pathological examination showed a perihistiocytoma. Thus, chemotherapy was advised but not done. Abdominal examination revealed a soft, firm palpable well defined tender mass at the right lower quadrant extending to the pelvis. Hernia orifices and genitalia were free as well as renal angles. A digital rectal examination revealed a retro rectal mass invading the posterior wall of the rectum and normal mucosa. Colonoscopy was normal.

Computed tomography (CT) showed large well defined mass in the pelvis located at the presacral area, measuring 15 x 10 x 20 cm in size, with calcification and much dilated tortuous venous drainage channels; erosion and osteolytic destruction of coccyx and S5 were present. The tumor extended to the left ischiorectal fossa pushing the rectum right antero-laterally and the urinary bladder superiorly (fig. 1). CT scan of the thorax was normal.

Fig. 1. CT finding of a huge mass filling the whole pelvis with infiltration of sacral bone

Laparoscopic incision biopsy was performed. Histopathology revealed hyper cellular spindle cell tumor and no mitotic activity. The case was discussed in multidisciplinary meeting and the consensus was for angioembolization followed by surgical resection. Angiographic evaluation and super selective embolization for right internal iliac feeding branches was performed (fig. 2).

Fig. 2. Angio-CT showing complex vascular network of the tumor

Three weeks post-embolization the patient underwent complete surgical excision of the mass through abdomino-perineal approach, the tumor was resected en bloc including rectum, sigmoid and oscocygum and a permanent colostomy was performed. The mass weighted 1.5 kg and measured 18 x 11x 9.5 cm (fig. 3).

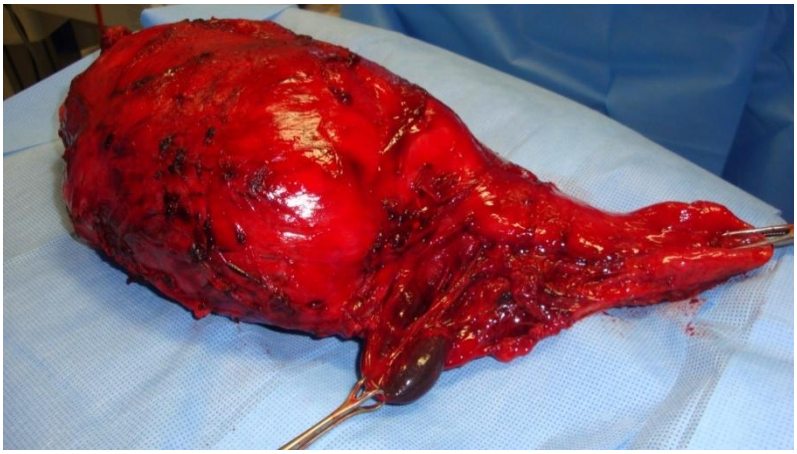

Fig. 3. Specimen of resected mass with intact mesorectal surrounding fascia

Intraoperatively, the hypervascular tumor was dissected successfully and carefully from all adjacent structures - urinary bladder, both ureters, as well as iliac vessels and sigmoid colon. Metastatic nodules were noted only on cecum and one ileal loop and were wedge resected as frozen sections turned positive. The postoperative recovery was, except stress incontinence grade II, uneventful and he was discharged in good general condition. Glivec (Imatinib) therapy has been started because of the metastasis to the cecum and small bowel as well as the giant size of the tumor.

Histopathology revealed extra-gastrointestinal stromal tumor (EGIST)**,** mixed type**,** predominant spindle cells type with 20% necrosis of the tumor. The tumor was highly cellular with high grade histological; margins were positive for the tumor, mitotic rate 11/50 HPF and lymphovascular invasion. The pathology TNM staging – pTNM was recorded as T4 N0 M1.

DISCUSSION

Extensive pelvic surgery in oncologic patients is highly demanding because of the irregular and complex shape of the bony pelvis, numerous muscles attachments and the proximity of major blood vessels, nerves and visceral organs. Surgeon's ability with the extent and involvement of vital structures determine the resectability, keeping in mind that inadequate clearance results in local recurrence. Retrosacral space is a virtual space also called retrorectal space and retrorectal tumors are rarely encountered in surgical practice. Irrespective of their origin they cause similar symptoms and due to their location in presacral space. Although in 26-50% of cases are asymptomatic, the majority of patients present with vague symptoms reflecting the compression, displacement or invasion of pelvic structures, viscera and nerves (4), and occasionally with perirectal pain, mass sensation, constipation, painless rectal bleeding, change in caliber of stool, or urinary frequency (6).

Generally, malignant or inflammatory tumors present with pain (7). Differential diagnosis of retro-rectal tumors can be narrowed using a combination of diagnostic tools. Thorough history and comprehensive clinical assessment including per rectal examination are essential as retro rectal tumors are palpable as extrinsic masses, and they are usually soft and compressible (7). These features may lead to misdiagnosis unless the examiner is careful and suspicious in his examination (2). In case of rectal bleeding, colonoscopy can rule out any mucosal pathology, on the other hand, barium enema can detect extrinsic mass but it will not add additional information (7).CT or MRI scan are the optimal imaging modality to delineate the margin, location and the extent of the tumor as well as possible invasion and displacement of adjacent structures, which is vital for decision making regarding surgical approach, also will add more information regarding the metastases as well, when dealing with malignant tumors (8, 9). Radiological evidence of sacral erosion is the only reliable indicator of malignant pathology as in reported case (10).

Angiography is advisable for highly vascularized tumor to evaluate the relation of the major blood vessels to and around the tumor to define the road map for the resection, in the same time it will illustrate the vascularisation of the tumor which can be tackled by selective embolization in order to decrease the tumor size by blocking the feeding branches. This multidisciplinary approach markedly decreased blood

loss and improved visualization to help in achieve complete surgical resection and resolution of clinical symptoms (11, 12).

Complete surgical resection is the main-line of treatment for all presacral tumors even if they are thought to be benign (4).The approach is dictated by the size, site, and the extent of the tumor also the tissue planes between neighboring structures, which mandate a more aggressive approach if it's malignant tumor. The surgeons need to think three dimensionally in approaching such a huge tumor and in many patients both abdominal and pelvic dissection are required. Moreover, positioning of the patient plays an essential role for total excision. The presacral space may be approached anteriorly (abdominal), posteriorly (transsacral / transcoccygeal), combined anterior-posterior, an anterior approach is performed in a tumor with lowest extension above the fourth level of the sacral element, while the posterior approach preferred for small tumors which doesn't extend above the level of the fourth sacral elements(13). Third approach is the combination between two methods for large tumor beginning under the fourth level of the sacral element and extending above it and it is selected for high grade malignant disease involving adjacent organs (13). These different kinds of approaches should offer a wide abdominal and pelvic exposure in order to achieve good hemostasis as the surgeon may encounter considerable difficulties in controlling presacral bleeding. Overall, 45%-50% of presacral tumors are malignant or have areas of malignant changes in them (7). The consistency may vary and solid tumors are more prone to be malignant than cystic lesions (60% *vs.* 10 %) (14).

Successful surgical dissection demands optimal exposure, skill in dealing with intestinal adhesions, meticulous hemostasis that is maintained throughout the procedure, a thorough the knowledge of anatomy, a plan of attack the tumors at difficult anatomic sites and experience in reconstruction is needed. Undoubtedly, the best results will be obtained by high volume centers with special interest in this form of surgery.

CONCLUSIONS

Surgical approach with different technique of dissection following the path of the least resistance is a wise policy in working round large tumors. Tumor angioembolization may precede surgery for selected patients with large, highly vascularized tumors.

It is certainly a team work involving a panel of expert colorectal surgeons, interventional radiologists and medical oncologist with significant clinical experience.

NEW ANTIBIOTIC IN TREATING EXTENSIVELY DRUG-RESISTANT TUBERCULOSIS

Extensively drug-resistant tuberculosis (XDR-TB) is a form of tuberculosis that is resistant to at least rifampicin and isoniazid as well as to any member of the quinolone family and at least one of the following second-line anti-TB injectable drugs: kanamycin, capreomycin, or amikacin. Treatment requires extensive chemotherapy for up to two years and can cause serious side-effects. A significant number of patients with XDR-TB develop resistance to treatment. A group of Korean researchers conducted a clinical trial on the use of linezolid in the treatment of pulmonary XDR-TB (sputum-culture–positive after six months of treatment). The researchers found that 87% of patients enrolled in the study had no positive cultures after 6 months of treatment with linezolid. In the study, 82% of patients experienced clinically significant adverse reactions, resolved quickly after briefly stopping the drug or using the lower dose. The study concluded that linezolid is a therapeutic option in XDR-TB but dose adjustment is necessary to reduce adverse effects in long-term treatment (Myungsun Lee, Jongseok Lee, Matthew W. Carroll et al. Linezolid for Treatment of Chronic Extensively Drug-Resistant Tuberculosis**.** *N Engl J Med*, 2012; 367:1508-1518).

SEVERE INVASIVE LISTERIOSIS - CASE REPORT (Abstract): Listeriosis is a rare food borne infection which, in the invasive form, presents as bloodstream infection, central nervous system infection, materno-fetal infection, or focal infection. Certain immunosuppressive conditions have been identified as risk factors for severe invasive disease. The invasive forms of listeriosis are associated with a high case fatality rate. We present the case of a 62 year old male with an unremarkable medical history admitted to the Iasi Infectious Diseases Hospital for fever, headache, ataxia, and diplopia. Physical examination revealed high temperature, confusion, relative bradycardia, and signs of meningeal irritation. Laboratory test showed leukocytosis with neutrophilia, pathological CSF findings (high WBC count with predominance of neutrophils, low glucose and high protein levels), increased liver enzymes (ALAT, ASAT, AP, γGT), and important renal impairment (normal levels at presentation). No abnormalities at chest x-ray, cranial CT and abdominal ultrasound. CSF and blood cultures were positive for *Listeria monocytogenes*. Under antibiotics (ampicillin and ciprofloxacin), the course was marked by respiratory failure requiring mechanical ventilation, coma, hypotension, tachycardia, and death 12 days after admission. The particularity of this case consists in the association of the two classical forms of invasive listeriosis, meningitis and bacteriemia, with a focal infection, acute hepatitis, and a course marked by multiple organ dysfunction syndromes and exitus in a previously apparently healthy individual. **Key words**: LISTERIOSIS, MENINGITIS, BACTERIEMIA, MULTIPLE ORGAN DYSFUNCTION SYNDROME.

Listeriosis is a rare but potentially serious infection caused by *Listeria monocytogenes*. This agent has been recognized as a human pathogen for over 80 years. Epidemiological investigations during the past 30 years have shown that epidemic or sporadic listeriosis is mainly caused by consumption of contaminated food (1). Food borne listeriosis can occur in large or small outbreaks or as sporadic cases; however, the predominant form of disease is probably that of single sporadic and unrelated cases (2). The widespread distribution of *Listeria monocytogenes* provides numerous potential ways by which the disease may be transmitted to humans, although it is now generally accepted that the consumption of contaminated food is the main route of transmission (2). The infection has three major clinical presentations: bloodstream infection, CNS infection, materno-fetal listeriosis) (3).

Listeriosis is diagnosed by positive culture from a normally sterile site (clinical specimens such as blood, cerebrospinal fluid (CSF) (1) When *Listeria* causes disease, it is usually severe with a high case fatality rate of 20-50% (4, 5).

CASE REPORT

In February 2012, a 62-year-old man presented to the Infectious Diseases Hospital for fever, chills, headache, vomiting, and cervical pain, symptoms that occurred four days earlier, associating after two days, ataxia and diplopia. His medical history was unremarkable except for hearing loss requiring auditory prosthesis. Physical examination revealed high temperature (39.5°C), confusion, relative bradycardia (74/min), signs of meningeal irritation, frequent vomiting, and diplopia.

On admission, laboratory findings were: white blood cell (WBC) count 10,850 per mm^3 (88.7% neutrophils), hemoglobin level 12.2 g%, erythrocyte sedimentation rate 115 mm/h, urea 45 mg%, creatinine 1.39 mg%, alanine aminotransferase (SGPT) 37 UI/l, alkaline phosphatase (AP) 192 UI/l, gamma glutamyl transferase (γGT) 69 UI/l. CSF exam revealed WBC count 714 per mm^3 (78% neutrophils), glucose level 0.20 g/l (blood level 1.25 g/l), protein level 4.62 g/l, chloride level 6.60 g/l. Chest radiography revealed no pulmonary abnormalities, cranial computed tomography showed no features suggestive for brain abscess, normal abdominal ultrasound. HIV test was negative. Cultures from blood and CSF were performed and empirical treatment with ampicillin associated with pathogenic therapy was initiated. Two days later, blood and CSF cultures showed a heavy growth of *Listeria monocytogenes*. An epidemiological history including food consumption was taken, and consumption of raw milk on a regular basis was found.

On day 4, the course was marked by a continuous alteration of mental status, leading to coma and requiring specific management in intensive care unit. Ampicillin was associated with ciprofloxacin. Biochemical exams revealed elevated liver enzymes and acute renal failure. The dynamic of laboratory parameters is detailed in the tab. I.

TABLE I

Evolution of laboratory parameters

Parameter	Day 1	Day 4	Day 5	Day 7	Day 8	Day 9	Day 11
WBC/mm^3	10 850	9680	-	9610	-	26 980	40 670
(Neutrophils %)	88,7	78,9		83,4		82,9	94
Urea mg%	45	179	206	201	116	-	191
Creatinine mg%	1,39	5,50	7,27	4,99	2,38	-	3,81
ALAT UI/l	37	130	84	53	49	-	-
AP UI/l	192	340	270	-	239	-	-
γGT UI/l	69	221	165	-	-	-	-
CSF WBC/mm^3	714					960	
CSF glucose g/l	0,20					0,30	
CSF protein g/l	4,62					9,31	

On day 6, the patient developed respiratory failure requiring mechanical ventilation. On day 8, fever occurred again and ventilator-associated pneumonia was sus-

pected. Therefore, new blood and tracheal aspirate cultures were performed and an antiinfectious therapy with vancomycin, colistin and caspofungin replaced the initial antibiotic association. Despite adequate vasopressive therapy the patient presented persistent hypotension and died 12 days after admission.

DISCUSSION

Listeria is widespread in the environment. It can be found in soil, vegetation and animals. Considering the high exposure rate, the pathogenicity of this organism must be low. Listeriosis is a rare disease, with an annual incidence in most countries of <100,000 inhabitants (3, 5). Whereas much has now been learned about epidemic listeriosis, little is known about sporadic listeriosis which, in fact, represents the majority of cases (6).

Listeria is a facultative intracellular, Gram-positive, motile rod which causes both sporadic disease and outbreaks of food borne infection in humans. The genus *Listeria* comprises six species (*L. monocytogenes, L. ivanovii, L. innocua, L. welshimeri, L. seeligeri* and *L. grayi*). Almost all cases of human listeriosis are due to *Listeria monocytogenes* (2). This organism occurs ubiquitously in nature and, therefore, it is not possible to eliminate it totally from raw produce or ready-to-eat products prepared without a bacterial inactivation step (5). Consequently, humans are exposed regularly to *Listeria* (3). The main route of transmission is believed to be through consumption of contaminated food. *Listeria monocytogenes* is not a spore-producing bacterium and does not have unusual characteristics which allow survival in conditions commonly used in food processing (2). The bacterium is particularly successful in causing food-borne disease because it survives food-processing technologies and, unlike many pathogens, can continue to multiply slowly at low temperatures (7). Dietary risk factors (such as unpasteurized milk or other dairy products) for sporadic listeriosis have been assessed through case-control studies (1). The peak of human listeriosis occurs during late summer and autumn; the reasons for this being unknown (2).

The incubation period between consumption of contaminated foods and onset of clinical listeriosis is extremely variable and ranges from the first day to over 90 days (2). It is not known whether the differences in incubation period after oral ingestion are dose or strain dependent, or perhaps reflect unknown differences in host susceptibility (2). Certain conditions have been identified as risk-factors for severe invasive listeriosis, including the extremes of age, malignancies, diabetes mellitus, alcoholism, liver disease and other immunosuppressive diseases and treatments (3). The major host defense against listeriosis is cell-mediated immunity and, therefore, individuals with T-cell dysfunction seem to be particularly at risk for contracting the infection (8). Listeriosis also occurs in previously apparently healthy individuals without any of the above risk factors (2). Serious systemic listeriosis in previously healthy individuals has been reported, but is rare (9).

Listeria monocytogenes causes two forms of listeriosis: non-invasive gastrointestinal form and invasive form.

In immunocompetent individuals, non-invasive listeriosis develops as a typical febrile gastroenteritis; in immune-compromised adults, listeriosis can manifest as sepsis or meningoencephalitis. Invasive listeriosis can also be acquired by the fetus from its infected mother via the placenta (10). The onset of meningo-

encephalitis can be sudden, as in our patient, with fever, intense headache, vomiting, and signs of meningeal irritation. Rhomboencephalitis (with signs of ataxia, cranial nerve deficits), involving the brainstem, may be an unusual clinical form. *Listeria monocytogenes* can also produce a wide variety of focal infections: skin lesions, pleuropulmonary, eye or joint infection, lymphadenitis, liver impairment, brain or spleen abscess, cholecystitis, peritonitis, osteomyelitis, pericarditis or myocarditis, arteritis, necrotizing fasciitis. Focal non-meningeal infections are uncommon and very few cases affecting the liver have been reported (11). Two patterns of liver infection have been described: solitary or multiple liver abscesses and acute hepatitis with elevated liver enzymes (11). Recent observations that gastrointestinal disease and/or fever may be the only symptom in the majority of cases suggest that there may be a considerable number of undiagnosed subclinical cases of this infection (9).

Despite the high contamination rates of certain foods with *Listeria monocytogenes*, listeriosis is a relatively rare disease as compared with other common food borne illnesses, such as *Campylobacter* or *Salmonella* infection. However, because of its high case-fatality rate, listeriosis is, after salmonellosis, the second most frequent cause of food borne infection-related deaths in Europe (1). Clinicians may need to exercise more caution since the outcome involves increased morbidity and mortality.

The particularity of the reported case consists in the association of the two classical forms of invasive listeriosis, meningitis and bacteriemia, with focal infection, acute hepatitis, with a course marked by multiple organ dysfunction syndromes and death, in a previously apparently healthy individual.

RETROSTERNAL GOITERS (Abstract): The term of retrosternal or substernal goiter means that more than 50% of thyroid gland descends in the thorax. **Material and methods:** There is a retrospective study on retrosternal and substernal goiter and its patological features among 2482 patients who underwent thyroidectomy between 2000 and 2010 in the First Surgery Clinic of Iaşi. Retrosternal goiter was identified 54 patients (2.17%). All patients were refered to surgery from the Clinic of Endocrinology. **Results**: Mean age at diagnosis was 55.3 ± 3.58 years, and most cases were found in women (83.3%). The clinical pictures of retrosternal goiter was dominated by compressive disorders. Thyroid function abormalities were identified by hormonal assays performed on Endocrinology Clinic Iasi in 15 cases (27.7%). The diagnosis of retrosternal goiter was suggested by clinical examination and confirmed by imagery: thorax X ray, ultrasonography, CT scan. The cervical approach was being safely performed. Only in 8 cases (14,8%), sternotomy was necessary. There was no mortality and morbidity was 5.5% (3 cases). The length of stay in the hospital was 4.3 days. We compared our recent data with a previous report on retrosternal and thoracic goiter treated in First Surgery Clinic of Iasi during 1950 to 1979 and published in the journal "Chirurgia" in 1981. **Conclusions**: Retrosternal goiter is a particular form of thyroid surgical pathology presentation with declining incidence. Diagnosis and treatment of retrosternal goiter involve a multidisciplinary team. The endocrinologist has an important role in diagnosis and postoperative follow-up. Surgery is the treatment of choice for substernal goiters, but there are still some controversies on surgical approach, and complication rate. The cervical approach can be safely performed in almost all cases but when required, sternotomy should be performed without hesitation. **Key words**: SUBSTERNAL GOITER, RETROSTERNAL GOITER, THYROIDECTOMY

Substernal goiter was first described by Albert von Haller in 1749, but the term was introduced in the medical literature by de Souza and Smith.

The term of retrosternal, substernal or cervicomediastinal goiter refers to goiter of which more than 50% of thyroid gland goes down into the thorax. According to the relationship with aortic arch, Huins et al. proposed a classification which indicates the type of necessary surgical approach: degree I: goiter goes down up to aortic arch (cervi-

cal approach), degree II : goiter goes beyond aortic club to the pericardium (the approach needs cutting the upper part of the sternum), degree III: goiter goes behind the rigth atrium (medial sternotomy is necessary) (2).

Different statistics give an incidence of 1-30% of thyroidecomies or 1 in 5.000 individuals (1).

True or primary intrathoracic goiters are very rare (1%), develop of ectopic thyroid tissue situated within mediastinum (mostly posterior) and receive their vessels from mediastinum.

Secondary cervicomediastinal goiters which will be discussed in this study develop by extension of the thyroid within the thorax and their vessels arise normally of superior and inferior thyroid vessels. The treatment of retrosternal goiters is a challenge for surgeon. Total thyroidectomy is the golden standard for cervicomediastinal goiters.

MATERIAL AND METHODS

From January 2000 to December 2010, 2482 patients underwent thyroidectomy in the First Surgery Clinic, University Hospital "St. Spiridon" Iassy. After reviewing the files we identified 54 patients (2,17%) with mediastinal extension of thyroid gland. A mediastinal goiter was defined as the goiter that, in the judgment of surgeon, both preoperatively and intraoperatively extends below the plane of thoracic inlet when the neck is hyperextended. Data from files: preoperative, intra and postoperative, surgical protocols and pathological findings were statistically analyzed. Theese data were compared with o previous statistics regarding cervicomediastinal goiters surgically treated in the First Surgery Clinic of Iasi during 1950-1979 and published in the Journal of Surgery (Chirurgia) in 1981 (3).

RESULTS

During the analyzed interval (2000-2010), among 2482 thyroidectomies there were identified 54 cases of cervicomediastinal goiters representing 2.17%. There was an obvious higher incidence in females (45 females (83.3%) and 9 males) with a sex ratio between females and males of 5/1. Mean age at diagnosis was 55.3±3.58 years with limits between 36 and 82 years. Mean age in women was higher than in men (56.15±1.5 vs 51.5±5.1). 90.7% of cases have been diagnosed after 40 years and 68 % after 50 years.

In the studied group there were 39 cervico-mediastinal goiters (72.2%) and 15 mediastinocervical goiters (27.8 %). There were no cases of primary or independent mediastinal goiters in this study; opposed to the group from 1950-1979 in which 3 cases were found (3).

The most important clinical symptoms of retrosternal goiter were compressive symptoms which were more important in large goiters deeply descending in the thorax. Dyspnea and cough was most frequent – 40 cases (70.07%) and more severe in aging patients. Dysphagia was seen in 8 cases (14.8 %) and dysphonia in 6 cases (11.1%). Compression on thoracic veins was seen in 4 cases (7.4%) with secondary dilated superficial veins of the neck.

TABLE I

Symptoms and signs of cervicomediastinal goiters

	2000-2011 – 54 cases	**1950-1979 – 100 cases**
Cervical mass	39 (72,2%)	79%
Dyspnea/cough	40 (74,07%)	59
Dysphagia	8 (14,8%)	16
Dysphonia	6 (11,1%)	10
Superior vena cava syndrome	4 (7,4%)	6
Hyperthyroidism	7 (12,9%)	15

Cervical mass were detected by palpation was the most cases (tab. I).

Hormonal assessment made in the Clinic of Endocrinology Iasi detected 15 patients (27.7%) with thyroid dysfunction: 7 hyperthyroid and 8 hypothyroid patients. 11 patients had associated cardiovascular abnormalities confirmed by ECG: sinus tachycardia – 8 cases, atrial fibrillation – 3 cases, ventricular extrasystoles – 2 cases.

The diagnosis of retrosternal goiters was suggested by clinical examination and confirmed by imagery. Chest X-ray identified a rounded mass with regular margins, situated in the upper part of the anterior mediastinum, in midline or paramedian positon, sometimes in slightly lateral position with trachea deviation. The upper pole of the mass was less visible being confounded with soft tissues of the base of the neck (fig. 1). In 4 cases calcifications were seen within the goiters (fig. 2). Trachea was deviated in most cases. Profile X-ray identifies the lower pole of the goiter, situated in the anterior mediastinum, anterior of the trachea and pushing the esophagus (fig. 3).

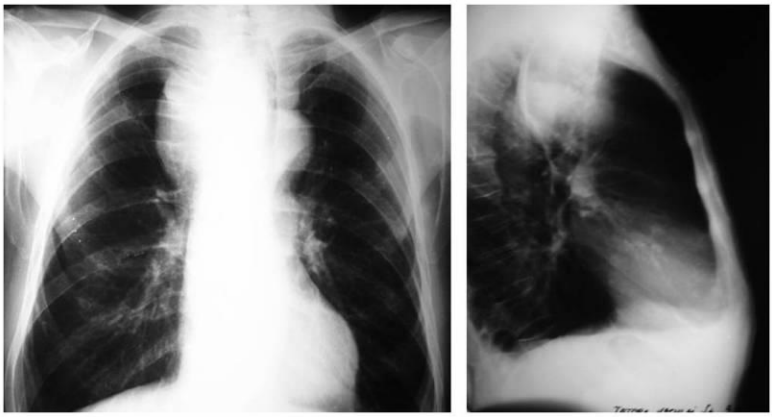

Fig. 1. Thorax X-ray postero-anterior and profile.
Enlarged superior mediastinum due to a soft tissue opacity of 10/6 cm, which deviates trachea to the left side and is situated anterior from the trachea – plonged goiter

Fig. 2. Cervical and thorax X-ray: trachea deviation to the right in the cervical and thorax part due to soft tissue opacity of 10/6 cm. The lower pole of the mass descends to 2 cm. from he o arch and has multiple calcifications within central and peripheral area – pronged goiter with calcifications'

Fig. 3. Cervical X-ray profile: well delimited in homogenous soft tissue opacity of 11/8 cm situated in the anterior cervical area, with the lower pole situated under the sterno-clavicular joint.

Ultrasound examination, done in all cases, has identified the dimensions of the thyroid, the echogenicity of the nodules, the dominant place of the gland, its vessels and its vascular reports (fig .4).

The most useful examination was computed tomography. This was done in 16 cases and gave us important information regarding vascular reports and laringeal nerve position allowing the anticipation of surgical approach and intraoperative difficulties.

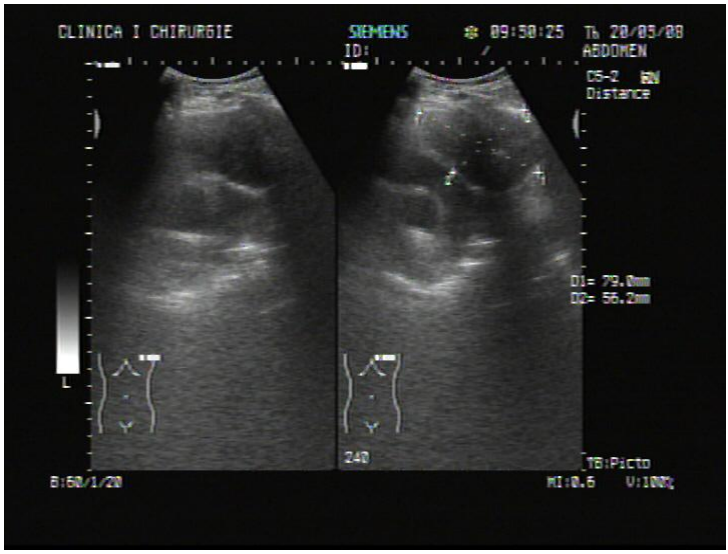

Fig. 4. Cervico-mediastinal ultrasound examination: hypoechoic, homogenous mass, well delimited, of 79/56 mm situated behind left clavicle and behind the sternum, and superior from the thoracic aorta, without Doppler signal inside: plunged aorta

The most useful examination was computed tomography. This was done in 16 cases and gave us important information regarding vascular reports and laringeal nerve position allowing the anticipation of surgical approach and intraoperative difficulties.

The 99mTechnetium scintigram was done in 44 cases and confirmed the presence of radiotracer within the thorax.

Direct laringoscopy showed preoperative laringeal nerve palsy in 3 cases (5.5%)

Surgery was done by cervical approach initially and sternotomy was necessary in 8 cases (14.8%) (fig. 5) After exposure of the gland in the neck, the blood supply of the upper pole and the middle thyroid veins were isolated and ligation was done. Parathyroid glands were identified and preserved of harm. The inferior thyroid vessels and the laryngeal nerve were identified when possible, but at times this could not be accomplished until the intrathoracic part of the gland had been delivered from the mediastinum. This was done either by digital mobilization alone or by addition of a spoon technique. Infrequently further exposure was necessary and was done by median sternotomy to allow complete mobilization. After mobilization of the intrathoracic part of the goiter the inferior thyroid vessels if not already controlled, were ligated and divided, and the goiter was completely removed (fig. 6).

The volume of retrosternal goiter was:

- large goiter (up to 200 g) - 5 cases (9,25 %);
- very large goiter (200-300g) - 40 cases (74.08%)
- giant goiter (over 300g) - 9 cases (16.67%)

Macroscopically retrosternal goiters were multinodular (76%), with a solitary nodule (15 %) and rarely diffuse (9%).

Pathological examination showed coloid goiter – 31 cases (57.4%), hyperplastic hyperfunctional goiter – 7 cases (13%), adenomatous goiter – 6 cases (11.1%) and malignant nodules in 3 cases (5.5 %).

Total thyroidectomy was performed in 41 cases (76%) and subtotal thyroidectomy in other cases.

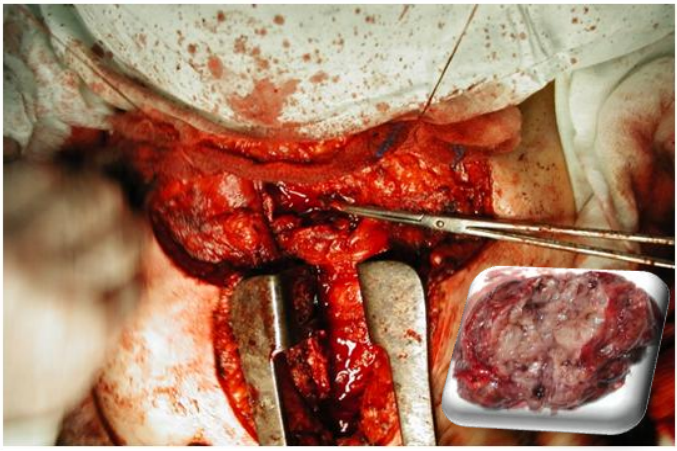

Fig. 5. Medial sternothormy for retrosternal and posterior nodular and cystic goiter. The resected goiter is showen in the lower right part of the figure.

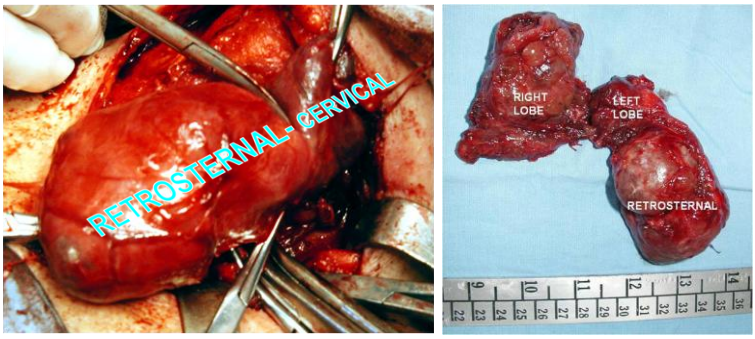

Fig. 6. Total thyroidectomy through cervical approach for retrosternal goiter (left). Resected goter (right)

There was not intraoperative mortality, Morbidity was seen in 5.5% of cases: 1 case of transitory hypoparathyroidism, a unilateral laringeal nerve palsy and a post-operative bleeding which required reintervention for haemostasis.

Average length of stay in the hospital was 4.3 day. The patients were followed from one month to 5 years in the Clinic of Endocrinology and no relapse was seen.

DISCUSSION

The current literature data use different terms such as retrosternal goiter, substernal, intrathoracic or mediastinal goiter. The term of substernal goiter is used when more than a half of thyroid gland descends in the thorax. There is no consensus regarding the plunger goiter. Moron and Shen define these goiters as goiters of which more than a half of their mass is situated under the upper thorax opening (4,5). Makaieff proposed 3 criteria to define a plonger goiter: goiter with substernal development when the neck is in operatory position, a substernal extension of minimum the width of two fingers, the need for supplementary extraction maneuvers (6). Zainine R defines plonger goiters in cases in which the lower pole of the gland is not palpable when neck is hyperextended and differentiates them from endothoracic or ectopic goiters by the fact that thyroid intrathoracic parechima is linked to the cervical part of the gland by a bridge of thyroid parenchyma (7). It is important to emphasize that large cervical goiters have an intrathoracic part in 20 % of cases. Factors that could facilitate the migration of the goiter from cervical region into the thorax may be: gravity, negative intrathoracic pressure and a potentially receptor space within the thorax. In rare cases a goiter develops “de novo”, primary within the mediastinum (intrathoracic goiter). Taking into account the reports with venous brachicephalic trunk the plonger goiters are divided prevascular and retrovascular (7). Most of substernal goiters are situated within anterior mediastinum in prevascular position as may be also in our data. Posterior goiters are seen in 10-15 % of cases (8). In our study the frequency of posterior plonger goiters was 3%.

The incidence of retrosternal goiters in our clinic decreased from 4.1% during 1950-1979 (100 cases among 2400 thyroidcctomies) to 2.1% in this study, and this may be due to a precocious detection and treatment of this particular form of goiter. All over the world iodine deficiency is the most important cause of goiter, but in areas with normal or increased iodine supply, Hashimoto’s thyroiditis is the main cause. In our cases there was noticed an increase of inci-

dence on autoimmune thyroiditis from 7 % in the previous group to 13 % in the actual group. Although there is a well known increased incidence of goiter in women (sex ratio F/M=5/1), the incidence of cervicomediastinal goiter is even higher in females in our study. Mean patients' age was 55.3 with limits between 36 and 82 years in concordance with other reported data (7). Patients between 51-60 years are particularly affected, the age being more advanced than that of patients with normally situated goiters. The fact that 90 % of female patients with retrosternal goiter have more than 40 years demonstrates that these goiters have a long silent evolution during which they first develop in the normal position and then migrate within the thorax. By comparison with our first study there was noticed an increased incidence of retrosternal goiter in aging patients. 79 % of patients studied between 1950-1979 had more than 40 year and 90.7% of patients in this study have more than 40 year.

Regarding the symptoms, only 5.5 % of our cases had no symptoms and were found by imagery techniques. Torre gives a similar percentage (5.5%) on 237 patients (9). Most patients presented with a cervical part of their goiter, and only in 3 cases the thyroid was not found at cervical level. In literature such cases may represent up to 11.8%10.

Compressive symptoms were dominant in our patients (tab. I). The incidence of compressive symptoms was similar in both groups and that demonstrates that a goiter that descends into the thorax may produce compression.

Laringeal nerve palsy was preoperatively detected in 3 cases (5.5%) with a similar incidence with other authors (6% in Vadasz report) (11). This could have the significance of a thyroid cancer (3 cases in our group).

As in other series (12) most of our patients were in an euthyroid state, and only 11% had hyperthyroidism. The prevalence of hyperthyroidism in patients with retrosternal goiter is estimated to 9.4% and 13.8 % of cases (6, 13, 14). Preoperative evaluation of thyroid function is mandatory because hyperthyroid patients must receive an appropriate preoperative treatment.

Dysphagia was seen in our 14.8% to 16% of our patients and is revealing sign for the development of retrosternal goiter on left side or within posterior mediastinum with esophageal compression (15).

The syndrome of superior vena cava was detected in 6% and 7.4% of cases (11).

The preoperative evaluation of retrosternal goiter is very important. Direct laringoscopy must identify laryngeal nerve compression (10%-11% of cases) and tracheal compression (increased from 59 % to 74 % of case). Thorax X-ray is a useful and not expensive method to discover retrosternal goiter. It shows superior mediastinal opacity with or without tracheal deviation (16). It is the most frequent sign seen in the literature (60%-90%) (7).

Ultrasound examination confirms the thyroid features of the mass which descends into the thorax. It was performed in the actual studied group and may approximate the goiter volume, the echogenicity of the nodules and their vascularity.

Cervical and thoracic computed tomography has opinion the optimal sensitivity (17) to evaluate intrathoracic extension and its place, the degree of tracheal narrowing and most of all the reports of goiter with vascular and nervous structures (18). Other authors consider magnetic resonance imaging the most precise method to detect the reports of goiter with brachiocephalic trunk, subclavian artery, aortic arch and other structures of the superior mediastinum (19). Faringoesofageal transit and tracheobronchial fibroscopy could eliminate or identify an invasion due to a thyroid cancer (6).

These evaluations are sufficient for the diagnosis of retrosternal goiter and allow the surgeon to plan the surgical approach.

The factors which decide surgical approach are: the dimensions of goiter, bilateral lesions, and the goiter in the posterior mediastinum, extension under the aortic arch, superior vena cava syndrome, and suspicion of obstruction of the trachea by a malignant lesion. Although rarely necessary, sternothomy may be indicated for giant substernal goiter or in patients with previous cervical surgery (relapse was noticed in some studies in up to 37% of cases) (20). After De Perot two factors frequently require medial sternothomy: medial ectopic goiter and suspicion of an invasive cancer (21). Rarely, medial sternothomy is required in order to mobilize a large substernal goiter which is associated with perithyroid inflammatory lesions (Hashimoto's thyroiditis), or in reinterventions for a goiter which extends below the aortic arch (22).

The removal of large substernal goiters may be done, with a few exceptions, by cervical approach with the patient in semi-Fowler position, with the neck hyperextended. A large cervical incision offers an appropriate acces. Subhyodian muscles may be cut laterally possibly the omohyoidian muscle tendon too. The medial thyroid vein is than ligated and cut in order to allow mobilization of the thyroid gland. The thyroid part situated within the thorax in than pulled up and medially with a special concern for the dissection of posterior cervical fascia outside of the thyroid gland.

In order to avoid a lesion of the superior laryngeal nerve, the branches of the superior thyroid vein are safely ligated on the surface of the thyroid gland. Because in cervicomediatinal goiter the laryngeal nerve and parathyroid glands are dificult to be identified, a subcapsule dissection is of choice. Similarly, the thyrotimic ligament must be ligated directly on the surface of the thyroid in order to avoid an injury of inferior parathyroid gland. Sometimes the parathyroid glands are situated on the anterior and lateral surface of the gland and must be safely dissected and preserved. O small margin of thyroid tissue must be preserved at the level of Zuckerkandl body, because at this level may be situated anterior, laterally or frequently posterior the laryngeal nerve.

Total thyroidectomy is recommended in all cases because a relapse may create difficult problems of surgical technique (23).

Minimal invasive thoracoscopic approach or robotic-assisted is now possible in specialized centers with very good results (24, 25). Robotic surgical techniques for removal of substernal goiter and other thyroid masses with mediastinal extension, in combination with cervical incision are also effective. Robotic-assisted techniques can complement video-assisted thoracic surgical techniques and amplify indications for minimally invasive surgery (26).

Independently of the used approach technique in the removal of large substernal goiters the personal experience of the surgeon offers a clear advantage in order to avoid morbidity and mortality associated with this surgery. Surgical management of patients with substernal goiter requires an appropriate preoperative diagnosis, a considerable experience of the surgical team, and must be performed in specialized centers (27).

Most of substernal goiters are benign: diffuse, coloid or adenomatous nodular goiters. The incidence of malignancy in these goiters may be up to 12 %28. It was of 6% in our cases. Risk factors for malignancy are: familial history of thyroid cancer, history of irradiation of the neck, cervical lymph node enlargement (grade C recommendation) (29).

Postoperatively the patient must be monitored in the ICU. Assisted ventilation overnight may be necessary in cases with

previous difficulties at intubation, large dissection of the neck, upper airway edema.

Postoperative complications are more frequent than those associated with thyroidectomy for cervical goiters: transient laryngeal nerve palsy occurs in 7 % and permanent laringeal nerve palsy occurs in 4 % of cases. The incidence of transient hypoparathyroidism is 10% and that of permanent hypoparathyroidism is 2.6 % (30). tracheomalacia is a severe but rare complication and compressive heamatoma and edema of the upper airway need intubation. Mortality associated with surgery is rare (1.1%). Surgical complications are associated with large goiters suggesting an increased caution in these patients (31). Intrathoracic goiters reaching carina tracheae have a high risk of postoperative complication and mortality (32).

No mortality was noticed in the group operated recently but in the previous group mortality was of 2%. There were 3 cases of surgical complications (5.5%), one being a bleeding which needed reintervention for haemostasis. Length of stay in the hospital after surgery decreased from 12.5 day for the first group to 4.3 in the actual group, that fact being an obvious progress.

CONCLUSIONS

Retrosternal goiters are a particular form of thyroid surgical pathology with a decreasing incidence. The diagnosis and treatment of retrosternal goiters involve o multidisciplinary team.

A retrosernal goiter is a clear indication for surgery.

It is important to clarify preoperatively the relationship between goiter and other structures of neck and mediastinum in order to plan the optimum surgical approach. The best investigation for these reports is neck and mediastinum CT.

Total thyroidectomy is the treatment of choice. When necessary, manubriothomy or sternothomy may be performed without hesitation.

The treatment of retrosternal goiters must pe performed only in specialized centers, in which surgeons' experience guarantees a minimal postoperative morbidity.

HOW DO PARENTS EXPERIENCE THE RARE DISEASE OF THEIR CHILD? (Abstract): **The aim of the study** is to identify the opinions of caregivers of children with rare diseases regarding some aspects of their life or those of their child. The rare diseases included are: cystic fibrosis, phenylketonuria and hypothyroidism. **Material and methods**: A number of 35 parents provided socio-demographic data and answered to a questionnaire with 19 items. Data were processed using *SPSS v. 20.0.* **Results**: 90% of parents consider that their relationship with their partner did not change after the time of diagnosis. More than 75% of parents discussed their worries about the illness with their life partner. They consider that the most affected aspects of their child's life are: relationship with friends and school activities. Most mothers self-evaluate themselves as being more involved in child's health problem compared to their partner. Parents declared that they consulted a health professional to cope with stress (32.7% of parents consulted a psychologist and 19.6% a psychiatrist). No change was identified by parents regarding the child' relationship with their siblings or teacher. **Conclusions**: Psychological support should be provided to parents having a child suffering from a rare disease. Comparative results are provided. **Keywords**: RARE DISEASE, CAREGIVER, PATIENT, CHILD.

A rare disease is defined as one affecting less than 1 in 2,000 people, and more than 6,000 diseases are identified, conforming to the EURORDIS report.

Over 30 million European citizens are affected by one rare disease (1).

A rare disease is a social challenge, with national programs providing equal access to medical services for all patients with healthcare problems and to support costs related to them.

Living with a rare disease is also a challenge for both pediatric patients and their families. Affected children experience loss of social, educational and economic opportunities and difficulties in receiving medical care in good time caused by the need for a specialized medical team or proper medical investigation, with the latter sometimes being delayed (2, 3). After a clear diagnosis, the relationship with the medical encounter is crucial, the doctor-patient

relationship influences the quality of life of a patient with a rare disease. Even if studies identified that such a patient is actively searching information and help, the difficulties and importance of providing information about a rare disease are a challenge also for the healthcare provider (4).

Most of the families are affected by the child's health condition: more financial expenses are needed to cover the specialized medical care, medical treatment, specialized equipment, and special education services (5). In addition, considering the type of disease, some families must travel to obtain a clear diagnosis, or they have to settle in a new location in order to have access to the treatment or medical equipment. Greater geographical distances between patients and physicians have been identified in a study lead by EURORDIS (6). Professional difficulties for parents are also noted, with some studies identifying a high level of unemployment among parents of children with rare diseases and a lack of social network (7, 8). A rare disease does not influence only a patient's and caregiver's life, but also the other children in the family. Some studies demonstrate that the quality of life of the sibling of a child with a rare disease is also affected (9).

Family plays a central role in assuring the quality of life of children affected by rare diseases. Around the world, support programs for parents of children with rare diseases were developed within the last decade. They help the caregiver cope with stress and train them to develop parental skills in order adjust properly to life with a rare disease. That is why factors like economic status, professional duties or other socio-demographic data like marital status, type of chronic disease, geographic area or the possibility to access medical services are also studied. The psychological and physical well-being of the career will influence the quality of life of the affected child. In a recent study in Germany (10) it was revealed that the marital status influences this level, with single parents of children with cystic fibrosis obtaining significantly lower scores for quality of life than partnered parents. The mother of children with rare disease are usually affected mentally and physically, having significant lower than average physical and mental well-being scores (7, 11, 12). Also, single mothers and full-time employment seem to increase the level of stress among mothers of children with rare diseases. A study of Dellve et al identified that fathers are more likely to need supportive programs than mothers focusing on family competence (8). That is why, a family centric support should also be considered in cases of children living with rare diseases.

Since the parent psychological and physical health is important, the present study focuses on the opinion of parents regarding the disease and on some difficulties that they must deal with: personal problems or issues related to their child's life.

MATERIAL AND METHODS

Sample

53 caregivers of children diagnosed with rare diseases were included in the research. Children are registered and supervised by medical teams in a university child hospital in north-eastern Romania. The parents were questioned while they were staying with their children in the hos-

pital. The pediatric patients were registered with cystic fibrosis, hypothyroidism or phenylketonuria.

The participants were informed about the purpose of the study, they agreed to fill in the papers after they had read and signed the inform consent. It was explained that consent could be withdrawn at any stage of the research and they were assured about the confidentiality of the data that they provided.

Instruments

The participants had to complete two documents. The first one referred to socio-demographic data: age, gender, environment, religion, marital status and educational level. The second document was designed specifically for parents having children with rare disease and included nineteen items focusing on identifying the parents' opinion regarding their child's life at home, at school, how the disease is seen by relative or friends, or how they relate the disease with family or religious factors.

Statistical procedure

The collected data were processed using *SPSS version 20.0* for Windows and the following types of statistical methods were used:

- descriptive statistics, which pursued the central tendency and dispersion indicators (the mean and standard deviation) for socio-demographic characteristics and medical data. Also, included were the frequency of answers to all nineteen items, for both male and female caregivers.
- *chi-square* tests were used to point if there are any associations between various categorical variables: the items of the questionnaire in association with socio-demographic data and the type of chronic disease.

Ethical conduct

The research was approved by the ethical committee of "Sf. Maria" University Hospital for Children, Iasi, Romania.

RESULTS

Descriptive analysis

Socio-demographic data gathered information about gender (male/female), age, environment (rural/urban), religion, ethnicity, marital status (single, in relationship and married), educational level (primary, secondary, high school and university degree or uneducated). The data is presented in first table.

Collected data also included medical information about the chronic disease and child's age and gender. A total of 63.3% were boys and 36.4% were girls. The average is M = 7.1± 6.44, ranged 1 to 22-year-old. More than half of the patients (68.8%) are aged between 1 and 6-year-old, 28.1% are aged between 6 and 12-year-old, and the rest (3.1%) are older than 12-year-old

The distribution of rare diseases of their children is the following:

- cystic fibrosis 39.6 %,
- phenylketonuria 30.2%
- hypothyroidism 30.2%.

When parents were asked about their participation in child's treatment (see tab. II, *Item* 19), all fathers declared that are not more caring about their child's disease than mothers. In the case of female subjects, 70% appreciated that they are more concerned about it.

TABLE I.
Socio-demographic data

Variables	**N (%) or M ± standard deviation**
Gender	
male	N = 20 (37.7%)
female	N = 33 (62.3%)
Age	M = 33.5 ± 8.22 (ranged 18-55 years old)
Environment	
urban	N = 26 (49.1%)
rural	N = 27 (50.9%)
Religion	
Orthodox	N = 48 (90.6%)
Pentecostals	N = 3 (5.7%)
Adventist	N = 2 (3.8%)
Marital status	
single	N = 3 (5.7%)
in relationship	N = 2 (3.8%)
married	N = 48 (90.5%)
Educational level	
primary school	N = 3 (5.7%)
secondary school	N = 8 (15.1%)
high school	N = 27 (50.9%)
university	N = 8 (15.1%)
uneducated	N = 7 (13.2%)

TABLE II
The frequency of answers for total/male/female participants

I	**Items and multiple answers**	Total (%)	Male (%)	Female (%)
1.	*I think the time given to my child is*:			
	a. less than that given to other children	3.8	5	3.1
	b. the same time as other children	48.1	50	46.9
	c. longer than the time given to other children	42.3	40	43.8
	d. I do not know how to appreciate	5.8	5	6.3
2	*I discussed the diagnosis of my child with family members*			
	a. yes	98.1	95	100
	b. no	1.9	5	0
3.	*I advised my relatives to have screening for this disease*			
	a. yes	46.2	50	43.8
	b. no	53.85	50	56.3
4.	*I think the other siblings have inappropriate manifestations of it*:			
	a. rarely	8.5	5.9	10
	b. often	2.1	0	3.3
	c. never	89.4	94.1	86.7

I	Items and multiple answers	Total (%)	Male (%)	Female (%)
5.	*It is hard for me to see my baby's disease difficulties*			
	a.yes	47.1	31.6	56.3
	b.no	49	63.2	40.6
	c.I do not know	3.9	5.3	3.1
6.	*When the members of my family learned about my child's illness, they*:			
	a. encouraged me	62.3	75	54.5
	b. helped me	34	25	39.4
	c. I noticed no change	3.8	0	6.1
7.	*When they learned about my child's illness, school teachers*:			
	a. started to isolate him	4.5	0	6.7
	b. began to favor him	0	0	0
	c. started ironing it	0	0	0
	d. began to protect him	54.5	57.1	53.3
	e. I have not noticed changes in teacher behavior	40.9	42.9	40
8.	*When they learned about the illness, the friend of my child*:			
	a. begun to protect him/her	33.3	37.5	31.6
	b. started to isolate him/her	0	0	0
	c. started ironizing it/her	3.7	0	5.3
	d. started to bypass him/her	7.4	0	10.5
	e. I have not noticed changes in the behavior of my child's friends	55.6	62.5	52.6
9.	*Regarding the illness, I blame*:			
	a. family	10.3	14.3	8
	b. child	0	0	0
	c. God	23.1	21.4	24
	d. unhealthful	61.5	64.3	60
	e. ignorance of the family	0	0	0
	f. doctors	2.6	0	4
	g. mother	2.6	0	4
	h. father	0	0	0
10.	*I've checked a second opinion regarding the illness of my child*			
	a. yes	43.1	42.1	43.8
	b. no	56.9	57.9	56.3
11.	*The relationship with my partner had changed since we learned about the diagnosis*			
	a. yes	5.8	5.3	6.1
	b. no	94.2	94.7	93.9
12.	*The relationship with my other children has changed since the diagnostic*			
	a. yes	2.2	0	3.7
	b. no	97.8	100	96.3

I	Items and multiple answers	Total (%)	Male (%)	Female (%)
13.	*When I'm upset and want to talk to someone about my child's suffering, I call on*:			
	a. the life partner	78.4	78.9	78.1
	b. friends	11.8	10.5	12.5
	c. acquaintances	0	0	0
	d. service colleagues	0	0	0
	e. grand parents	0	0	0
	f. priest	0	0	0
	g. physician	5.9	5.3	6.3
	h. other parents who have a child in the same situation	3.9	5.3	3.1
14.	*I consulted a psychologist to help me cope with this situation*			
	a. yes	32.7	21.1	39.4
	b. no	67.3	78.9	60.6
15.	*I consulted a psychiatrist to help me cope with this situation*			
	a. yes	19.6	10.5	25
	b. no	80.4	89.5	75
16.	*When I think about my child, the hardest thing to deal with is*:			
	a. fear of death	25.5	22.2	27.6
	b. fear of treatment	4.3	11.1	0
	c. fear of pain	17	11.1	20.7
	d. fear of illness	53.2	55.6	51.7
17.	*I think my most difficult child must bear*:			
	a. the pain	44	31.6	51.6
	b. treatment	24	26.3	22.6
	c. disease	32	42.1	25.8
18.	*The most affected aspect of my child's life I think is*:			
	a. school activity	40.7	37.5	42.1
	b. relationships with friends	44.4	62.5	36.8
	c. family relationships	7.4	0	10.5
	d. intimate relationships	7.4	0	10.5
19.	*I think I'm involved in treating my child's disease more than my partner is*.			
	a. yes	44.7	0	70
	b. no	55.3	100	30

Comparative analysis

To determine whether there are any associations between type of disease, child's gender, child's age, parents' gender and each item, chi square tests were used. The statistical interest is represented by the cells with positive and negative adjusted residuals within a (-2, +2) interval.

The chi square tests used to determine the association between parents' gender and environment (rural/urban) and each of our instrument's items show no significant associations.

The type of disease

The chi square tests used to determine the association between child's disease and each of our instrument's items show an association with:

- *Item 5*: $\chi^2(4) = 15.239$, $p = .004$.

Two positive adjusted residuals were identified.

- In the case of phenylketonuria, there were more participants in the category of parents who do not understand the child's difficulties with the disease than would be expected by chance;
- in the case of cystic fibrosis there were more participants in the category of parents who understand the child's difficulties with the disease than would be expected by chance.

Also, two negative adjusted residuals were identified:

- in the case of phenylketonuria there were less participants in the category of parents who understand the child's difficulties with the disease than would be expected by chance;
- in the case of cystic fibrosis there were less participants in the category of parents who did not understand the child's difficulties with the disease than would be expected by chance.

- *Item 7:* $\chi^2(4) = 15.475$, $p = .004$.

By inspecting the adjusted residuals, resulted two positive ones.

- concerning phenylketonuria, there were more participants in the category of parents who think their child's teacher started to isolate him/her than would be expected by chance,
- in the case of hypothyroidism there were more participants in the category of parents who do not see any modifications in their child's teachers' attitude than would be expected by chance.

- *Item 10*: $\chi^2(4) = 7.701$, $p = .021$.

By inspecting the cross tabulation, two positive adjusted residuals were revealed:

- in the case of phenylketonuria there were more participants in the category of parents who think their child's teacher started to isolate him/her than would be expected by chance;
- in the case of hypothyroidism there were more participants in the category of parents who do not see any modifications in their child's teachers' attitude than would be expected by chance.

- *Item 16*: $\chi^2(6) = 17.186$, $p = .009$.

In the case of this item, two positive and two negative residuals were found.

- in the case of phenylketonuria, there were less participants in the category of parents who find it difficult to deal with the fear of death than would be expected by chance and more participants in the category of parents who find it difficult to deal with the treatment than would be expected by chance.
- in the case of hypothyroidism, there were more participants in the category of parents who find it difficult to with the fear of death than would be expected by chance and less participants in the category of parents who find it difficult to deal with the fear of the disease than would be expected by chance.

- *Item 17*: $\chi^2(4) = 12.753$, $p = .013$.

In this case, one negative and two positive residuals resulted.

- in the case of phenylketonuria, there were less parents in the category that think it's difficult for their children to face the pain and more parents in the category that think it's difficult for their children to face the treatment than would be expected by chance.
- in the case of cystic fibrosis, there were more parents in the category that think it's difficult for their children to face the pain than would be expected by chance.

Child's gender

The chi square tests used to determine

the association between child's disease and each of our instrument's items show an association with the item No 17 - $\chi^2(2) = 9.557$, $p = .008$.

By inspecting the cross tabulation, one negative and one positive adjusted residual were noticed: in the case of boys, there were less parents, and, in the case of girls, there are more parents in the category that think it's difficult for their children to face the pain than would be expected by chance.

Child's age

To provide a comparative analysis considering the age of the children, three groups were considered: 0-6 years old, 6-12 years old, and over 12 years old. The chi square tests used to determine the link between child's age and each of our instrument's items show the following significant associations:

- *Item 5*: $\chi2(4) = 16.124$, $p = .003$

with two positive and two negative adjusted residuals:

- in the case of children aged between 1 and 6 there were less participants in the category of parents who understand the child's difficulties with the disease and more in the category who do not understand the child's difficulties with the disease than would be expected by chance,
- in the case of children aged between 6 and 12, there were more participants in the category of parents who understand the child's difficulties with the disease and less in the category of parents who do not understand the child's difficulties with the disease than would be expected by chance.

- *Item 12:* $\chi2(2) = 20.988$, $p = .000$ - one positive and one negative adjusted residuals:
  - in the case of children older than 12 years, there were less participants in the category of parents who do not think their relationship with their other children has changed and more in the category who believe their relationship with their other children has changed than would be expected by chance.
- *Item 13*: $\chi2(6) = 28.163$, $p = .000$ - two positive and two negative adjusted residuals:
  - in the case of children aged between 1 and 6, there were more participants in the category of parents who turn to their life partner and less in the category who turn to their friends than would be expected by chance,
  - In the case of children aged between 6 and 12, there were less participants in the category of parents who turn to their life partner and more in the category of parents who turn to their friends than would be expected by chance.
- *Item 14*: $\chi2(2) = 11.158$, $p = .004$

with two positive and two negative adjusted residuals:

- in the case of children aged between 1 and 6, there were less participants in the category of parents who turned to a psychologist and more in the category who did not turn to a psychologist than would be expected by chance,
- in the case of children aged between 6 and 12, there were more participants in the category of parents who turned to a psychologist and less in the category of parents who did not turn to a psychologist than would be expected by chance.

- *Item 15:* $\chi2(2) = 12.470$, $p = .002$ - two positive and two negative adjusted residuals:
  - in the case of children aged between 1 and 6, there were less participants in the category of parents who turned to a psychiatrist and more in the category who did not

turn to a psychiatrist than would be expected by chance,

- in the case of children aged between 6 and 12, there were more participants in the category of parents who turned to a psychiatrist and less in the category of parents who did not turn to a psychiatrist than would be expected by chance.

- *Item 16*: $\chi 2(6) = 13.672$, $p = .034$ - two positive and two negative adjusted residuals.

- in the case of children aged between 1 and 6, there were less participants in the category of parents who feared death and more in the category who feared the disease than would be expected by chance,

- in the case of children aged between 6 and 12, there were more participants in the category of parents who feared death and less in the category of parents who feared the disease than would be expected by chance.

DISCUSSION

Dealing with a rare disease is a challenge for both patients and parents, but also for the medical team. A multidisciplinary team is needed, to share decision and knowledge. Individually tailored treatments are provided, that is why the treatment is also a source of psychological distress, especially when family is vulnerable (single caregiver, unemployed or family difficulties) or the child presents some problems (behavioral problems, deficiencies, adolescence, psychological disturbances).

The present research focused on the caregiver's opinion regarding some aspects of the parent and the child's life. The results showed that mothers are more involved in child's treatment, and this aspect is revealed also by fathers who were questioned. Treatment, in case of rare disease, is extremely important, and closely-supervised diets or early identification in the changes in the patient's physical status are extremely important (13,14). This aspect has also been identified by other researchers, showing that mothers are more often hospitalized or more involved in child' treatment and diets. Mothers seems to need more psychological support and they are more often looking for a professional help.

No significant associations were identified between parents' gender and environment (rural/urban) and each of the instrument's items. In a study of Medfort *et al.* (15) it was pointed that socioeconomic factors were not associated with parental wellbeing among parents of children diagnosed with phenylketonuria. Some other studies showed that age of the child did not impact the difference of quality of life between single and partnered parents (10).

The limitations of the study. The first limitation is due to the small number of parents. This aspect is due to the small number of children registered in the university hospital where the study was conducted. The second limitation is determined by the unbalanced number of parents considering the gender, so comparative results were not possible to be revealed. Taking into consideration the limitations of the study, results should be treated with caution.

CONCLUSIONS

For both patients and families, living with a rare disease is a ongoing learning experience. Research should address the many challenges in the management of rare disease and focus on identifying factors that improve life for people with rare diseases. Patient well-being does not involve

only medical care, but also psychological support, for both patient and caregivers, especially mothers, single parents or the unemployed. Financial expenses and investments in studying rare diseases is approached differently by medical teams from different countries. This vulnerable population must be cared for carefully to reduce psychological and physical distress for those affected by this type of illness.

TRATAMENTUL CHIRURGICAL AL TUMORILOR CUTANATE. PREZENTARE DE CAZURI

G. Stătescu, Mihaela Curic, Delia Farcaş, Luminița Ivan
Spitalul Clinic Militar de Urgență "Dr. Iacob Czihac" Iaşi

SURGICAL TREATMENT OF SKIN TUMORS. CASE REPORT (Abstract): This is the overview of several hospitalized cases of skin tumors this year based on which we analyzed the information in the literature concerning the clinical features, the evolution and therapy of these skin neoplasms. The tumors that develop in the skin fibrous tissue sometimes on a prior lesion need to be analyzed from a multidisciplinary perspective, therefore it is essential for the surgeon, the pathologist and the oncologist to consistently cooperate and to solve all issues related to the evolution of the case, which may be at times less favorable. **Patients and method:** In what follows we will introduce two clinical cases of dermato-fibrosarcoma protuberans (Darier-Ferrand) met in our recent practice this year, accompanied by the data found in the specialized literature concerning the clinical features, evolution and therapy of these quite rare skin lesions. Also we present another two cases of skin neoplasm. **Results:** All operated patients have survived since the surgery without any indication of relapse. **Discussion:** The attention of the surgeons is focused quite rarely on such skin tumors, since the patients with such lesions are usually treated by dermatologists. This cases we met in the recent years made us analyze the specialized literature in this field and to draw different conclusions. **Conclusions:** Each skin tumor where there are doubts concerning the diagnosis must be treated with extreme care and caution. We personally prefer a larger excision of an apparently benign tumor rather than making an insufficient excision. The operated patients must be consistently monitored throughout their lives. **Key words**: SKIN TUMORS, DERMATO-FIBROSARCOMA PROTUBERANS , TUMOR RELAPSE, METASTASES.

Aceste tumori care se dezvoltă din țesutul fibros de la nivelul pielii (tumori fibrohistiocitare), uneori pe o leziune preexistentă, necesită o abordare multidisciplinară fiind necesară colaborarea coerentă dintre chirurg, anatomopatolog şi oncolog şi pentru a nu avea surprize neplăcute datorate evoluției ulterioare nefavorabile a cazului. *Dermatofibrosarcomul protuberans* (Darier-Ferrand) este o tumoră cu malignitate intermediară care recidivează frecvent şi poate metastaza dar numai după recidive repetate. Afectează de predilecție tinerii şi adulții de sex masculin. În toate cazurile de leziuni maligne rolul chirurgului devine important deoarece excizia largă a tumorii cu limite de securitate oncologică reprezintă componenta principală a protocolului terapeutic. Prezentăm două cazuri clinice de dermatofibrosarcom întâlnite în practica noastră din ultimii ani, împreună cu datele găsite în literatura de specialitate cu privire la particularitățile clinice, evolutive şi terapeutice ale acestor leziuni cutanate destul de rar întâlnite.

MATERIAL SI METODA:

Cazul 1. Pacientul S. S. de 39 de ani se prezintă la un consult de rutină afirmând că este deranjat din ce în ce mai des de către o formațiune proeminentă situată în 1/3 inferioară a gambei stângi, pretibial care la fiecare atingere mai tare de alte corpuri sângerează uşor şi chiar îl doare. Pacientul prezintă această formațiune cutanată de aproximativ 15 ani, dar despre care poate spune că a fost mai mică inițial şi că a crescut în volum în ultima perioadă de timp. La examenul obiectiv se constată pe fața antero-internă a gambei stângi, în 1/3 inferioară, pretibial o formațiune tumorală cutanată cu un mic pedicul şi un aspect de "ciupercă" cu diametrul de circa 1 cm, de culoare vineție şi aspect conopidiform la exterior.

Având acceptul pacientului se excizează limitat această formațiune cutanată, sub anestezie locală şi se trimite la examen anatomopatologic.

Macroscopic tumora are aspect de "ciupercă" lobulată, de culoare violacee, vineție, de aproximativ 1cm diametrul, de consistență crescută, iar examenul microscopic evidențiază celularitate tumorală asemănătoare fibroblastelor, cu aranjament storiform în jurul vaselor de sânge caracteristice dermatofibrosarcomului protuberans (fig. 1).

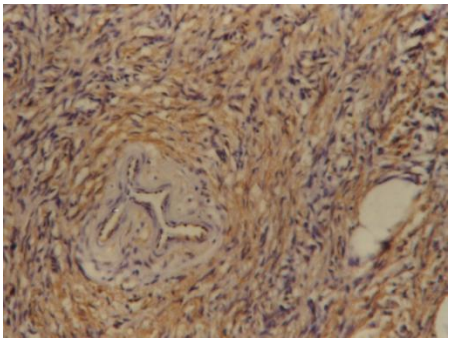

Fig. 1. Ob 20x.Col. IHC pentru CD34-pozitivitate citoplasmatică in celulele tumorale

În aceste condiții am reintervenit chirurgical practicând excizie largă cu limite de securitate oncologică în suprafață şi în profunzime în jurul cicatricei (fig. 2) de după prima intervenție chirurgicală acoperind defectul cutanat rămas printr-un lambou romboid rotativ. În acelaşi timp am mai excizat două formațiuni situate premaleolar drept pentru a fi siguri că pacientul nu mai rămâne cu alte posibile leziuni.

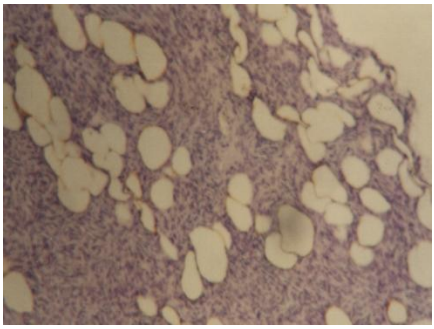

Fig. 2. Ob20x.Col.IHC pt S100-invazie în țesutul adipos

S-au efectuat testele de imunohistochimie care au evidențiat pozitivitate citoplasmatică intensă in toate celulele tumorale pentru Vimentin şi CD34 şi focală pentru Actin SM şi negativitate pentru S100, CD68,CKc,HMB45.De asemenea s-a decelat pozitivitate nucleară intensă si omogenă pentru Ki67 in 4-5% din celulele tumorale ceea ce a permis incadrarea cazului in grupa de malignitate joasă. Testele de imunohistochimie confirmând diagnosticul de dermatofibrosarcom protuberans şi prin excluderea altor forme de exemplu dermatofibromul, pacientul a fost îndrumat către medicul oncolog pentru luare în evidență şi supraveghere ulterioară. Evoluția pacientului a fost favorabilă neconsemnându-se recidivă locală şi nici un fel de metastaze la 18 luni de la intervenția chirurgicală.

Cazul.2. Pacientul G.H. de 38 de ani se prezintă la un consult chirurgical cu bilet de trimitere de la medical dermatolog pentru prezența unei formațiuni situată la nivelul trunchiului, dorsal, pe spate fiind suspicionat de la început de un melanom malign al trunchiului. S-a intervenit chirurgical practicându-se de această dată excizia cutanată în limite oncologice *per primam* .

Examenul anatomopatologic microscopic evidențiază caracteristicile unui dermatofibrosarcom protuberans (fig. 3), iar imunohistochimia confirmă diagnosticul (fig. 4).

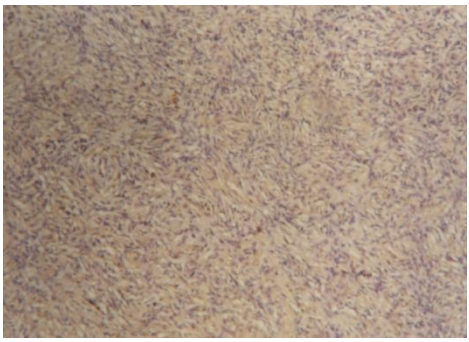

Fig. 3. Ob.20x. Col.IHC pt Vimentin-aranjament storiform

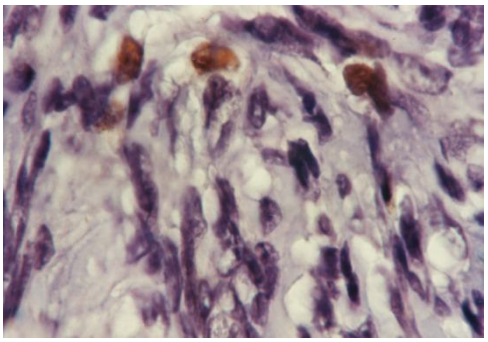

Fig. 4. Ob100x Col.IHC pt Ki67 – colorație nucleară difuză şi omogenă

Cazul 3. Pacientul Gh. S. de 71 de ani se prezintă în serviciul nostru pentru a se opera de o formațiune tumorală cutanată mare situată în regiunea temporală dreapta fiind refuzat de către serviciul de chirurgie al spitalului județean de care aparținea.

După pregătirea de rigoare datorită tarelor asociate s-a intervenit chirurgical sub anestezie locală practicându-se excizia acestei formațiuni. Examenul anatomopatologic efectuat.

Fig. 5. Tumora cutanată a pacientului Gh. S

Cazul 4. Pacientul C. B de 76 de ani se prezintă în serviciul nostru fiind deranjat de o formațiune axilară stângă mare.

După o scurtă investigare şi pregătire

s-a intervenit chirurgical sub anestezie locală şi s-a extirpat această formaţiune. La explorările efectuate s-au decelat metastaze hepatice. Examenul anatomopatologic efectuat a decelat degenerare sarcomatoasă. Pacientul a fost îndrumat către serviciul de oncologie pentru tratament complementar.

Fig. 6. Formaţiunea cutanată a pacientului C. B.

DISCUŢII

Dermatofibrosarcomul protuberans (Darier-Ferrand) este o tumoră cu malignitate intermediară care recidivează frecvent şi metastazează după recidive repetate.

Afectează de predilecţie tinerii şi adulţii de sex masculin. Clinic tumora se poate dezvolta oriunde dar apare mai frecvent pe trunchi şi pe extremităţi. Evoluţia tumorilor este marcată de numeroase recidive, metastazele fiind mai rare (apreciate la 1-2%) şi sunt localizate în plămâni sau în ganglionii limfatici regionali (1). Microscopia electronică a pus în evidenţă faptul că celulele tumorale sunt fibroblaste deoarece au un reticul endoplasmatic dezvoltat care sintetizează activ colagen. Diagnosticul acestor forme tumorale se realizează strict prin examen histopatologic, la simplul examen microscopic adăugându-se recent si criteriile imunohistochimice bazate pe o serie de markeri, şi anume: Vimentin+, S100−, CD34+(2).

Incidenţa recidivelor locale şi a metastazelor este in toate referinţele studiate mai mare la cei eronat diagnosticaţi şi deci trataţi incorect iniţial. Mortalitatea legată de evoluţia neoplaziei variază intre 0-6% la 10 ani de la prima intervenţie chirurgicală şi este semnificativ redusă (0-1%) la cei trataţi iniţial corect(3,4).

Tratamentul de elecţie este cel chirurgical si constă in excizia tumorii in limite de siguranţă oncologică, apreciate prin examenul histopatologic extemporaneu (*„frozen - section") sau* la parafină urmat, dacă este cazul, de reexcizie. Majoritatea autorilor consideră că o limită de 2 cm de la marginea macroscopică a zonei modificate este suficientă. La aceasta se asociază evidarea limfoganglionară, locoregională dacă este prezentă adenopatia. În cazul recidivelor, se fac excizii largi şi evidare limfoganglionară de principiu. În ambele situaţii, radioterapia se poate asocia postoperator (4).

În cazul tumorilor prezentate tardiv, adesea metastazate, se consideră că excizia

chirurgicală îmbunătăţeşte prognosticul vital prin încetinirea evoluţiei tumorilor secundare .Sintetizând, in final, datele din literatură, am remarcat faptul ca există mai multe puncte de consens, dar si aspecte aflate încă in dezbatere (cum ar fi eventualele criterii de clasificare).

Punctele de consens acceptate sunt utile practicienilor:

- potenţialul de malignizare a oricărei formaţiuni cutanate, in special a celor expuse la stimuli mitotici repetaţi, constituie un risc real;
- posibilitatea existenţei in evoluţia tumorii a unei perioade lungi asimptomatice sau cu semne clinice şterse, nespecifice, impune prudenţa in evaluarea tuturor leziunilor cutanate;
- frecventele erori de diagnostic, in special in cazul tumorilor suprainfectate/ulcerate pot influenta negativ evoluţia;
- excizia chirurgicală corectă reprezintă componenta de bază a tratamentului;
- tratamentul chirurgical incomplet/incorect are consecinţe cel puţin la fel de nefaste ca şi lipsa tratamentului;
- posibilitatea decelării recidivelor locale sau a metastazelor la un interval mare de timp după cura chirurgicală aparent corectă , impune urmărirea pacienţilor pe termen lung (5,6).

CONCLUZII

În faţa celui mai mic dubiu de diagnostic pentru orice formaţiune tumorală cutanată atitudinea medicală trebuie să fie prudentă. Din acest motiv trebuie să efectuăm o excizie mai largă de la bun început a unei formaţiuni benigne decât o excizie insuficientă a uneia maligne.

Examenul histopatologic al piesei este obligatoriu. Postoperator pacientul trebuie îndrumat către medicul oncolog pentru a fi luat în evidenţă.

Monitorizarea pacienţilor trebuie făcută periodic la început, apoi anual.

TREATMENT CHOICES IN THE TUMORS OF THE INNER ANGLE OF THE EYE (Abstract). Surgery of the tumors of the inner angle of the eye is difficult given the fact that beside tumor size, local peculiarities (concave area, thin and adhering skin, internal ligament, orifices, and tear duct), eyelids -mobile structures, vicinity and importance of visual receptor) need to be considered. **Aim:** To determine, based on data in the literature, what are the treatment choices in the various types of tumors of the inner angle of the eye. **Material and methods:** During a six-year interval (2004-2009) we diagnosed with and treated for tumors of the inner angle of the eye 135 patients. Patients age, sex, environment, causes – tumor epidemiology, and course length have been studied A thorough history, including the clinical features and progression of the tumor, previous treatments, as well as aspects related to the general pathologic picture was obtained from every patient. The treatment included tumor excision and subsequent reconstruction, the methods used for covering the defect and the type of used tissue depending on the local characteristics. The main areas of the study are: type and onset area of the tumor, tumor size and implicitly the size of postsurgical defect and the method for the reconstruction of postsurgical defect. **Results:** The reconstruction plan was individualized and included at least one alternative option depending on the size and depth of the excision. Aiming at best functional and esthetic results has lead to changes in the classical techniques which proved beneficial. **Conclusions:** The comparative analysis of these methods allowed us finding the most effective treatment of these tumors. For best results the collaboration plastic surgeon-ophthalmologist-maxillofacial surgeon-neurosurgeon was often required. We support the radical tumor removal with intraoperative pathologic confirmation. Surgical approach according to a previously established plan gives treatment safety, this paper suggesting the best type of surgery planning, thus representing a short guide to preoperative options. **Key words:** TUMOR, INNER ANGLE OF THE EYE, TUMOR REMOVAL, SURGICAL RECONSTRUCTION

Patologia tumorală a ariei interne a ochiului, în stadiile incipiente, nu prezintă dificultate pentru un chirurg, deoarece pleoapele au o structură elastică, excizia unei formațiuni cu diametrul sub 0,5 cm putînd beneficia de o sutura directă a defectului (1, 2).

În mod normal o pierdere de substanță mai mică de 1/3 din lungimea pleoapei poate fi compensată prin adaptarea ulterioară a țesuturilor. Totuşi în aceste cazuri plastiile locale cu triunghiuri încrucişate ori lambouri de rotație sau avansare se impun pentru o vindecare fără sechele cicatriciale

importante.

Formațiunile tumorale cu diametre ce impun o excizie mai mare de 1-1,5 cm obligă la folosirea unei metode de acoperire de tipul plastiei cu piele liberă, lambouri de rotație ample sau lambouri pediculate. Uneori reconstrucțiile acestei regiuni se pot practica folosind lambouri pediculate lungi sau cele liber transferate. În studiul nostru acestea au fost folosite limitat doar în cazurile în care marimea exciziei impunea o suprafață mare de acoperit (3).

Din punct de vedere al exciziei tumorii, condițiile locale nu permit ca acestea să fie largi, cu asigurarea unor limite de siguranță suficiente. De aceea considerăm că se impune utilizarea în cazul tumorilor din această regiune a unei metode care să asigure o excizie limitată a țesuturilor, cu o pierdere de substanță minimă în afara leziunii tumorale (4).

În reconstrucția postexcizională în afară de dimensiunea tumorii, se va ține seama și de particularitățile locale: tegumente aderente, caruncula și ligamentul intern, orificiile și canalul lacrimal, peoapele – structuri mobile și structura lor, vecinatatea și importanța receptorului vizual (5).

Utilizarea grefelor de piele în refacerea defectelor de substanță la nivelul jumătății interne a pleoapelor și a unghiului intern, reprezintă o metodă care oferă, în general, satisfacție în ceea ce privește calitatea țesutului și aspectul acestuia în timp.

Utilizarea lambourilor de vecinatate se impune ca o consecință a defectelor de țesuturi postexcizionale, care interesează toate structurile moi, pînă la planul osos.

Au fost inventariate în acest scop metodele propuse în literatură, utilizându-se în relație cu caracteristicile locale pre- și postexcizionale toate tipurile de lambouri de vecinatate (6).

Bazîndu-se pe circulația întimplătoare, lambourile de vecinătate pot fi translate sau rotate, acoperind astfel defectul postexcizional. Deşi cu un țesut de calitate apropiată celui a unghiului intern, aceste lambouri sunt limitate de dimensiunea pleoapei şi de menținerea funcționalității ei (7).

MATERIAL ŞI METODE

Am realizat un studiu pe un lot de 135 pacienți cu tumori ale ariei unghiului intern al ochiului, în perioada 2004 – 2009, în cadrul Clinicii de Chirurgie Plastică Reconstructivă a Spitalului Clinic de Urgențe Iaşi.

S-a luat în considerație vârsta, sexul, mediul de proveniență, caracteristicile tumorii. Am evaluat referințele din literatura de specialitate pentru metodele de tratament aplicate în relație cu particularitățile pacienților incluși în studiu (8).

Informațiile au fost acumulate prin anamneză, consemnând detaliile evolutive şi caracteristicile clinice ale tumorii, tratamentele efectuate anterior şi comorbiditățile fiecărui pacient.

Am stabilit planul operator pentru fiecare caz în parte, utilizînd excizia cea mai sigură şi completă pentru eradicarea formațiunii tumorale şi estimând modalitatea de reconstrucție postexcizie (9).

Experiența practică chirurgicală acumulată a permis utilizarea metodelor cele mai eficiente în reconstrucția defectelor tisulare postexcizionale, cu efecte funcționale şi estetice minime (10, 11).

Au fost apreciate în studiul comparativ rapoartele regionale față de elementele structurale importante (caruncură, ligament intern, canale lacrimale); tratamentul chirurgical aplicat (tipul de excizie); tipul de reconstrucție postexcizională în relație cu dimensiunile defectului de țesut rezultat;

rezultatele cicatriciale şi funcțional - estetice postoperatorii.

Direcțiile de studiu au inclus: tipul, aria de debut şi dimensiunile tumorii, extinderea defectului postexcizional şi metoda de reconstrucție a acestuia.

REZULTATE ŞI DISCUȚII

Debutul tumoral se realizează la nivelul structurilor de vecinatate, cel mai frecvent la nivelul pleoapei inferioare, de unde datorită laxității țesuturilor se produce relativ rapid o invazie tumorala locală. La aceasta contribuie mobilitatea zonei, vascularizația optimă, umiditatea şi traumatismele locale mai frecvente.

Tumorile benigne sunt semnificativ mai numeroase (71,1%) decît cele maligne, şi sunt reprezentate ca formațiuni tegumentare în stadiul incipient, necomplicat, pentru care sunt suficiente excizia şi sutura (χ^2=141,80; GL=1; p<0,001) (fig. 1).

Tumorile maligne ale unghiului intern cu 39 (28,9%) cazuri au fost în majoritate carcinoame bazocelulare cu stadiu evolutiv de la ulcerație la tumora vegetantă, cu sau fără infiltrație locală (fig. 2).

Tratamentul leziunilor necomplicate s-au realizat în majoritatea cazurilor prin excizia leziunii şi sutura tegumentară. Plastiile locale s-au impus ca urmare a dimensiunilor tumorale sau pentru un aspect cicatricial mai bun din punt de vedere estetic. Defectele postexcizionale estimate în cazul tumorilor complicate cu caractere clinice clare de malignitateau fost preponderent de dimensiuni ce depaşesc 1,5 cm diametru. Acest aspect corelat cu condițiile regionale justifică complexitatea reconstrucției (11, 12) (fig. 3).

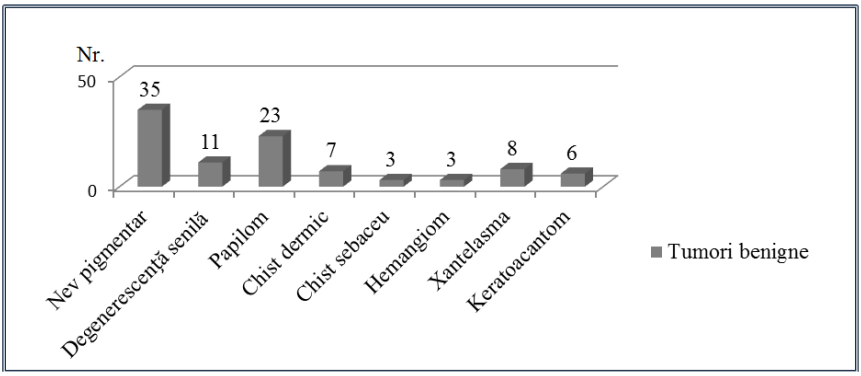

Fig. 1. Frecvența tumorilor benigne ale ariei unghiului intern la pacienții incluşi în studiu

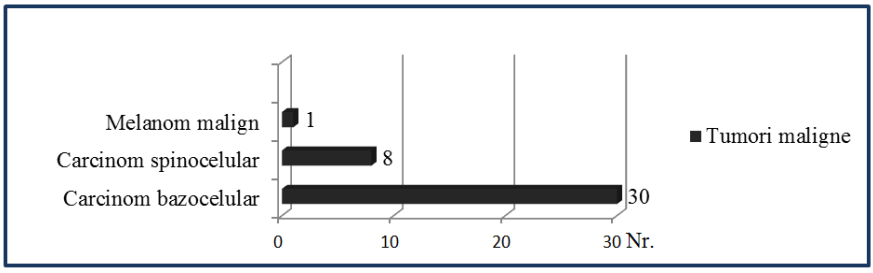

Fig. 2. Frecvența tumorilor maligne ale ariei unghiului intern la pacienții incluşi în studiu

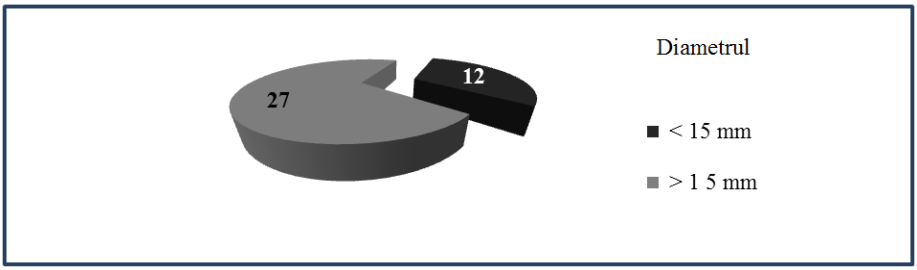

Fig. 3 Evaluarea comparativă a dimensiunilor defectelor de țesut după excizie, la pacienții incluşi în studiu

Planingul tratamentului în cazul leziunilor tumorale complicate a avut în vedere dimensiunea tumorală, corelată cu estimarea clinică a invaziei locale. În afară de aceste aspecte s-a ținut cont de capacitatea de reconstrucție şi de factorul estetic şi importanța acestuia pentru pacient (13) (tab. I).

TABELUL I

Abordul chirurgical al unghiului intern în realție cu dimensiunea tumorii

Tehnica	Marimea defectului		
	Mic (<5mm)	Mediu (5-10mm)	Mare (>10mm)
Sutură primară	X		
Sutură primară + cantotomie	X	X	
Sutură primară + cantotomie + cantoliză		X	
Sutură primară + cantotomie + cantoliză + lambou de veciatate		X	X
Grefă tarso-conjunctivală + lambou tegumentar		X	X
Grefă tarso-conjunctivală + grefă de piele		X	X
Grefă marginală compozită + grefă de piele		X	X
Lambou tarsoconjunctival + grefă de piele			X
Grefa compozită + lambou facial			X

În raport cu grupele de vârstă am utilizat grefa de piele liberă la pacienții cu vârsta de peste 65 ani, însă distribuția cazurilor în cadrul acestei perioade, nu prezintă diferențe semnificative comparativ cu practicarea lamboului de vecinătate (χ^2=7,96; GL=5; p=0,158) sau a celui pediculat (χ^2=5,46; GL=2; p=0,065) practicat numai la pacienți cu vârsta cuprinsă între 45-64 ani (fig. 4).

Reconstrucțiile postexcizionale au necesitat reinserția ligamentului intern în două cazuri, în care invazia tumorală interesa această structură, iar după retracția

lamboului refacerea unghiului intern a impus reconstrucția ligamentului intern. Proceduri de reconstrucție asociate sau practicat la un număr redus de pacienți (χ^2=48,18; GL=1; p<0,001).

Tumorile ce depășec dimensiuni de 10 mm, în contextul regiomal, pot fi asociate chiar în cazul celor benigne cu rezultate funcționale modeste (tab. II).

Planificarea reconstrucției necesită să includerea inițială a unor variante în relație cu dimensiunile şi profunzimea exciziei şi care vor fi adaptate la necesitățile operatorii.

Urmărirea unor rezultate cu caracteristici funcționale şi estetice cît mai bune a dus la modificarea unor tehnici clasice, care şi-au confirmat utilitatea în cadrul studiului (14, 15).

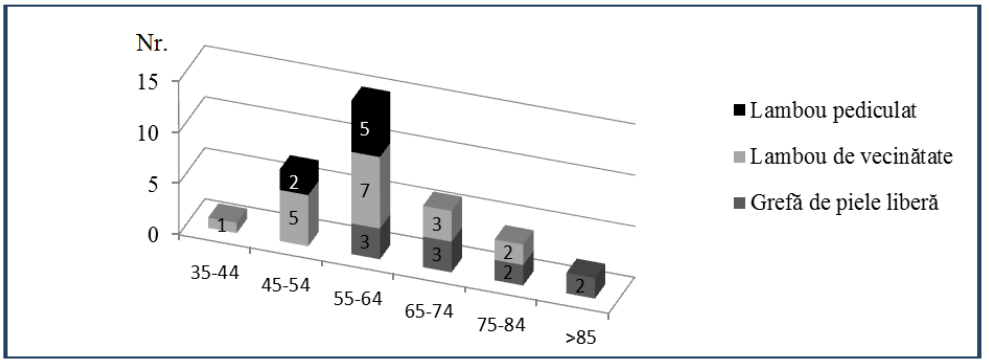

Fig. 4. Repartiția pe grupuri de vârstă a metodelor tratamentului chirurgical al tumorilor complicate

TABELUL II

Evaluări asupra rezultatelor tratamentelor chirurgicale

Tipul tumoral	Dimensiunile formațiunii (mm)	Tipul de recondtrucție	Rezultate cicatriciale	Rezultate functionale
Tumori benigne	<5	sutură	+++	+++
	5-10	plastie locală	+++	+++
	>10	plastie locală	+++	+
Epiteliom bazocelular	<5	plastie locală	+++	++
	5-10	lambou vecinătate	++	+/-
	>10	grefa de piele, lambou pediculat, alt lambou	+/-	+/-
Epiteliom spinocelular	<5	grefa de piele, lambou vecinătate	++	+
	5-10	grefa de piele, lambou pediculat	+	+/-
	>10	lambou pediculat, alt lambou	+/-	-

Dimensiunile exciziilor tumorale mai mici de 5 mm au fost abordate prin suturi directe sau plastii cu lambouri încrucişate în relație cu poziționarea acestora : localizările la distanță de carunculă – sutură directă sau localizările din preajma caruncu-lei – plastie cu lambouri.

In leziunile cu dimensiuni cuprinse între 5 - 10 mm, diametrul exciziei, a fost utilizată pentru acoperirea defectului grefa de piele (daca excizia nu interesa toate planurile până la cel osos).

Practicarea lamboului frontal a constituit a doua obțiune pentru cura reconstructivă a defectelor cu dimensiuni mai mari de 5 mm, acesta având o mobilitate mare dar şi posibilitatea ajustării în funcție de defectul postexcizional. Refacerea este grevată totuşi de grosimea tegumentului frontal (tab. III) (fig. 6).

TABELUL III

Reprezentarea schematică a rezultatelor

Marimea defectului (mm)	**Metoda**	**Nr.**	**Rezultate funcțional - estetice**
> 15	Transfer liber	0	+
	Lambouri pediculate	9	+
	Grefe de piele	26	++
<15	Lambouri de rotație	11	+++
	Lambouri triunghiulare	29	+++
	Lambouri de avansare	17	++++
	Aproximare directă	43	+++++

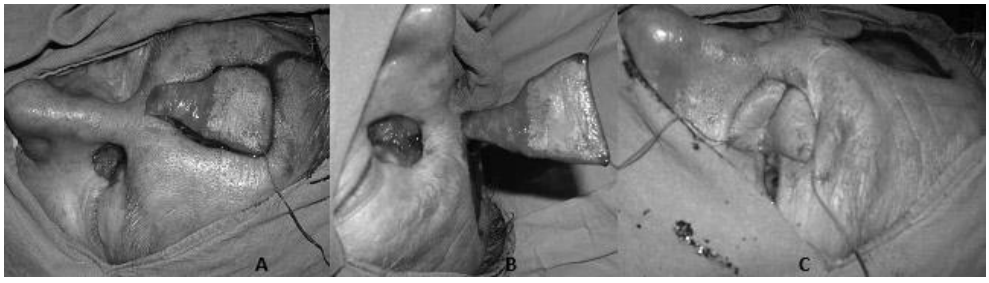

Fig. 6. Etapele operatorii cu lambou frontal dezepidermizat pentru unghiului intern

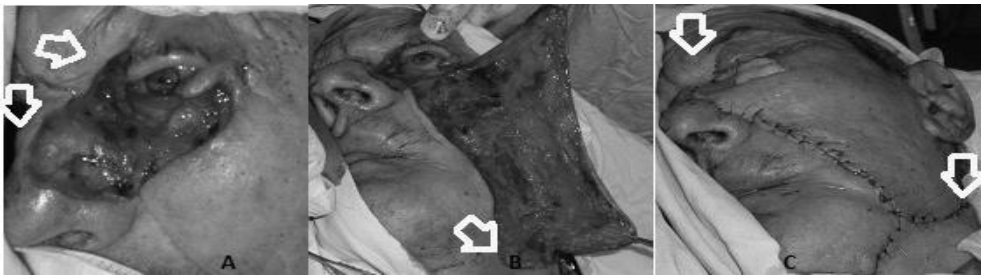

Fig. 7. Etapele operatorii cu lambou cervico-facial pentru tratamentul unui defect important al unghiului intern al ochiului

Pentru leziunile cu dimensiuni mai mari de 10 mm trebuie folosite lambouri care sa aducă un surlus de țesut, dar care să asigure şi o refacere de calitate a regiunii orbitare (fig. 7).

CONCLUZII

Analiza comparativă mai multor metode a permis aprecierea orientării spre alegerea unui tratament eficient al tumorilor de unghi intern al ochiului.

Planul operator a fost specific pentru fiecare formațiune tumorală în parte, necesitând de multe ori colaborarea între oftalmolog şi chirurgul plastician, dar şi cu chirurgul maxilo-facial sau chiar neurochirurgul.

Rezultatele cercetărilor pledează pentru abordarea formațiunii tumorale în mod radical, excizia completă a formațiunii trebuind certificată intraoperator, deoarece recidivele tumorale la acest nivel sunt urmate de cele mai multe ori de operații complexe, cu efect important asupra fizionomiei şi psihicului pacientului.

Abordarea chirurgicală după un plan prestabilit, cu variante posibile conferă siguranță în tratamentul tumorilor de la nivelul ariei unghiului intern al ochiului, iar lucrarea de față sugerează varianta optimă de planing al operației, constituindu-se ca un ghid succint de orientare preoperatorie.

SINONASAL HEADACHE – REALITY OR MIS-DIAGNOSIS? (Abstract): Facial pain can be the presenting, and sometimes the only, complaint of many disorders that originate from cranial structures. One causes of facial pain/headache is sinusitis, in both its acute and its chronic presentation. Successful management of headache is preceded by the identification of an etiology and precise diagnosis. **Material and methods**: A prospective study was carried out on a series of 71 patients treated in the ENT Department of Iasi "Sf. Spiridon" Hospital between January and august 2009 for pathology implying facial pain, headache, facial pressure, nasal obstruction, rhynoreea. The therapy was medical and surgical and pursued nasal desobstruction, sinusal drainage and ventilation. Data regarding different parameters were analyzed pre and post therapy. **Results:** After the proper treatment for each situation, the parameters analyzed improved significantly, although, in some cases the main accuses regarding the pain remained unchanged or slightly ameliorated. **Conclusions**: Depending on the clinical suspicion of the possible etiologies of facial pain and headache, the appropriate consultations should be made. For concerns of head and neck lesions or sinus-related headache, an otolaryngologist should be consulted. If a primary headache syndrome or a cranial neuralgia is of concern, the patient should be evaluated by a neurologist. Dentists and oral surgeons should be involved. In some cases, a psychiatry referral is appropriate. The surgical treatment can be effective if the pathology meets the criteria of sinonasal facial pain. **Key words**: SINUS-RELATED FACIAL PAIN, CHRONIC SINUSITIS, HEADACHE, NASAL ENDOSCOPY

Durerea este un simptom frecvent întâlnit în cadul afecţiunilor rinosinusale, datorită inervaţiei bogate senzitive şi vegetative a foselor nazale şi a anexelor acestora. Cefaleea este o durere situată deasupra liniei orbito-meatale iar o durere facială, inferior acesteia. Există numeroşi pacienţi cu cefalee sau durere facială ce consideră această suferinţă datorată unei sinuzite, diagnostic stabilit de ei-înşişi sau chiar de catre un medic (1) .

Cefaleea de origine rinosinusală se poate împarţi în două categorii:

- algiile simptomatice ale unei sinuzite, cu un diagnostic în general simplu,
- algiile fară sinuzită, mai dificil de diagnosticat, fiind considerate rezultatul unui dezechilibru trigemino-simpatic.

Cefaleea de cauză nazală suscită în continuare vii controverse. În cazul unui sindrom cefalalgic rino-sinusal, trebuie analizate cele trei mari mecanisme fiziopatolo-

gice de durere: durerea prin exces de nociceptie, durerea neurogenă şi durerea psihogenă. Recunoaşterea lor va orienta conduita terapeutică, dar nu de puţine ori, putem întâlni asocierea acestora (2).

Tegumentul jumătăţii superioare a piramidei nazale este inervat de nervii supratrohleari şi infratrohleari din ramului oftalmic al trigemenului, iar tegumentul jumătăţii inferioare de nervul infraorbitar, ram al nervului maxilar din trigemen.

Mucoasa nazală primeşte o inervaţie bogată din nervul oftalmic (V1), nervul maxilar (V2). Acesta din urmă este strâns conectat cu ganglionul neurovegetativ pterigo-palatin. Inervaţia sinusului maxilar este dependentă de ramuri ce provin din nervul maxilar: nervul mare palatin, nervul nazal, nervul infraorbitar. Celulele etmoidale anterioare sunt inervate de nervul etmoidal anterior, cele posterioare şi sfenoidul de nervul etmoidal posterior şi ramuri din sfenopalatin. Sinusul frontal primeşte o inervaţie din nervul supraorbitar, ram din oftalmic (V1).

Un stimul electric, chimic sau mecanic la nivelul mucoasei rinosinusale declanşează o durere locală şi/sau reflectată (iradiată). Zonele cele mai sensibile sunt cornetele nazale, ostiumurile sinusale, septul, canalul nazo-frontal. Mucoasa sinusală este puţin sensibilă. Cornetul inferior proiectează durerea la arcada dentară maxilară, procesul zigomatic, regiunea orbitară, cornetul mijlociu iradiază durerea spre regiunea temporo-zigomatică, ochi, frunte. Fenomenul de convergenţă a aferenţelor nociceptive trigeminale la nivelul cortexului senzitiv explică non-discriminarea senzorială între tegumentul şi mucoasa rino-sinusală (3) .

Durerea din sinuzită este binecunoscută, sinuzitele sunt acute sau cronice, limitate la un sinus sau la mai multe, infecţioase propriu-zise sau de însoţire a unui proces tumoral. Examenul clinic, endoscopic şi imagistic pun diagnosticul şi ghideaza atitudinea terapeutică. Tratamentul acestor dureri rinosinusale se suprapune cu tratamentul etiologic al afecţiunii declanşatoare, al sinuzitei. În toate cazurile, examenul endoscopic şi imagistic al nasului şi sinusurilor paranazale trebuie să elimine o patologie rinosinusală subjacentă.

Sechelele dureroase ale sinuzitelor operate - Traumatismul nervos periferic reprezintă principala cauză a sechelelor dureroase postoperatorii. Sinusul maxilar este cel mai frecvent implicat, cel mai rar sinusul frontal şi etmoidal. Durerea este de tip ”neuro-vascular” asociată unei afectari nervoase a nervului infraorbitar sau a ramurilor sale şi are un complex de manifestări vasomotorii şi secretorii foarte bogate: rinoree, lăcrimare abundentă, eritem şi edem cutanat. Algia evoluează în pusee, declanşată de variaţiile de temperatură, de stimularea mecanică a nervului. Tratamentul acestui tip de patologie dureroasă este în primul rând preventiv, în cursul intervenţiei chirurgicale iniţiale. Tratamentul curativ este dificil, având în vedere mecanismul neurogen al durerii şi constă în tratamentul cu antidepresive, antiepileptice, blocuri de ram nervos (6).

Cefaleea de ”vacum sinus” a lui Sluder (1927) - Este cauzată de obstrucţia mecanică aseptică a infundibulului frontal ducând la o hipopresiune dureroasă a sinusului frontal cu un edem secundar al mucoasei. Durerea orbito-frontală determinată de acest sinus este exacerbată de efortul de acomodare la citire. Restabilirea ventilaţiei sinusale face se dispară simptomatologia. Barotramatismul sinusului frontal este de doua ori mai frecvent decât al sinusului maxilar. Examenul imagistic confirma

hiperplazia in cadran a mucoasei sau epanşamentul intrasinusal sero-mucos sau serohematic.

Cefaleea din ageneziile sinusale (sinus frontal sau sinus maxilar) - Se caracterizează prin durere surdă, foarte rar intensă, cateodată asociată cu manifestari vasomotorii oculare. În realitate, maformaţia sinusală nu explică de una singură sindromul dureros, având în vedere frecvenţa ageneziilor sinusale asimptomatice, mai ales frontale descoperite imagistic (7).

Sindroml de ganglion pterigo-palatin al lui Sluder (1908) - În acest sindrom apare o durere paroxistică la rădăcina nasului şi periorbitar, unilaterală, iradiind catre mastoidă şi ceafă. Această durere se asociază cu manifestari vaso-secretorii: congestie nazală, strănut, lăcrimare, eritem hemifacial, senzaţie de plenitudine auriculară.

Anestezia pe cale endonazală sau infiltrarea ganglionului pterigopalatin cu xilocaina prin canalul palatin posterior pe cale transpalatină fac sa dispara simptomatologia. Acestă patologie se aseamană cu sindromul de nerv vidian al lui Vail.

Sindromul nervului nazal al lui Charlin - Acest sindrom este responsabil de dureri paroxistice la nivelul aripii nazale şi periorbitare, unilaterale asociate de manifestări vaso-secretorii: rinoree abndentă, strănut, lăcrimare, hiperemie palpebrală şi conjunctivală. Examenul clinic evidenţiază sensibilitatea ramurilor terminale ale nervului naso-ciliar. Anestezia capului cornetului mijlociu face sa dispara simptomatologia (2).

Aceste sindroame istorice ale lui Sluder şi Charlin sunt acum asimilate algiei vasculare a feţei (8).

Cefaleea "nazală" - De la începutul secolului, numeroase algii cranio-faciale fară cauză organică propriu-zisă cum sunt migrena şi cefaleea de tensiune, au fost considerate a avea o cauză nazală oligosimptomatică. Au fost incriminate deviaţiile septale, nasul ingust, hipertrofiile de cornete, sinuzitele posterioare latente etc. Multiple manevre chirurgicale cu viză antalgică au fost efectuate de rinologi intre anii 1940-1950. De aproape 30 de ani, cea mai mare parte a acestor intervenţii au fost privite cu neîncredere fiind considerate abuzive, chiar nefaste. În prezent, răspandirea examenului endoscopic, a imagisticii CT si IRM rinosinusale, progresul neurochimiei au permis reconsiderarea acestor algii aşa zise "nazale" (9,10) .

Diferite modificări anatomice ale cavităţilor rinosinusale au fost descrise: un contact mucos între cornetul nazal superior sau mijlociu şi septul nazal, o deviaţie de sept cu o creastă septală, o concha bulosa mai voluminoasă, un mucocel, dehiscenţa intrasinusală a nervului oftalmic. Aceste anomalii sunt luate în considerare dacă sunt de aceeaşi parte cu durerea craniofacială (11,12).

MATERIAL ŞI METODĂ

Am evaluat un numar de 71 de pacienţi internaţi în Clinica ORL a Spitalului "Sf. Spiridon" Iaşi în perioada ianuarie-august 2010 pentru investigaţii şi tratament privind o patologie rinosinusală însoţită de cefalee, durere cranio-facială, senzaţie de presiune facială.

La examenul clinic se evidenţiază următoarea patologie rinosinusală asociată sau factori favorizanţi (fig. 1): deviaţie sept nazal, rinită cronică hipertrofică, polipoză nazală, focare infecţioase dentare.

Dintre cele mai importante acuze remarcăm durerea spontană, senzaţia de presiune facială, obstrucţia nazală, cefaleea, rinoreea anterioară sau posterioară.

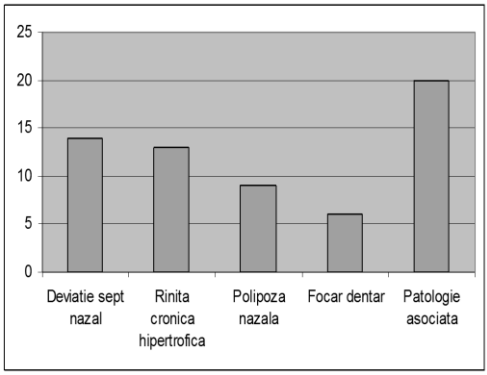

Fig. 1. Patologie asociată şi factori favorizanţi

Dintre investigaţiile imagistice, au fost disponibile radiografiile de sinusuri anterioare ale feţei, examene computer tomografice cu sau fără substanţă de contrast, investigaţii de imagistică prin rezonanţă magnetică. Pe aceste investigaţii s-au urmărit modificările anatomice şi patologice: deviaţii de sept nazal, creste septale, hipertrofii de cornete, puncte de contact osoase şi mucoase, voalarea sau opacifierea cavităţilor sinusale, prezenţa nivelului de lichid etc.

Mijloacele terapeutice au constat în tratament medicamentos, chirurgical sau combinat. Clasele de medicamente administrate au fost antibiotice, antiinflamatorii steroidiene şi nesteroidiene, antalgicele, vasoconstrictoarele nazale, corticoterapie topică nazală.

Tratamentul chirurgical a urmărit obstrucţia nazală, drenajul şi lavajul sinusurilor cu colecţii mucopurulente, cura radicală a sinusurilor afectate. Dintre intervenţii, au fost efectuate rezecţii subpericondromucoase ale septului nazal, septoplastii, mucotomii, cauterizari laser sau elecrocauterizări ale cornetelor nazale inferioare, excizia de concha bulosa, antrostomia maxilară intranazală, cura radicală a sinuzitei maxilare prin procedeul Caldwel-Luc, etmoidectomia anterioară.

În general pacienţii ce au suferit intervenţii chirurgicale au fost tamponaţi nazal pentru 24-48h sub protecţie antibiotică şi antalgice. Au revenit în clinică pe perioade de 7-10 zile pentru defibrinarea foselor nazale, panasamente, anemizari.

Vindecarea locală s-a obţinut la 14-20 zile postoperator constând în diminuarea zonelor denudate de mucoasă, dispariţia crustelor şi a secreţiilor seromucoase, dispariţia senzaţiei de obstrucţie nazală.

REZULTATE

Vom urmări în următoarele grafice evoluţia simptomatologiei comparativ pre şi postterapeutic.

Se observă diminuarea numărului de pacienţi ce acuzau durere facială precum şi scăderea severităţii acesteia (fig. 2).

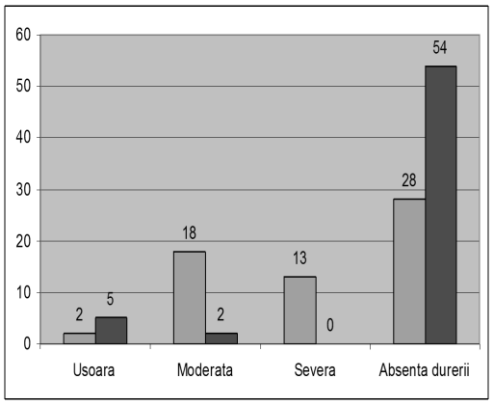

Fig. 2. Evoluţia durerii sub tratament

Senzaţia de presiune facială se diminuează semnificativ la marea majoritate a pacienţilor (fig. 3).

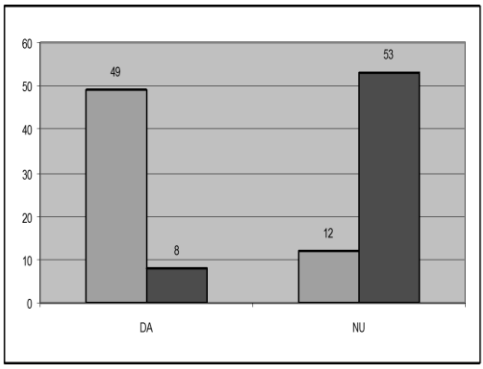

Fig. 3. Evoluţia senzaţiei de presiune facială

Postterapeutic, obstrucţia nazală a dispărut la marea majoritate a pacienţilor (fig. 4).

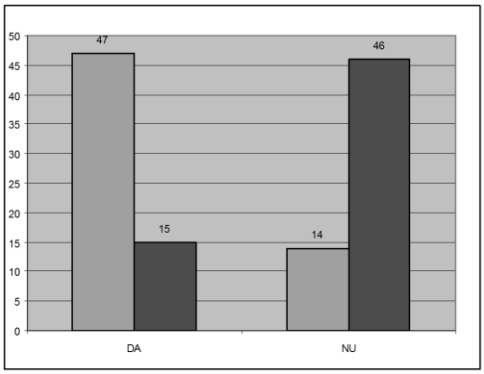

Fig. 4. Evoluţia obstrucţiei nazale sub tratament

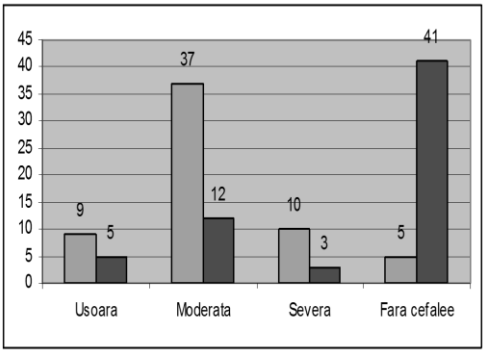

Fig. 5. Evoluţia cefaleei sub tratament

De asemenea s-a modificat semnificativ numarul pacienţilor ce sufereau de cefalee, la cei la care aceasta persistă scăzând în intensitate şi frecvenţă (fig. 5).

Un alt parametru evaluat a fost rinoreea, care în lotul studiat a fost iniţial prezentă la 65,57% din cazuri, iar postterapeutic s-a diminuat pâna la 22,95%.

DISCUŢII

Tarabichi raportează un studiu efectuat pe 82 de pacienţi operaţi pe cale endoscopică de sinuzită cronică asociată cu durere cranio-facială. Dupa un an de la operaţie, 38% din pacienţi acuzau în continuare durere deşi nu mai exista nici un tip de sinuzită; de asemenea, nu s-a putut stabili nicio corelaţie între severitatea durerii şi extensia sau localizarea afectarii rinosinusale preoperatorii. Autorii au concluzionat ca cefalalgiile non-sinusale trebuie luate în considerare la aproximativ o treime din pacienţii operaţi pentru sinuzită (4). O anamneză preoperatorie riguroasă trebuie să precizeze tipul durerii, topografia, factorii declanşatori, semnele asociate nazale, oculare, digestive. O cauză frecventă de cefalee (migrena, cefaleea de tensiune) nu exclude coexistenţa altui tip de cefalee.

În 1988, M. Stammberger a postulat că un contact mucos endonazal poate fi responsabil de cefalee prin intermediul secreţiei locale a unui neuropeptid, substanţa P. Stimularea mecanică, chimică, termică a fibrelor C ale nervului oftalmic sau a nervului maxilar determină eliberarea de diverse neuropeptide cum ar fi substanţa P, dar şi calcitonin-gene-related-peptide (CGRP) sau neurokinina A. Ramurile colaterale ale trigemenului, mai ales nervul oftalmic, ce inerveaza de asemenea meningele precum şi vasele sangvine intracraniene constituie sistemul ”trigemino-vascular” al lui Moskowitz.

Neuropeptidele algogene produse de fibrele nervoase trigeminale sunt la originea unei vasodilataţii, a unei extravazări plasmatice prcum şi a unei infiltrări plasmocitare. Acest mecanism fiziopatologic neuro-vascular este de asemenea incriminat in migrena şi algiile vasculare ale feţei (13).

Aplicarea locală sub control endoscopic a unui amestec de tetracaină 2% şi efedrină 1% pe zonele de conflict mucos pot determina ameliorarea sau dispariţia durerii. În acest caz, un tratatment chirurgical corector poate fi recomandat. Aplicarea mucoasă de capsaicină se poate efectua pentru a realiza o desensibilizare a receptorilor substanţei P şi degenerarea fibrelor C nociceptive aferente, fară modificarea sensibilitaţii mucoasei nazale. Tratamentul local cu capsaicină poate reduce durerea şi efectele vasculare ale aplicarii pe mucoasă de acid lactic sau de ser salin hiperton.

Indicaţia operatorie a fost aşadar propusă la adultul sau copilul care îndeplinea un anumit numar de criterii:

- cefaleea a fost tratată de un neurolog şi nu s-a ameliorat prin terapie medicală,
- nu există semne de sinuzită propriu-zisă decelabilă prin examen endoscopic sau imagistic,
- endoscopia şi imagistica pun în evidenţă un contact mucos de aceeaşi parte cu dureea,
- cefaleea dispare sau se ameliorează după aplicaţia topică a unui anestezic local pe zona de conflict mucos.

Intervenţia chirurgicală sub control endoscopic corectează anomalia anatomică decelată: turbinectomie sau turbinoplastie, septoplastie, etmoidectomie anterioară etc. Corticoterapia locală se poate prescrie postoperator dacă fenomenele inflamatorii asociate sunt importante (14).

Rezultatele apreciate cu ajutorul Scalei Analogice Vizuale (VAS) nu evidenţiază diferenţe semnificative pe vârste, sexe, tip de durere, vechimea acesteia, manevra chirurgicală efectuată. Dispariţia durerii sau scăderea frecvenţei de apariţie au fost înregistrate între 78 si 91% din cazuri la 12 luni.

Această ipoteză fiziopatologică a contactului mucos endonazal ce generează cefalee ramane controvesată. Un studiu recent al lui D. West a fost efectuat pe 101 pacienţi ce au fost consultaţi ORL pentru durere cranio-facială fară nici un semn obiectiv de sinuzita (endoscopic si CT). Studiul clinic a permis clasificarea durerilor faciale într-un cadru neurologic clar definit de Societatea Internaţională de Cefalee cu excepţia durerii de segment mijlociu al feţei ce aparţine cefaleei de tensiune. La majoritatea pacienţilor s-a ameliorat simptomatologia la administrarea de doze mici de Amitriptilină (10 mg/zi pe parcurs de 6 săptamâni). În caz de eşec s-a administrat Carbamazepina sau Propranolol. Nici un pacient nu a fost operat de vre-un contact mucos.[15,16]

CONCLUZII

Durerea facială şi cefaleea reprezintă unele din cele mai frecvente acuze ce aduc pacienţii în cabinetul ORL. Foarte puţini pacienţi ce se prezintă la medic cu diagnosticul iniţial de sinuzită, chiar au sinuzita.

Pacienţii ce au cu adevarat sinuzită, însoţită de semne şi simptome nazale, examen endoscopic şi imagistic concludent pot fi trataţi eficient obţinându-se o rată crescută de succes cu diminuarea pâna la dispariţie a simptomatologiei.

Datorită progresului mijloacelor de investigaţie imagistică precum şi a disponibilităţii tot mai mari a examenului endoscopic nazal, pacienţii pot fi mai corect diagnosticaţi şi se poate face o selecţie mai

corectă a cazurilor ce necesită tratament chirurgical.

Tratamentul chirurgical ar trebui să ramană ultima soluţie terapeutică după efectuarea unor consultaţii interdisciplinare oftalmologice şi neurologice. Cazurile ce vor urma un tratament chirurgical trebuie atent selecţionate pentru a întruni cât mai multe criterii ce indică faptul ca sindromul cefalalgic este de cauza rinosinusală.

Chiar şi în aceste condiţii, un procent însemnat de pacienţi trataţi chirurgical nu prezintă dispariţia simptomatologiei sau ameliorarea semnificativă a acesteia.

ASSESSMENT OF VISUAL FUNCTION UNDER TREATMENT WITH TOPICAL ANTI-GLAUCOMA AGENTS AND SYSTEMIC VASODILATORS. CLINICAL STUDY ON GLAUCOMA PATIENTS (Abstract)**:** The authors present some observations regarding the use of topical anti-glaucoma therapy and systemic vasodilators. **Material and methods**: The study was carried out on a series of 996 glaucoma patients, of which 54.1% with primary open-angle glaucoma, 5.7% closed-angle glaucoma, and 17.6% with normal intraocular pressure. **Results**: Intraocular pressure and visual field were assessed after the use of such therapeutic methods as carbonic anhydrase inhibitors (dorzolamide) and prostaglandin (latanoprost) and dorzolamide (cosopt) association. **Conclusions**: The favorable progression of glaucoma could be improved by using new etiopathogenic mechanisms and treatment approaches. **Key words**: OPEN-ANGLE GLAUCOMA, ANGLE-CLOSURE GLAUCOMA, RETINAL CIRCULATION, TOPICAL THERAPY

Neuropatia glaucomatoasă este un răspuns la acțiunea factorilor de risc primar, interacționând cu cei secundari, între care şi predispoziția genetică, dar nivelul presiunii intraoculare (PIO) este factorul principal în inducerea neuropatiei optice (NO). Indiferent dacă NO, la om, este urmarea patologiei scurgerii trabeculare în glaucomul primar cu unghi deschis (GPUD) sau a celor secundare (GS) ori are o bază genetică, iar la animalele vertebrate (iepure, câine, şoarece, şobolan sau maimuță) este indusă experimental, PIO crescută determină o afectare a retinei. S-a confirmat şi posibilitatea ca o PIO scăzută, să determine o progresie mai lentă a modificărilor glaucomatoase.

La pacienții cu glaucom cu tensiune normală (GTN), factorii de risc primar pot fi reprezentați de modificările hemodinamice cronice, localizate în microcirculația oftalmică. Aceşti factori lezează, în principal, celulele ganglionare retiniene (CGR) şi axonii lor localizați în zone unde vascularizația este limitată, cum ar fi retina şi capul

nervului optic (microvascularizația *laminei cribrosa*).

Localizarea patologiei microvasculare în subregiuni de la nivelul capului nervului optic explică afectarea focală a CGR şi subțierea fibrelor nervoase, inițiind neuropatia optică glaucomatoasă, cu interes în cunoaşterea modelelor pentru dezvoltarea agenților neuroprotectori în glaucom (1, 2, 3, 4).

MATERIAL ŞI METODE

Studiul efectuat în Clinica a II-a Oftalmologie, Spitalul Clinic „Prof. Dr. N. Oblu", pe un număr de 8118 pacienți, internați în perioada 2006-2010, împărțiți în 2 loturi, cel tratat pentru afecțiuni generale oftalmologice (7122 cazuri: 87,7%), celălalt format din 996 (12,3%) pacienți cu glaucom, şi subîmpărțiți în relație cu forma clinică: 539 (54,1%) cu GPUD; 225 (22,6%) cu GTN; 57 (5,7%) glaucom primar cu unghi închis (GPUI) şi 175 (17,6%) cu GS.

Pentru studiul comparativ al efectelor neuroprotectoare a diferitelor programe terapeutice utilizate, pacienții cu GPUD şi GTN au fost împărțiți în 3 loturi: unul martor, cu pacienți care nu au primit medicație neuroprotectoare, fiind tratați prin scăderea PIO; al doilea care a primit medicație topică, certificată şi de alte studii (1, 2) ca având acțiune neuroprotectoare şi al treilea care a primit medicația locală pentru scăderea PIO, asociată cu una cu acțiune generală.

Cei 764 (76,7%) pacienți cu GPUD şi GTN au fost studiați în relație cu aspectul câmpului vizual la prima vizită (pierdere incipientă, medie şi avansată), conform Ghidului European de Glaucom (1, 2), constatându-se că 268 (35%) aveau o pierdere incipientă de câmp vizual, 442 (57,8%) - moderată şi 54 (7%) - avansată.

Dintre pacienții cu afectare incipientă, 165 (61,6%) au fost împărțiți în 3 subloturi, cu câte 55 (33,3%) pacienți care au fost informați asupra tratamentului ce li se va efectua, precum şi asupra efectelor adverse şi termenelor la care se va face evaluarea.

REZULTATE ŞI DISCUȚII

1. Evaluări asupra evoluției PIO medii. Pentru a vedea efectul asupra funcției vizuale (CV) al medicației administrate am inclus în studiu numai pacienții cu pierdere glaucomatoasă incipientă, evaluați în decurs de 1 an. Câmpurile vizuale au fost analizate la 6 luni, concomitent cu înregistrarea valorilor PIO (2).

La prima prezentare, examinarea pacienților a inclus: PIO (curbă nictemerală), examenul complet al polului anterior şi al celui posterior, perimetria computerizată statică, simțul cromatic, pahimetrie, OCT). De asemenea, s-au realizat investigații privind patologia asociată (diabet zaharat, hipertensiune arterială, ateroscleroză) şi factori de risc corelați (vasospasm, lipidemie).

Inițial, PIO a avut valori semnificativ crescute. Curba nictemerală a fost evaluată cu ajutorul unui aplanotonometru Goldmann, pe parcursul a 24 ore, la intervale fixe. Curba inițială a fost efectuată pentru a se determina profilul tensional nictemeral, iar orele de măsurare a PIO au fost standardizate: 9, 12, 15, 18, 21, 24 şi 6. În funcție de curba nictemerală, s-a calculat presiunea medie, valorile extreme şi diferența între acestea (variațiile tensionale nictemerale). La şase luni s-a repetat curba nictemerală la aceleaşi intervale orare. Valorile PIO au fost corectate în funcție de grosimea corneei centrale, după ecuația Herndon (Alcon Ocuscan RXP®). Lotul martor, format din 55 pacienți, a avut media tensiunii 24,11±2,65 mm Hg (tab. I).

TABELUL I

Evoluția presiunii intraoculare medii în intervalul orar, la prima internare şi la 6 luni (lotul martor)

	Orele							Media
	9	**12**	**15**	**18**	**21**	**24**	**6**	
PIO medie	25,02	25,65	25,07	23,96	22,82	22,47	23,80	24,11
DS	4,49	3,06	2,43	2,62	2,60	2,93	3,81	2,65
PIO medie	**16,19**	**16,68**	**16,30**	**15,58**	**14,83**	**14,61**	**15,47**	**15,66**
DS	**2,78**	**1,99**	**1,58**	**1,71**	**1,69**	**1,90**	**2,47**	**1,70**
Scăderea PIO (%)	35,29	34,97	34,98	34,97	35,01	34,98	35	35,05

2. Aspecte privind eficiența unor programe terapeutice. Tratamentul cu diverse topice antiglaucomatoase a determinat o scădere semnificativă a PIO ($p=6,85*10^{-38}$), valori aflate sub nivelul țintă, calculat individual pentru pacienții incluși în studiu, presiunea țintă fiind considerată cea maximă calculată după inițierea tratamentului, care determină încetinirea evoluției glaucomului.

Tratamentul cu topice antiglaucomatoase a inclus inhibitori ai anhidrazei carbonice (IAC), cum este dorzolamida care, similar cu ceilalți IAC, acționează asupra fluxului sangvin ocular, cu efect considerat neuroprotector (3, 4). Unele studii (1, 2, 3, 4) sugerează că modificările glaucomatoase pot apărea şi din cauza reducerii fluxului sangvin la nivelul nervului optic, iar IAC sistemici determină vasodilatația, această observație stând la aprecierea de rutină a rezervei de perfuzie cerebrală. Mecanismul poate fi în parte legat de cascada retenției CO_2 cu oxidul nitric şi Ca^{+2}, cu blocarea calciului (5). Inhibitorii anhidrazei carbonice ar putea creşte fluxul sangvin la nivelul retinei şi a nervului optic, având implicații în reducerea ischemiei în glaucomul acut, retinopatia diabetică şi alte boli vasculare (6). Atât brinzolamida cât şi dorzolamida ajung în concentrații suficiente pentru a dilata vasele retiniene. Un studiu realizat de Harris et al. (7) a sugerat că dorzolamida poate creşte viteza fluxului retinian fără să afecteze parametrii retrobulbari; acelaşi studiu a arătat o creştere a sensibilității la contrast după o lună de tratament cu dorzolamidă topică. Un studiu pe şobolani glaucomatoşi sugerează că dorzolamida poate avea proprietăți neuroprotectoare, dar nu este clar dacă rezultatele apar prin scăderea PIO sau este un efect independent de aceasta (8, 9).

Al doilea grup a fost tratat cu dorzolamidă, în asociere cu o prostaglandină sau în combinație fixă: dorzolamidă cu timolol 0,5% (Cosopt). PIO medie inițială a fost 24,73±2,78 mm Hg (tab. II).

TABELUL II

Evoluția presiunii intraoculare medii în intervalul orar, la prima internare şi la 6 luni
(al doilea grup tratat cu dorzolamidă, în asociere cu o prostaglandină sau în combinație fixă)

	Orele							Media
	9	**12**	**15**	**18**	**21**	**24**	**6**	
PIO medie	25,49	26,11	25,75	24,73	23,49	23,18	24,35	24,73
DS	4,51	3,14	2,74	2,72	2,73	3,04	3,75	2,78
PIO medie	**16,60**	**17,15**	**17,02**	**16,71**	**17,04**	**16,55**	**17,02**	**16,87**
DS	**1,86**	**1,54**	**1,67**	**1,86**	**1,50**	**1,74**	**1,82**	**0,6**
Scăderea PIO (%)	34,88	34,33	33,90	32,43	27,48	28,63	30,10	34,88

S-a observat o scădere medie semnificativă a PIO la 6 luni, cu o aplatizare a curbei, eficiența cea mai mare fiind înregistrată dimineața, atunci când PIO era inițial mai ridicată ($p=4,44*10^{-39}$).

Al treilea grup de pacienți a primit medicație locală cu topice antiglaucomatoase, asociată cu un vasodilatator cerebral (nicergolină 30 mg), administrat pe parcursul a 6 luni, cu acțiune asupra receptorilor alfa-adrenergici.

Nicergolina îmbunătățește fluxul sangvin, neurotransmiterea, metabolismul şi activitatea anti-oxidantă. Studii experimentale au arătat efectul hipotensor ocular, probabil prin stimularea transmiterii colinergice la nivel ocular (6, 10) (tab. III). S-a înregistrat o scădere semnificativ statistică a PIO la 6 luni ($p=2,43*10^{-41}$), ceea ce a însemnat pentru întregul lot o scădere medie de 31,79%.

TABELUL III

Evoluția presiunii intraoculare medii în intervalul orar, la prima internare şi la 6 luni (al treilea grup de pacienți a primit medicație locală cu topice antiglaucomatoase, asociată cu un vasodilatator cerebral)

	Orele							**Media**
	9	**12**	**15**	**18**	**21**	**24**	**6**	
PIO medie	25,89	26,13	25,60	24,55	23,64	23,40	24,65	24,84

Scăderea PIO (%)	34,62	34,59	33,59	29,85	29,00	29,06	31,19	31,79

*3. Unele rezultate asupra evoluției câmpului vizu*al. Inițial, s-au obținut două sau trei câmpuri vizuale, incluzând aria 24-2 standard şi perimetria în ax albastru – galben.

Într-o perioadă de 5 ani, au fost efectuate 21603 examinări de câmp vizual la 1637 pacienți dintre care 748 (45,67%) au fost anormale, iar 703 (43,0%) aveau indici corespunzători, dar la retestare anomaliile s-au evidențiat la 604 (85,9%). Pentru pacienții tratați cu topice antiglaucomatoase, fără a conține dorzolamidă, sensibilitatea medie a fost inițial de 33,9±1,29 dB iar după tratament a ajuns la 33,46±1,16 dB, cu o scădere de 0,44 dB, ceea ce arată că tratamentul topic a reuşit să încetinească evoluția bolii glaucomatoase, exprimată printr-o evoluție favorabilă a câmpului vizual (p=0,009).

La grupul tratat cu dorzolamidă, sensibilitatea medie inițială a fost 34,09±1,04dB iar după tratament, 34,35±0,89 dB, ceea ce a însemnat o creştere a sensibilității medii cu aproximativ 0,26 dB, rezultat care poate pune în discuție curba de învățare a analizei funcției vizuale sau modificarea sensibilității medii datorate creşterii fluxului sangvin ocular, atât la nivelul capului nervului optic, cât şi la cel retinian. Cum şi alți autori (3, 4) au implicat acest ultim mecanism ca fiind mai plauzibil, pacienții fiind selectați omogen, efectul ar fi trebuit să fie vizibil la toate grupurile incluse în studiu. Evoluția favorabilă a câmpului vizual a avut valori semnificative (p=0,044).

Grupul tratat cu nicergolină a avut o evoluție favorabilă semnificativă, de la 33,95± 0,99 dB înaintea tratamentului, la 34,46± 1,12 dB după acesta, deci o creştere de 0,51 dB (p=0,000525). Evoluția favorabilă poate fi explicată prin efectele nicergolinei asupra fluxului sangvin, urmat de scăderea directă a PIO sub acțiunea nicergolinei. Această evoluție a fost remarcată şi în alte cercetări (9, 10), unele folosind electrofiziologia retinia-

nă (PEV) ca metodă de explorare cantitativă.

CONCLUZII

Tratamentul diversificat al glaucomului a determinat scăderea semnificativă a PIO la fiecare din cele trei subgrupuri, totalizând 165 de pacienți cu GUD. Studiul a evidențiat că anumite programe terapeutice au determinat o evoluție mai lentă a degradării câmpului vizual, față de evoluția naturală acceptată de aproximativ 1 dB/an sau au indus o creştere a sensibilității medii, prin activarea altor mecanisme decât cele primare de scădere a PIO.

Studiul a arătat că deşi PIO a fost scăzută semnificativ, în proporții asemănătoare (35,05% la grupul 1; 34,88% la 2 şi 31,97% la al treilea), evoluția parametrilor a fost diferită, mai favorabilă la pacienții la care influența asupra fluxului sangvin ocular a fost mai mare. Răspunsul optim a fost constatat la pacienții tratați general cu nicergolină (-0,44 dB la grupul 1; 0,26 dB la 2 şi 0,51 dB la 3).

Rezultatele privind posibilitatea încetinirii evoluției nefavorabile a bolii glaucomatoase sunt obținute în variate studii clinice care au dovedit existența unor noi mecanisme etiopatogenice, precum şi noi orientări de tratament, unele acționând prin scăderea PIO, altele prin creşterea fluxului sangvin ocular.

HEPATOTOXICITY-CURRENT CONCEPTS AND MECHANISMS (Abstract): Liver is the main organ with critical metabolic functions, contributing to the biotransformation of numerous molecules. It has an essential role in converting and clearing of active agents and it is extremely vulnerable to the toxins. The use of chemicals (drugs, abuse substances, poisons, industrial and occupational agents, herbal remedies and dietary supplements) is an important cause of hepatic cells damages, most of them being involved in the development of liver injury. Three types of mechanisms may be responsible for the occurrence of liver toxicity: overdose, drug allergy and idiosyncratic reaction. This review aims to highlight the category of chemicals responsible for the architecture damage and liver function disturbances. The influence of various agents on the liver function may be accompanied by a multitude of manifestations, represented by the increase in liver enzymes activity, hepatocytolysis or liver failure. It is very important to recognize the commonly involved compounds, identify their adverse effects, especially during the drug associations, identify their mechanisms of action, predict and limit their harmful effects in contact with the body. Considering the clinical repercussions of chemical-mediated liver injuries, this review brings into attention several potential hepatotoxic compounds and their pathophysiological mechanisms. **Keywords:** HEPATOTOXICITY, ORGANIC SOLVENTS, ACETAMINOPHEN, ALCOHOL, METALLOIDS.

The purpose of the review is to illustrate the primary mechanisms of the liver toxicity induced by a wide variety of endo-exogenous agents. In this article we listed the most common causes of hepatocytolysis described in the medical literature: drugs (acetaminophen, antibiotics, statins), occupational chemical agents from the group of organic solvents (CCl_4, toluene, styrene), metalloids (As), alcohols (white spirit, ethyl).

Hepatotoxicity

Hepatotoxicity represents the chemical damage or malfunction of the liver due to an overload of drugs or chemicals. This may result not only from direct toxicity of the primary compounds but also from an

immunologically-mediated response or a reactive metabolite (1).

There are several causes for hepatotoxicity: usage of drugs with potential toxic effect for the liver when other medication is not available (e.g. anti-tuberculosis agents), overdosage by not respecting the medical prescription, for suicidal purpose, self-medication (2). Consumption of medications, herbal and dietary supplements causing liver damage has an annual incidence rate of approximately 20 cases per 100,000 per year. If in the United States and Europe the antibiotics produce the most cases of hepatic damages, in Asia, herbal and dietary supplements are especially responsible for most liver disturbances (3).

The acetaminophen is one of the most commonly utilized drugs worldwide. It can be found under the name of N-acetyl-p-aminophenol (APAP) in the USA, Paracetamol in Europe and other countries around the world. Paracetamol is the most incriminated drug in self-poisoning in Europe. In the United States, it became the first cause of acute liver failure, up-ranking viral hepatitis. Usually, toxic doses causing hepatic failure are over 150 mg/kg, yet a study suggests that lower doses of APAP may confer acute liver injury and some patients have presented with acute liver failure despite consumption of "safe" doses of APAP (3, 4). It is also known that the antituberculosis drugs may induce hepatotoxicity as a secondary effect (5).

Literature data reveal that the administration of carbon tetrachloride ($CCl_{4)}$ in laboratory animals resulted in liver injury, with a variety of manifestations consisting of steatosis, centrolobular necrosis, inflammation, fibrosis, and liver cancer (5).

Other experimental researchers show that combination of CCl_4 and acetaminophen resulted in liver damage, due to the potentiation of their hepatotoxic effects. Liver damage was biochemical and histopathological objected by the increase of alanine aminotransferase, aspartate aminotransferase activity, elevated pro-inflammatory cytokine levels, hepatic oxidative stress and characteristic architectural disturbances (6).

White spirit is the main volatile solvent contained in the polyurethane gloss paint. Also, it was observed because of accidental excessive inhalation of the paint vapor, nausea, somnolence, and hepatotoxicity (7).

Styrene is a colorless aromatic hydrocarbon available in liquid form and highly volatile. In its pure form, it gives a sweet smell. The primary source of exposure in the environment is from plastic materials, rubber industries, packaging materials, insulations, and fiberglass and carpet industry. Experimental research demonstrated that oral administration (using an esogastric device) of different doses of styrene dissolved in corn oil, for 42 days, determined dose-dependent increase in plasma superoxide dismutase (SOD) and protein carbonyl values. Moreover, it was registered an increase in lipid peroxidation (LPO) and reactive oxygen species (ROS) levels, as well as an intensification of the styrene influenced glucose-6-phosphatase (G6Pase). On the other hand, it was observed a decrease in ferrous reducing antioxidant power (FRAP) and in total thiol molecules (TTM) values in the liver tissue (8).

Toluene

Toluene (methyl-benzene) is a colorless liquid, with high vapor pressure and an aromatic odor, naturally found in crude oil and tolu tree and mostly used in the paint

industry as a solvent, and in the fuel and chemical industry. Cresols are known to be more toxic than others upon exposure (benzaldehyde, benzoic acid, cresols or methylphenols, methyl-catechol and methylresorcinol). Exposure to these substances often occurs by inhalation of contaminated air or by accidental ingestion. The toluene is metabolized by the liver. It has been established that the inhalation of toluene by the rats caused hepatic injury observed by increased levels of aminotransferase and malondialdehyde. It has been observed that liver cell apoptosis, mediated by increased activity of Bcl-2-associated X protein (Bax) and caspase-3 enzymes, is also present (9).

Ethanol

Alcoholic liver disease (ALD) is a major health problem worldwide, for which no successful treatments are available. The pathogenesis of ALD is characterized as steatosis, inflammation, fibrosis, cirrhosis, which eventually leads to hepatocellular carcinoma (HCC) (10).

The Complement system plays a crucial role in microbial defense and clearance of apoptotic cells, emerging evidence suggesting that it is an important contributor to alcoholic liver disease.

The studies have demonstrated that the complement has an important role in the development of the alcoholic liver disease. It was observed that the complement 1q (C1q) has a beneficial influence on the recovery of hepatic damages produced by ethanol.

Following a study, where was used a group of genetically modified C57BL / 6J (WT) female rats, which were fed during 25 days with a liquid diet containing ethanol, it was observed that prolonged exposure to alcohol was accompanied by the presence of liver damage, steatosis and an increased expression of proinflammatory cytokines (11).

Chronic alcohol intoxication is associated with an intensified oxidative stress. However, the mechanisms by which ethanol triggers an amplification in the production of reactive oxygen species (ROS) and the involvement of mitochondria in the development of oxidative stress hasn't been sufficiently studied. The biochemical and proteomic data obtained in various experimental researchers suggest that one of the main causes of the increase in ROS generation is represented by an enhanced oxidation of glutamate in response to long-term alcohol exposure. In the sequence of glutamate oxidation, liver mitochondria from alcoholic rats generated more superoxide anion and hydrogen peroxide (H_2O_2) than in the presence of other substrates, as well as in control organelles. In the alcoholic rat mitochondria, the rates of H_2O_2 production and nicotinamide adenine dinucleotide (NAD) were reduced in the presence of glutamate. They were almost twice higher than in the control group. The proteomic study revealed a higher content of glutamate dehydrogenase in liver mitochondria of rats with chronic exposure to alcohol. Simultaneously, the content of mitochondrial catalase decreased in comparison with the control group. Each of these factors stimulates the production of ROS in addition to ROS generated by the respiratory chain complex I. The results are demonstrating that glutamate contributes to alcohol hepatotoxicity by increasing the oxidative stress at the mitochondria level (12).

Cocaine

Cocaine-induced liver toxicity is occa-

sionally described in humans, and interesting interactions with other "recreational" drugs are rarely presented (13). Hepatotoxicity appears usually hours to a few days after an overdose and includes acute hepatic necrosis. Serum aminotransferases and lactate dehydrogenase levels are excessively increased initially, associated with a lower increase in alkaline phosphatase. When the prothrombin time is abnormally raised may suggest disseminated intravascular coagulation. Liver histology shows centrolobular necrosis and fatty change (14).

On the other side, cocaine toxicity it is considered as a cause of fever of unknown origin. Young males with unexplained transaminase elevation must be evaluated for recreational drug use. Multiple drug interactions can alter the histological pattern of liver injury in susceptible patients. Recreational drug use is an important cause of anicteric liver injury (13).

Arsenic

Liver is a well-known affected organ by the arsenic exposure. The mechanism by which arsenic causes liver injury is incompletely understood. However, several viable mechanisms have been identified experimentally. A mechanism by which arsenic induces liver injury involves aberrant lipid metabolism, oxidative stress, altered cytokine serum levels, conducting to inflammation. The concentrations of arsenic required to cause direct hepatotoxicity are high and therefore concerns exists especially in areas of high (ppm) arsenic contamination. Some experimental studies suggested that arsenic, around these concentrations, may sensitize the liver to damage from a second consecutive hepatotoxic injury. These findings are alarming, based on the increasing rate of liver diseases (e.g. nonalcoholic fatty liver disease - NAFLD) in the developed world, wherein arsenic contamination is generally below levels required to cause direct hepatotoxicity (15).

STATINS

The HMG-CoA reductase inhibitors statins are lipid-lowering drugs currently recommended for patients with high cholesterol levels to reduce the risk of developing cardiovascular diseases. Besides their beneficial effect, they also have major side effects like hepatotoxicity and myopathy. In a large prospective study conducted for several years (2004-2012), in the United States it was noted that, of the 1188 cases reported with drug-induced hepatotoxicity, 22 cases were attributed to a statin. The authors suggested that the latency period for the occurrence of the hepatocytolysis ranging from 34 days to 10 years (16).

Herbs and dietary supplements

Multiple experimental types of research and clinical trials reported liver toxicity with toxic compounds from vegetal products, herbal remedies and dietary supplements (for example, poison from *Amanita phylloides* species of mushrooms, pyrrolizidine alkaloids from chaparral leaf, germander and comfrey, or other mixtures of plants).

CONCLUSIONS

Toxic hepatitis is frequently a result of exposure to various chemical substances, like drugs, poisons, industrial and occupational agents, herbal remedies and dietary supplements and it is well-known that it has the potential to affect the daily life quality of patients.

The most important pathogenic mechanisms of hepatotoxicity are: up-regulation

of proinflammatory cytokines activity, intensification of reactive oxygen species production, lipid peroxidation, various immunological, enzymatic and metabolic dysfunctions.

Occupational exposure, as well as the domestic one, at many singular chemical agents or on the mixture of different compounds with hepatotoxic potential, requires advanced investigations procedures, coherent evaluation, efficient preventive and effective curative methods.

GENETIC AND EPIGENETIC BIOMARKERS FOR EARLY DETECTION, THERAPEUTIC EFFECTIVENESS AND RELAPSE MONITORING IN BLADDER CANCER (Abstract): Urinary bladder cancer is the fifth most common cancer in the Western world and is responsible for about 3% of all cancer-related deaths. Because most advanced invasive or metastatic cancers have low cure rates, risk assessment and early detection of the clinically occult premalignant phases of neoplasia are a particular importance. Many tumor biomarkers for bladder cancer have been evaluated for use in detecting and monitoring bladder cancers tissue specimens, bladder washes, and urine specimens but, none of the biomarkers reported to date has shown sufficient sensitivity and specificity to detect the entire spectrum of bladder cancers in routine clinical practice. The limitations of established prognostic markers requires us to identify better molecular parameters that could be of interest in predicting the prognosis of bladder cancer patients, in particular, the high-risk patient groups that are at risk of progression and recurrence. Methylation is an important molecular mechanism in the development of bladder cancer and could be used as a prognostic and diagnostic biomarker, because hypermethylation of several gene promoters was detected in urine sediment DNA from bladder cancer patients. Aberrant patterns of epigenetic modification could be, in the near future, crucial indicators in cancer diagnosis, prognosis, and additionally could be good targets for developing novel therapies while maintaining quality of life. **Key words**: BLADDER CANCER, BIOMARKERS, EPIGENETICS, EPIGENETIC THERAPY

Carcinogenesis is a complex process involving a series of steps in the transformation from a normal to a malignant cell. In an individual's lifetime, a gradual accumulation of mutations or "hits" to the involved genes results in the sporadic neoplasm, whereas the inherited form results from the transmission of one or more of the necessary mutations to successive generations (1). Despite the great advances in the last decade of identifying and characterizing relevant molecules individually, a more comprehensive approach may be required to fully understand the complex network of genes, their protein products, and their various cellular interactions.

Genomics-based approaches are ideally suited to identify and study the complexities of the normal cellular machinery and its multiple step perturbations that result in dysregulation of cellular proliferation, migration, adhesion, differentiation, apoptosis, DNA replication, DNA repair, angiogenesis, and cellular responses to growth factors and drugs (2).

Biomarkers are cellular, biochemical and molecular (proteomic, genetic and epigenetic) alterations by which normal, abnormal, or simply a biological process can be recognized or monitored. They are used to measure and evaluate normal biological processes, or pharmacological responses to a therapeutic intervention. Biomarkers are measurable in biological media, such as: tissues, cells, and fluids. Identification of early disease-stage biomarkers has potential value for the prevention, early detection and treatment of several cancers, including bladder cancer, too.

To diagnose bladder cancer cystoscopic examination represents the gold standard, but this method is costly, incurs substantial patient discomfort, and has variable sensitivity. The development of highly reliable, noninvasive tools for bladder cancer diagnosis would facilitate early detection and help to define the role of molecular biomarkers in prognostic evaluation at the time of initial diagnosis of patients with bladder cancer (17).

More than 90% of bladder cancers are transitional-cell carcinomas and approximately 60% of these are low grade, non-muscle-invasive transitional-cell carcinomas. After endoscopic resection, the majority of bladder cancer patients develop cancer recurrences, 16–25% of which are high-grade cancers. Approximately 10% of patients with non-muscle invasive bladder cancers subsequently develop invasive or metastatic cancer. Almost 25% of patients with newly diagnosed bladder cancer have muscle-invasive disease, the vast majority being cancers of high histological grade. Almost 50% of patients with muscle-invasive bladder cancer already have occult distant metastasis (6).

Patients with bladder cancer are monitored for cancer recurrence or progression by periodic cystoscopy and urine cytology, the frequency of which varies depending on the risk factors associated with the disease.

In cases of bladder cancer, life-long surveillance is required to detect subsequent tumor recurrence. Current patient-monitoring protocols generally consist of cystoscopic evaluations and urine cytology every 3–4 months for the first 2 years and at longer intervals in subsequent years. Voided urine cytology is a highly specific, non-invasive adjunct to cystoscopy (23). It has good sensitivity for the detection of high-grade bladder cancers but poor sensitivity for low-grade disease.

In the USA, Food and Drug Administration (FDA) has already accepted urinary tests for monitoring patients with bladder cancer, including the bladder tumor antigen *stat* test, bladder tumor antigen TRAK test, the fibrinogen–fibrin degradation products test, UroVysion, ImmunoCyt, and the nuclear matrix protein 22 assay (22).

The identification of major cancer susceptibility genes such as VHL and WT1 has provided important insights into the molecular basis of cancer, germline mutations in such genes are rare and account for an increased cancer risk in only a small segment of the population common polymorphic variants, which alone do not cause cancer, can in certain environments or in concert with other genetic alterations influence cancer development or progression (7, 8).

CHROMOSOMAL CHANGES IN BLADDER CANCER

Studies of cytogenetics have identified changes in the structure and copy number of chromosomes in transitional cell carcinoma of the urinary bladder cancer(18). Studies made on loss of heterozygosity (LOH) have demonstrated that the loss of 17p, 3p, 13q, 18q or 10q is found in high grade , high stage bladder cancer(19).Loss of 9q was also observed in high grade cancer, fact that suggests that the loss of 9q could be a primary event in the tumor genesis of bladder.

GENETIC AND EPIGENETIC BIOMARKERS IN BLADDER CANCER

Tumor genesis is a multiple step process that results from the accumulation and interplay of genetic and epigenetic mutations.

Whereas genetics refers to the study of information inherited on the basis of gene sequence, epigenetics is the study of inherited reversible changes in gene function or other cell phenotypes that occur without any change in DNA sequence.

DNA methylation represents an epigenetic mechanism used for the long-term silencing of gene expression.

Many studies have been made concerning the biological roles in bladder cancer development and progression. Researchers have studied some prognostic biomarkers such as : proto-oncogenes and oncogenes , tumor-suppressor genes, cell cycle regulators, and cell-adhesion molecules. Some correlations have been made between tumoral biomarkers and tumor progression. Biomarkers like : p53, retinoblastoma (Rb), epidermal growth factor receptor (EGFR), E-cadherin appear to be of prognostic value with regard to bladder cancer metastasis, recurrence and cancer specific survival (20).

Inactivation of gene expression by the abnormal methylation of CpG islands can act as a 'hit' for the generation of cancer. Many tumor-suppressor genes contain CpG islands and show evidence of methylation-specific silencing.

The hypermethylation of CpG islands around the promoter region and decreased expression of the tumor suppressor genes RUNX3, RASSF1A,p16, RARâ, and E-cadherin have been reported in transitional cell carcinomas of the bladder (12). It has been recently recognized that aberrant hypermethylation events can occur early in tumorigenesis, predisposing cells to malignant transformation (3).

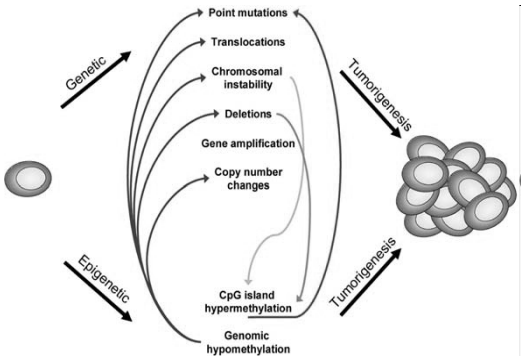

Fig. 1. Genetic and epigenetic changes in bladder cancer tumorigenesis

Promoter hypermethylation of CpG islands is strongly associated with tumor development, stage, recurrence, progression, and survival in transitional-cell carcinomas of the urinary bladder.The presence of methylation has been significantly associated with advanced-stage carcinomas, high tumor progression rates, and increased mortality rates compared to tumors without methylation (21). The methylation status could therefore be useful as a diagnostic and prognostic biomarker for bladder cancer and could also be used as a therapeutic target for bladder cancer in the clinical setting (16).

EPIGENETIC ALTERATIONS DETECTED FROM URINE

Some epigenetic events occur early in the disease process and in this case molecular diagnosis may allow their detection before symptomatic or overt radiographic manifestations. Because of this, from a clinical point of view the most promising application for methylation analysis is the detection of cancer or the utilization of methylation as a prognostic biomarker (10, 11).

The screening of bodily fluids such as the urine may ultimately provide a truly non-invasive diagnostic modality, thereby limiting the need for the current imaging techniques that provide anatomical details with-

out a definitive pathological correlation (13). The hypermethylation of several gene promoters has been reported in DNA isolated from bladder cancer tissues and urine sediment. These studies revealed that the detection of aberrant promoter methylation in urine is feasible and appears to be more sensitive than conventional cytology (4).

Recent studies have reported the feasibility of detecting DNA hypermethylation in voided urine and urine sediment and its potential role as a tumor biomarker for bladder cancer early detection.

Using a quantitative real-time polymerase chain-reaction assay the researchers examined the urine sediment DNA from 175 patients with bladder cancer and 94 age-matched control subjects for the promoter hypermethylation of nine genes (APC, $p14^{ARF}$, CDH1, GSTP1, MGMT, CDKN2A, RARβ2, RASSF1A, and TIMP3). The combined methylation status of four genes (CDKN2A, $p14^{ARF}$, MGMT and GSTP1) presented 69% sensitivity and 100% specificity (14, 15).

In another research study has been examined the methylation profile of four tumor-suppressor genes(APC, RASSF1A and $p14^{ARF}$) from matched sediment DNA in urine specimens obtained before from 45 bladder cancer patients, before surgery as well as normal controls (5, 9). Hypermethylation of at least one of the three tumor suppressor genes was found in the matched urine DNA from 39 from 45 patients, with a 87% sensitivity and 100% specificity.

The detection of DNA hypermethylation in voided urine represents a promising biomarker of the early detection and surveillance of bladder cancer.

DRUG DEVELOPMENT AND EPIGENETIC THERAPY

Unlike genetic alterations such as mutations, epigenetic changes such as DNA methylation are potentially reversible. This property of DNA methylation patterns makes epigenetic changes an attractive target for cancer therapy, and represents the basis of epigenetic therapy.

5-Azacytidine and 5-aza-deoxycytidine (decitabine), nucleoside analog inhibitors of DNA-methyltransferases (DNMTs) have been widely used *in vitro* cell culture systems to reverse abnormal DNA hypermethylation and restore silenced gene expression (25).

These drugs can be used therapeutically either alone or in combination with other therapeutic modalities such as chemotherapy, immunotherapy or radiation therapy.

CONCLUSIONS

A better understanding of the molecular mechanisms involved in the carcinogenesis and progression of bladder cancer has identified a large number of molecular biomarkers, each presenting a potential diagnostic and prognostic value.

The convergence of molecular biology, biotechnology, computer science, and statistics has spawned the field of genomics, a discipline that studies the complexity, diversity, evolution, regulation, and structure of the biological information stored as a digital code in the chromosomes. Medical applications of this rapidly changing field enable a greater understanding of the genetic and epigenetic events that contribute to the complex biological processes underlying human carcinogenesis.

ACHIEVEMENTS WITHIN THE MILLENNIUM DEVELOPMENT GOAL NUMBER 5-MATERNAL HEALTH -I N ROMANIA (Abstract): Among the eight Millennium Development Goals (MDGs) adopted by the United Nations in 2000, Goal Number 5 focused on Improve the Maternal Health. **Aim:** This paper intends to assess the progress recorded in maternal health in Romania, from the perspective of the MDG number 5, at the target date of year 2015. **Material and methods**: The research represent a descriptive study (1990-2015) and an analysis of the related achievements, from the perspective of the MDG number 5. The specific targets and indicators recommended by the United Nations were: Target 5.A "Reduce by three quarters, between 1990 and 2015, the maternal mortality ratio" and Target 5.B "Achieve, by 2015, the universal access to reproductive health". **Results**: A significant downward has been recorded in the maternal deaths, approximately ten times, from 262 cases in 1990 to 28 cases in 2015. The proportion of the births attended in 2015 by skilled health personnel was 99%. The estimated prevalence rate for any contraceptive method pointed out that just two of three Romanian women of reproductive age, currently use contraceptive methods (69%). The Romanian adolescent birth rate was and remains high, 36 cases aged 15–19 years per 1,000 women in that age group. The antenatal care coverage decreased from 94% to 76%, along the studied interval. The estimated prevalence rate regarding the unmet need for family planning in 2015 was 9.5%. **Conclusions**: An important progress has been made in Romania, in achieving the MDG no. 5 - Improve Maternal Health - since 1990. The target 5.A. was achieved, whereas the target 5.B. revealed that in spite of the progress made, Romania still lags far behind the other countries of European Union. **Keywords**: MILLENNIUM DEVELOPMENT GOALS, MATERNAL HEALTH, MATERNAL DEATHS.

Women play a critical role in a society. They have their own job or duty, being involved in the postmodern society in many fields of activity: education, delivering health care, social services or acting as agents of social change. In the same time, they give birth, raise children and take care of their family. Women are worldwide living longer and healthier lives, despite large health inequities within and between countries (1).

In September 2000, at the beginning of the new millennium, 189 heads of state adopted the United Nations (UN) Millennium Declaration, with eight Millennium Development Goals (MDGs). The plan

was to support the countries to work together to improve the peoples live, to fight poverty in its many dimensions. That vision has represented the development framework for the entire world for 15 years, up to 2015 (2).

Each MDG had specific targets for 2015, and a number of indicators for monitoring the progress. All goals and their targets are measured in terms of progress since 1990.

- Goal No.1 – Reduce Severe Poverty
- Goal No.2 – Increase Compulsory Education Graduation Rate by 2012
- Goal No.3 – Promote Gender Equality and Empower Women
- Goal No.4 – Reduce Child Mortality
- Goal No.5 – Improve Maternal Health
- Goal No.6 – Combating HIV/AIDS, Tuberculosis and Other Diseases
- Goal No.7 – Ensure Environmental Sustainability
- Goal No.8 – Develop Global Partnerships for Development

Out of the eight development goals, the goal number 5 "Improve maternal health" is directly linked to woman's health.

We are now at three years after the target date – 2015 – by which the Millennium Development Goals have to be achieved. It is generally agreed that the MDGs have been a success worldwide and will be continued up to 2030 as Sustainable Development Goals (SDGs) (3). The paper intends to assess the progress recorded in maternal health in Romania, from the perspective of the MDG number 5, at the end of 2015 year.

MATERIAL AND METHODS

This research represents a descriptive study about the maternal deaths among Romanian women, in the interval 1990-2015 and an analysis of the related achievements, from the perspective of the MDG number 5. In the United Nations Millennium Campaign, Romania committed herself to reduce maternal deaths (4).

In order to help track progress toward this commitment, following specific targets and indicators recommended by the United Nations and the World Health Organization were used (2, 3):

Target 5.A. Reduce by three quarters, between 1990 and 2015, the maternal mortality ratio

Indicator 5.1.: Percent reduction in maternal mortality ratio, 1990–2015 (75%)
Indicator 5.2.: Births attended by skilled health personnel (90%)

Target 5.B. Achieve, by 2015, universal access to reproductive health

Indicator 5.3: Prevalence rate for contraceptive methods

Indicator 5.4: Adolescent birth rate (15-19 years) per 1,000 women in that age group

Indicator 5.5: Antenatal care coverage: at least one visit (100%)

Indicator 5.6: Unmet need for family planning (0%)

The comparison allows establishing the status (achieved or making progress) for each target. The phenomenon of maternal mortality has to be understood within the context of the pro- natalist policy promoted in Romania by the former communist regime before 1990, with dramatically impact on women's health (5). In order to perform an accurate and complete analysis, two supplementary indicators have been used: births rate and abortion rate.

The data sources were represented by the National Institute of Statistics, yearbooks of the Ministry of Health and Romanian Government, World Health Statistics.

RESULTS

Romanian fertility dramatically decreased at the beginning of 1990s after the fall of the former regime. The births rate dropped from values of 16.0 in 1989, respectively 13.6 live newborns per 1,000 inhabitants in 1990 to 9 in 2015. A similar tendency was recorded for abortions, as shown in table I, the total number of the performed abortions in 1990 being ten times higher compared to 2015 (6, 7).

TABLE I

Evolution of the abortion rate (1990-2015)

Year	Number of abortions	Abortion rate (per 1,000 live births)
1990	992,265	3,152.6
1995	502,840	2,124.9
2000	257,865	1,099.5
2005	163,359	735.8
2010	101,915	480.3
2015	70,885	352.6

Target 5.A.

A significant downward has been recorded in the maternal deaths, as described in table II (7). In 1990, the indicator 5.1 pointed out that the number of the deaths generated by complications related to delivery, pregnancy and confinement was approximately ten times higher (262 cases), compared to 2015 (28 cases).

TABLE II

Evolution of the maternal mortality ratio (1990-2015)

Year	Number of maternal deaths	Maternal mortality ratio (per 1,000 live births)
1990	262	0.83
1995	113	0.48
2000	77	0.33
2005	37	0.17
2010	51	0.24
2015	28	0.14

The indicator 5.2. calculated as the proportion of the births attended in 2015 by skilled health personnel was 99%, compared to the target of 90% (8).

Target 5.B.

The indicator 5.3. was calculated as the proportion of married or in-union women of reproductive age (15-49 years) who have their need for family planning satisfied and currently use contraceptive methods (%). The estimated prevalence rate for any contraceptive method increased from 57.3 to 69.8 percent between 1990 and 2015 (9).

The indicator 5.4 revealed in 2015 a Romanian adolescent birth rate of 36 cases aged 15-19 years per 1,000 women in that age group. This value was relatively stable along the interval 1990-2015. In any West European country, the rate doesn't exceed 10 births per 1,000 women aged 15-19 years, whereas in Eastern Europe the level varies between 25 and 40 is close to 50 (10).

The antenatal care coverage (Indicator 5.5.) describes the access and utilization of health care during pregnancy. The percentage of Romanian women aged 15–49 years who utilized antenatal care provided by skilled health personnel for reasons related to pregnancy at least once during pregnancy of the total live births decreased from 94% (urban 96%, rural 91%) to 76% (urban 74%, rural 79%) along the studied interval. The level recorded in Eastern Europe was of 95.7% (11).

The percentage of married or in-union Romanian women of reproductive age (15-49 years) who want to stop or delay birth child, but doesn't use any contraceptive method, in 2015 was 9.5%, Confidence Interval $_{80\%}$=5.3-15.7%.

The estimated prevalence rate regarding the unmet need for family planning (Indica-

tor 5.6.) in Europe was 9.7%, Confidence Interval $_{80\%}$=8.2-11.4% (12).

DISCUSSION

In Romania, the year 1990 marked the transition to democratic governance. The births rate was high before 1990, caused by the lack of the contraceptive methods and restrictive access to abortion. The policy was abolished at the end of 1989 and consequently, births rate dropped in the next year 1990 (5). The decline continued in the following 25 years, with a decrease rate 1990-2015 of 43.7%.

The most important consequences of the pro-natalist policy were: the abortions performed illegally and in precarious conditions, the high number of maternal deaths, children abandonment in case of unplanned or undesired pregnancy and infant deaths.

After 1990, the maternal mortality and abortion rate dropped as a result of implementing the family planning and reproductive health programs (6, 13). Many information and education campaigns regarding contraception and development of the family planning services conducted to an eight times lower maternal mortality ratio in 2015 (0.14 per 1,000 live births), compared to 1990 (0.83 maternal deaths per 1,000 live births) (7).

The target of a three-quarters reduction in 25 years of the 1990 maternal mortality ratio (MDG 5A) and that of achieving universal access to reproductive health (MDG 5B) together formed the two targets for MDG 5: Improve maternal health.

Both indicators 5.1 and 5.2 pointed out the accomplishment in Romania of the target 5.A "Reduce by three quarters, between 1990 and 2015, of the maternal mortality ratio".

The target 5.B "Achieve, by 2015, universal access to reproductive health" among Romanian population was not entirely met. Despite the lack of an explicit national value for the indicator 5.3, the favorable status is reflected by a level of "Prevalence rate for contraceptive methods" as increased as possible. By comparison with European countries, Romania is very close to the average prevalence rate recorded at continental level, of 69.6%. In the same time, the estimated prevalence rate for any contraceptive method of 69%, pointed out that just two of three Romanian women of reproductive age, married or in-union, have their need for family planning satisfied and currently use contraceptive methods (9).

An important medical and social issue is represented by the adolescent girls who are very vulnerable when they face the risks of a pregnancy and childbirth. In many countries births before age 18 has remained quite stable across age groups of women.

The indicator 5.4: "Adolescent birth rate (aged 15-19 years) per 1,000 women in that age group" was at least two times higher among Romanian young girls, then any other West European country.

Women attended during pregnancy by a physician, nurse or midwife may receive services vital to their health and that of their future children. The antenatal care can often help women prepare for delivery and understand warning signs during pregnancy and childbirth.

In 2015, the access and utilization of health care at least once during pregnancy was performed in one of four cases, pointing not an insufficient progress, but a genuine regress. Women' addressability to healthcare, especially in rural area, is still poor. The Romanian population coverage is not universal. Social Health Insurance is compulsory but covers only around 86% of

the population (14). Pregnant women, even uninsured, are entitled to a minimum benefits package that includes care during pregnancy.

Shortage of human resources (physicians and nurses), especially in rural area, combined to low health expenditure, both under the European Union average reduce the accessibility of the pregnant women to proper antenatal care. In rural area, the antenatal care coverage (Indicator 5.5) has to be improved much more, compared to urban area (15).

In 2015, one of ten married or in-union Romanian women of reproductive age (15-49 years) want to stop or delay birth child but doesn't use any contraceptive method. Despite the similar values for the indicator 5.6. characterize, in average, the whole European region, the Millennium Development Goal number 5 specifies that at the end of 2015, the unmet need for family planning have to be 0% (12).

CONCLUSIONS

An important progress has been made in Romania, in achieving the Millennium Development Goal No. 5 - Improve Maternal Health - since 1990.

The target 5.A - To reduce by three quarters, between 1990 and 2015, the maternal mortality ratio - was achieved. At the target date (2015), both indicators regarding the reduction of the maternal mortality ratio and the births attended by skilled health personnel have been attained.

The target 5.B - Achieve, by 2015, the universal access to reproductive health-revealed that in spite of the progress made, Romania still lags far behind the other countries of European Union. Within this MDG, three indicators regarding the adolescent birth rate, the antenatal care coverage and the unmet need for family planning represent a priority for health authorities and have to be optimized as Sustainable Development Goals.

NEWS

A NEW HOPE FOR AN OLD HEART? CAN INTERFERON-FREE THERAPY ALSO REVERSE THE HCV-INDUCED CARDIOMYOPATHY IN PATIENTS WITH END-STAGE HEART FAILURE?

Several studies have previously confirmed an association between hepatitis C virus (HCV) infection and cardiomyopathy, but none could really establish a pathogenic relationship. These issues have arisen because the classic, interferon-based therapy for HCV infection has severe cardiac side-effects, thus limiting its use in patients with advanced heart failure. The aim of this prospective large-scale study was to assess the benefits of using interferon free regimens in HCV-infected patients with non-valvular, non-ischemic cardiomyopathy, the standard treatment (consisting of ombitasvir, paritaprevir, dasabuvir and paritaprevir) being well-tolerated, free of cardiac side-effects. The authors were encouraged to conduct a large study because they observed that this treatment was very effective in a patient with rapidly progressive heart failure (NYHA III/IV class), who was already listed for heart transplantation. In order to have an acceptable hepatic functional status prior to the transplant, the patient received the interferon-free regimen and, surprisingly, after her complete HCV clearance, her cardiac function improved significantly to NYHA II class, heart transplant being no longer considered. The conclusion was that HCV was etiopathogenetically involved in myocardial dysfunction for at least two reasons: the interferon-free therapy does not eliminate any other cardiotropic virus (e.g. Coxsackie B3), nor does it have *"per se"* any antifibrotic or cardiac anti remodelation action. These promising findings need to be further confirmed on larger patient cohorts in this ongoing study (Poller W, Haghikia A, Kasner M *et al*. Cardiovascular Involvement in Chronic Hepatitis C Virus Infections - Insight from Novel Antiviral Therapies. *J Clin Transl Hepatol* 2018; 6(2): 161-167).

3. Spitalul Clinic de Obstetrică şi Ginecologie, Cuza Vodă Iaşi

CHROMOSOMAL EVALUATION IN COUPLES WITH REPRODUCTIVE DISORDERS – RETROSPECTIVE STUDY OF A SELECTED GROUP OF 266 COUPLES (Abstract): Reproductive Disorders (RD), manifested by the biological inability to conceive (primary sterility) or inability to carry a pregnancy to full term (infertility), affect 10-15% of reproductive-aged couples. The genetic etiology of RD is represented, in the majority of cases, by the chromosomal abnormalities. **Aim**: To retrospectively analyze the karyotype results in a selected group of couples with RD. **Material and method**: The present study was performed in 266 couples with RD: 80 (30,07%) with primary sterility (ST), 149 (56,01%) with Recurrent Spontaneous Abortions (RSA) and 37 (13,90%) with Stillborn Children (SC). A GTG-banded karyotype was performed on both partners of each couple. **Results**: We identified a chromosomal abnormality in 43 individuals (16,16%): 20 cases (7,51%) with ST, 13 cases (4,88%) with RSA and 10 cases (3,75%) with SC. The affected partner was female in 23 cases (8,64%) and male in 20 cases (7,51%). A X chromosome (numerical or structural) abnormality was detected in 18 cases (6,76%), most frequent X chromosome monosomy mosaicism in female and trisomy XXY in male; a balanced structural chromosomal abnormality (BSC) was detected in 23 couples (8,64%); in other two males with ST, the karyotype result was 46,XX. **Conclusions**: The results of our study are similar to other reported studies and underline the major etiologic role of chromosomal abnormalities in RD and the importance of chromosomal analysis for the etiologic diagnosis and genetic counseling of these patients. **Key words**: REPRODUCTIVE DISORDERS, CHROMOSOMAL ABNORMALITIES, KARYOTYPE

Tulburările de reproducere umane (TR) se caracterizează prin incapacitatea unui individ/cuplu de a concepe natural (sterilitate primară) ori prin incapacitatea de a menţine o sarcină sau de a da naştere unui copil viu, sănătos (infertilitate) (1,2).

Sterilitatea primară (ST) este definită ca fiind imposibilitatea unui individ de a forma gameţi viabili sau inabilitatea unui cuplu de a concepe un copil după un an de viaţă sexuală normală, regulată, în absenţa folosirii oricărui mijloc contraceptiv (2,3,4). ST reprezintă o problemă medicală importantă şi frecventă, afectând 10-15% dintre cuplurile cu vârstă reproductivă (2,3).

Infertilitatea (pierderile de sarcină) este caracterizată prin sarcini finalizate cu producerea de avorturi spontane (AS)/avorturi spontane recurente (ASR) (= 2 AS) sau naşterea unor copii morţi (NM) (2,3,4).

Avorturile spontane (AS) reprezintă pierderea inexplicabilă a unei sarcini, înainte de împlinirea a 20 de săptămâni complete de gestaţie (18 săptămâni după fertilizare) sau, dacă nu este cunoscută vârsta gestaţională, pierderea unui făt cu greutatea sub

400 grame (4). Se estimează că aproximativ 15-20% din sarcinile recunoscute clinic, se elimină prin AS, dar frecvenţa reală este probabil mai mare, 2/3 dintre AS producându-se pe parcursul unor sarcini nedecelate clinic (avorturi biochimice) (2, 3).

Avorturile spontane recurente (ASR) se caracterizează prin apariţia a 2 sau mai multe avorturi spontane consecutive la acelaşi cuplu (2, 3).

Moartea fetală intra-uterină (nou-născuţi morţi, NM), definită ca fiind moartea *in utero* a unui făt cu vârsta gestaţională mai mare de 20 de săptămâni, are o frecvenţă de circa 6,5/1000 nou-născuţi (4).

Cauzele TR sunt multiple : genetice, malformative, endocrine, imunologice sau de mediu (1, 2). TR pot afecta ambii parteneri ai cuplului, etiologia putând fi feminină, masculină sau de cuplu (2). Incidenţa factorilor etiologici implicaţi în producerea TR umane a fost apreciată într-un raport al Societăţii Americane de Medicină Reproductivă din 2006 : 25% cauze masculine, 27% cauze ovulatorii, 22% cauze uterine/ tubare, 9% endometrioza şi 17% cauze idiopatice (2).

Rolul factorilor genetici, reprezentaţi în principal de anomaliile cromozomiale, în producerea TR umane, a fost dovedit fără echivoc (5).

Cauzele genetice ale sterilităţii primare (ST) sunt reprezentate de anomaliile cromozomiale (numerice şi structurale ale gonozomilor şi anomaliile de structură echilibrate ale autozomilor) şi, mai rar, de boli monogenice sau multifactoriale (2, 6).

Circa 50-60% dintre avorturile spontane recurente (ASR) precoce (0-8 săptămâni) sunt determinate de o aneuplodie prezentă la făt, în timp ce odată cu creşterea vârstei gestaţionale, incidenţa anomaliilor cromozomiale scade, acestea fiind decelate în aproximativ 1/3 (35%) din ASR din trimestrul II de sarcină şi doar la 5% dintre nou-născuţii morţi din trimestrul III de sarcină (5,7,8).

In circa 5% dintre avorturile recurente, la produşii de avort au fost identificate aneuploidii segmentale (monosomii parţiale, trisomii parţiale sau asocierea de trisomii şi monosomii parţiale), care în cea mai mare parte au fost rezultatul unei malsegregări a cromozomilor derivativi, în cazul unei anomalii cromozomiale de structură echilibrată (ACSE) prezentă la unul dintre părinţi (9,10).

Scopul studiului a fost analiza retrospectivă a rezultatelor analizei cromozomiale, în cazul unui lot selecţionat de 266 cupluri cu tulburări de reproducere (TR).

MATERIAL ŞI METODĂ

Pacienţii

In perioada ianuarie 1998 - decembrie 2009 au fost evaluate clinic în cadrul Centrului de Genetică Medicală Iaşi, 266 cupluri cu tulburări de reproducere : 80 cazuri (30,07%) cu sterilitate primară (ST), 149 cazuri (56,01%) cu avorturi spontane recurente (ASR) şi 37 cazuri (13,90%) cu nou născuţi morţi (NM).

Metode

În cazul fiecărui cuplu cu TR a fost efectuată analiza cromozomială folosind un marcaj în benzi de tip G (450-550 benzi/ metafază).

S-a urmărit evidenţierea unor *anomalii cromozomiale numerice sau structurale*. Analiza cromozomială s-a bazat pe o cultură stimulată, de scurtă durată a limfocitelor T şi a fost realizată conform tehnicii Moorhead (1960) (11), adaptată în cadrul Laboratorului de Citogenetică al Universităţii de Medicină şi Farmacie „Gr. T. Popa" Iaşi. Analiza a cuprins mai multe etape : recoltarea sângelui periferic pe heparină sodică ; punerea sângelui în cultură (mediul de cultură este RPMI 1640 (9 ml), suplimentat cu ser de viţel fetal (1ml) şi glutamină (0,1 ml)) ; hipotonizarea, fixarea, etalarea şi colorarea. Metafazele au fost examinate cu microscopul Nikon, iar imaginile au fost captate cu un sistem automat de cariotipare

TABELUL I

Anomalii cromozomiale decelate la cele două sexe în cazul a 266 cupluri cu tulburări de reproducere (TR)

		Femeie	Bărbat
Tip anomalie cromozomială	**Număr (%)**	**Număr (%)**	**Număr (%)**

Cytovision (Applied Imaging).

Pentru fiecare caz au fost analizate un număr de minim 16 metafaze. În situaţiile în care au fost depistate anomalii, numărul de celule analizate a fost crescut la 32, 64 sau chiar 96.

REZULTATE

În cazul a 43 de cupluri (16,16%), cariotipul a relevat prezenţa unei anomalii cromozomiale (numerice sau structurale) la unul dintre parteneri: 20 cazuri (7,51%) la cuplurile cu ST, 13 cazuri (4,88%) la cuplurile cu ASR şi 10 cazuri (3,75%) la cuplurile cu NM. In 23 cazuri (8,64%) anomalia a fost decelată la femeie, iar în 20 cazuri (7,51%, la bărbat (tab. I).

Cele mai frecvente anomalii decelate au fost anomaliile cromozomiale de structură echilibrate (ACSE), prezente la 23 cupluri (8,64%), urmate de anomaliile de număr şi de structură ale cromozomului X, identifi-

* procentele au fost calculate în raport cu numărul de cupluri cu ASR

cate în cazul a 18 cupluri (6,76%), majoritatea lor fiind reprezentate de monosomia X în mozaic, la femeie şi de trisomia XXY (sindromul Klinefelter) la bărbat (tab. II, III şi IV). În alte 2 cazuri a fost decelat un cariotip 46,XX la bărbat, iar la 3 cupluri (1,12%) au fost decelate variante cromozomiale polimorfice, considerate normale: 9qh+ (2 cazuri) şi 1qh+ (1 caz) (tab. I, II , III).

La 20 de cupluri cu sterilitate (ST) (25% dintre cuplurile cu ST) a fost decelată o anomalie cromozomială, frecvenţa acestora fiind de aproape două ori mai mare la bărbaţi (13 cazuri- 16,25%), faţă de femei (7 cazuri - 8,75%). Cele mai frecvente anomalii decelate în aceste cazuri, au fost anomaliile de număr şi de structură a cromozomului X (12 cazuri- 15%), urmate de ASCE, reprezentate de inversii (6 cazuri - 7,50%) (tab. II).

La 13 (8,72%) dintre cele 149 de cupluri cu avorturi spontane recurente (ASR), a fost decelată o anomalie cromozomială, 8 (5,36%) dintre acestea fiind prezente la femeie. Cele mai frecvente anomalii decelate au fost ACSE (9 cazuri - 5,38%), majoritatea fiind inversii (6 cazuri - 4,02%), urmate de aneuplodii gonozomale (monosomia X în mozaic, 4 cazuri - 2,68%). (tab. III).

În cazul cuplurilor cu nou-născuţi morţi (NM), au fost decelate 10 cazuri cu anomalii (27,02%), cele mai frecvente fiind ACSE (8 cazuri-21,62%), urmate de aneuploidii gonozomale (2 cazuri- 5,40%) (tab. IV).

DISCUŢII

Ponderea anomaliilor cromozomiale decelate la lotul selecţionat al cuplurilor cu TR, a fost mai mare (16,16%), decât cea citată în alte studii similare: 8,9% - Pal (12), 9,04% - Nazmy (13), 5,53% - Espinoza et al (14) şi 1,97% Clementini et al (15,) probabil, datorită selecţiei clinice riguroase făcută anterior investigaţiei citogenetice. Per total, ponderea ACSE a fost mai mare (8,64%), faţă de cea a anomaliilor

TABELUL IV

Anomalii cromozomiale decelate la 37 cupluri cu nou-născuţi morţi (NM)

* procentele au fost calculate în raport cu numărul de cupluri cu NM

numerice şi structurale ale cromozomului X (6,76%), însă aneuploidiile şi anomaliile de structură ale cromozomului X au fost principala cauză a sterilităţii la cuplurile cu ST, în timp ce ACSE au reprezentat principalul factor etiologic genetic în cazul cuplurilor cu ASR şi NM (tab. II, III şi IV). Datele obţinute sunt concordante cu cele din literatura de specialitate (2, 5, 6).

Din totalul de 43 de anomalii cromozomiale decelate la cuplurile studiate, în 48,83% din cazuri, anomalia a fost prezentă la femeie, iar în 51,16% din cazuri, la bărbat, aceste rezultate fiind concordante cu cele prezentate în studii similare de Espinoza et al (54,7% la femei şi 54,3% la bărbaţi) (14) şi Clementini et al (51,82% la femei şi 48,78% la bărbaţi) (15).

Inversiile (15 cazuri - 5,63%) au fost cele mai frecvente anomalii cromozomiale structurale echilibrate (ACSE) decelate, urmate de translocaţii (5 cazuri - 1,87%). Cea mai frecventă inversie a fost cea a cromozomului 9 (2,63% - 7 cazuri), frecvenţă similară cu cea întâlnită în populaţia generală (1-3%) (tab. II, III şi IV). Inversia cromozomului 9 a fost întâlnită la toate cele trei categorii de cupluri cu TR (ST, ASR, NM), atât la femeie (4 cazuri), cât şi la bărbat (5 cazuri) (tab. II, III şi IV).

Implicarea inversiilor pericentrice ale cromozomului 9, inv(9)(p11q12) sau inv(9)(p11q13) în producerea TR este controversată, acestea fiind considerate variante normale. Numeroase studii efectuate de-a lungul timpului au încercat să elucideze mecanismul patogenic, luându-se în considerare necesitatea identificării purtătorilor inversiei inv(9) produse *de novo* sau a cazurilor familiale de inversie a cromozomului 9 (16, 17, 18, 19). Studiile privind organizarea heterocromatinei din regiunea pericentromerică şi din regiunea proximală a braţelor scurt (p) şi lung (q) ale cromozomului 9, au relevat o omologie între cele două regiuni 9p12 şi 9q13-21.1, în care se produc cel mai frecvent rupturi (*hotspots*), implicate în producerea recombinărilor cromozomiale (20). Multe secvenţe sunt duplicate în regiunea pericentromerică, fiind identificate blocuri mari de duplicaţii segmentale in interiorul şi între cele două regiuni pericentromerice 9p11–12 şi 9q11–12/13. Astfel, cele două regiuni cromozomiale conţin secvenţe identice în

proporţie de 97%, ceea ce favorizează recombinările cromozomiale aberante (21).

Cele mai frecvente translocaţii decelate, au fost translocaţiile robertsoniene (1,12% - 3 cazuri), toate fiind identificate la femei. Aceste rezultate au fost similare cu cele găsite în alte studii, raportul dintre purtătorii de translocaţii robertsoniene găsit de Espinoza et al fiind în favoarea femeilor (F : M =3,5 : 1) (14), la fel şi cel găsit de şi Orozco Quinono et al (F : M= 5,5 : 1) (22).

La 2 dintre bărbaţii cu ST şi azoospermie a fost identificat un sindrom de inversiune sexuală (bărbaţi 46,XX), determinat cel mai probabil de translocaţia genei SRY de pe cromozomul Yp pe cromozomul Xp în timpul *crossing over*-lui din meioza paternă.

Datele noastre sunt, în ansamblu, concordante cu alte studii şi relevă importanţa analizei cromozomiale la cuplurile cu TR, mai ales în situaţia în care, din ce în ce mai multe cupluri apelează la tehnici de reproducere asistată (fertilizare in vitro, FIV), ale căror protocoale impun obligatoriu efectuarea cariotipului la ambii membri ai cuplului, înaintea efectuării tehnicii respective.

CONCLUZII

În concluzie, rezultatele studiului nostru retrospectiv, concordante cu datele din literatură, evidenţiază rolul major pe care îl au anomaliile cromozomiale, în producerea TR umane, subliniind în acelaşi timp importanţa analizei cromozomiale pentru diagnosticul etiologic, managementul şi sfatul genetic acordat acestor cupluri, inclusiv în contextul aplicării în viitor a unei tehnici de reproducere asistată (FIV).

NOUTĂŢI

Mecanisme non-imunologice ale inhibitorilor de calcineurină explică efectul lor antiproteinuric în glomerulopatiile genetice

A fost raportat că tratamentul cu ciclosporina A (CyA) în combinaţie cu corticosteroizi, inhibitori de enzimă de conversie şi blocanţi ai receptorilor de angiotensină, a dus la scăderea rpoteinuriei la 3 pacienţi cu sindrom nefrotic (NS) datorat mutaţiei *WT1*. tratamentul cu inhibitori de calcineurină a indus o remisiune parţială a proteinurie la câţiva alţi copii cu forme genetice de NS, cum ar fi mutaţii ale genelor podocinei şi fosfolipază C epsilon. CyA a fost raportată de asemenea a fi eficientă la pacienţii cu sindrom Alport. Date recente au arătat că efectul antiproteinuric al CyA în aceste cazuri se poate datora unor mecanisme non-imune. CyA exercită un efect antiproteinuric prin prevenirea degradării proteinei sinaptopodina organizatoare a actinei şi prin downregulation a TRPC6. aceste emcanisme conduc la stabilizarea citoscheletonului de actină în podocitele renale. Acest effect benefic al CyA este interesant dar rezultatele e termen lung privind functionarea si nefrotoxicitatea încă lipsesc. (Bensman A, Niaudet P, Non-immunologic mechanisms of calcineurin inhibitors explan its effects in genetic glomerupopathies, *Ped Nephrol* 2010 ; 25 : 1197-1199).

THE USE OF HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY IN PHARMACEUTICAL ANALYSIS (Abstract): The aim of the study was to provide a review and strategy for the development and validation of a modern analytical method with nearly unparalleled accuracy in the pharmaceutical analysis. High performance liquid chromatography is an analytical method used to separate, identify and quantify components dissolved in a liquid solvent with a high analytical resolution. Because of its versatility, HPLC is used in a variety of industrial and scientific applications, such as pharmaceutical, environmental, forensics, and chemicals. Characteristics that should be considered during validation of analytical methods include specificity, linearity, range, accuracy, precision, detection limit, quantification limit, robustness. **Keywords:** HIGH PERFORMANCE LIQUID CHROMATOGRAPHY, PHARMACEUTICAL SUBSTANCES, VALIDATION.

The advancement of pharmaceutical research has brought to the attention of specialists a large number of pharmaceutical substances that require very high purity parameters. Degradation and contamination of pharmaceutical products begins during the synthesis process of the active molecule and it continues during formulation, packaging, transport and storage. During all those stages, the control of purity may be done using high-throughput analytical methods. The biological pathway of the active molecules can also be tracked from the moment of administration, using quantitative methods with high sensitivity that may also be used to confirm the proposed mechanism of action, dose and schedule of administration, efficacy, safety and association between benefit and risks of the drug.

High Performance Liquid Chromatography (HPLC) is one of the most commonly used techniques in biomedical analysis for separation, identification, and quantification of each component in a mixture (1, 2). It was introduced for the first time in 1980 as the official method for bulk drug analysis (United States Pharmacopoeia, 1980), due to its high sensitivity and specificity. It has become one of the most widely used or even the main method for official analysis in various pharmacopoeias such as The United States Pharmacopoeia and The European Pharmacopoeia (3-19).

Conventional regulations, such as those of the European Medicines Agency

(EMEA), the Food and Drug Administration (FDA), and the International Conference of Harmonization (ICH), state that validation of the method is essential in drug analysis.

The development of high-performance liquid chromatography methods generally includes the following steps: selection of the HPLC method and chromatographic system, selection of initial conditions, selectivity and system optimization, and method validation (20).

In order for the analysis procedure to be applied, it must undergo verification steps confirming its scientific validity. Validation is meant to demonstrate that the proposed method corresponds to the intended use. The statistical processing of the results of an analysis gives the possibility of obtaining the most probable value that is closest to reality (21-22).

For HPLC analysis with UV-VIS detection there are several validation schemes, which consider the parameters described next.

Specificity/Selectivity

A method is specific if it can be applied to a single analyte, while a method is selective if it can accurately and specifically quantify the analyte or analytes in the presence of other compounds. In the case of pharmaceutical substances, selectivity implies the ability to separate the analyte of degradation products, metabolites, excipients and other compounds present in the sample.

For HPLC methods, selectivity can be achieved through a good separation between the analyte and other components of the sample. Peak resolution should be greater than 1.5. Interferences are tested on multiple samples, from different sources, and the peak corresponding to interference with the same retention time must be less than 20% of the standard quantification limit and less than 5% then that of the internal standard used (3, 4, 21, 22).

Selecting the detection wavelength

For HPLC analysis with UV-VIS spectrophotometric detection, there is a peak in the chromatogram at the retention time corresponding to the analyte. The UV-VIS absorption spectrum of that peak is recorded, and by analyzing it the absorption maxima are highlighted.

The detection wavelength is selected as the one with the maximum absorbance value, considering the potential presence of various interferences. That value will be used for all subsequent determinations.

Identifying the peak corresponding to the analyte

Due to the fact that a particular compound behaves identically during any HPLC analysis if all operating conditions are identical, the detection of the analyte in different samples is based on the comparison of the retention time of the peak from the chromatogram of the sample with that obtained in the chromatogram of the reference substance. A difference of no more than ± 5% of is acceptable (23).

In order to increase the accuracy of the identification, the absorption spectrum of peak from the sample chromatogram must be compared to that of the reference solution analyzed under the same conditions in terms of stationary and mobile phase composition, flow, temperature, detection wavelength, reference wavelength.

Accuracy of identification could be quantified by choosing a threshold factor for overlapping spectra. If the accuracy of the identification is equal to or greater than that factor, the peak is considered to be identified and it is assigned to the analyte (22).

Assessment of peak purity

The evaluation of peak purity excludes the coexistence of several substances for the same peak. The control of purity in pharmaceutical analysis is based on the comparison of three spectra recorded during elution of the peak. Among those, two spectra are recorded at the increasing and decreasing inflection points of the peak and one at the tip of the peak. If those spectra are not the same, in theory, the peak contains a spectral impurity. It may be caused by one or more components separated simultaneously, by peaks that are not properly separated, or it may be due to baseline noise (3, 4, 21).

There is also the possibility of identical spectra due to peaks containing impurities at a very low concentration compared to the analyte or if the impurity and the analyte have the same or almost the same spectrum and similar elution time (21).

Linearity of the response function

Linearity is the ability of the method to produce results directly or indirectly proportional to the concentration of the analyte in the sample over a certain range of concentrations.

In order to evaluate the linearity of the method, the relationship between the signal provided by the detector (absorbance, height or area of the peak) and the concentration of the analyte in the sample is determined. That relationship may be linear, exponential, logarithmic, polynomial, or other, and it must be a monotonous, incremental or decreasing function over the entire concentration range studied (3, 4, 22).

The statistical method most commonly used to find the best correlation between experimental data and the calibration curve type is the linear regression method. The parameters that must be calculated using regression analysis are correlation coefficient (r), regression coefficient (r^2), vertical intercept, slope and standard deviation of the regression line, least squares regression. The correlation coefficient indicates a linear relationship if its value exceeds 0.999 (22-26).

Calibrating the detector response

In order to obtain reliable results, it is necessary to calibrate the detector response (UV-VIS spectrophotometer). To that purpose, duplicate series of solutions are prepared in a matrix identical to that of the sample to be analyzed, for the entire working concentration range. For each concentration, the mean value of the peak area is calculate and then plotted against the theoretical value. A linear regression curve confirms the truthfulness of the detector response (27-29).

Detection and quantification limit

The Detection Limit (LOD) is the minimum amount of a component that can be highlighted against a blank sample with a 1% confidence level.

The Quantification Limit (LOQ) is the minimum quantity of a component that can be quantified with certainty.

One of the most commonly used methods to estimate LOD and LOQ is based on the standard deviation and the slope of the regression line using the equations:

$$\mathrm{LOD} = \frac{3 \cdot \sigma}{S} \quad \text{and} \quad \mathrm{LOQ} = \frac{10 \cdot \sigma}{S}$$

where: σ is the standard deviation of the regression line and S is the slope of the regression line (27).

The calculated values of the detection and quantification limit must be confirmed through independent analysis of an appropriate number of samples that have concentrations close to both limits (27-29).

Working range

Routine analysis in the pharmaceutical industry is conducted in 80% to 120% concentration range relative to the actual concentration of the analyte (24).

Precision

Precision provides data on random errors and characterizes the degree of concordance amongst the analytical results on repeated application of the analytical method on the same homogeneous sample or sample prepared under identical conditions. It estimates how close the measured values are to each other for a number of measurements under the same conditions.

The ICH rules define accuracy as being composed of three components: system precision, method precision, intermediate precision and reproducibility (23, 30).

The precision of the chromatographic system is the ability to detect small changes concerning analyte concentration as a result of multiple determinations (injections) from a homogeneous sample under established working conditions and during one day of tests. It is estimated using the coefficient of variation, a small value of which is related to a more precise result.

The precision of the method is expressed by the value of the relative standard deviation (RSD) for the results of multiple measurements of a sample by the same analyst in the same laboratory using the same equipment within a short time using the same procedure on identical samples in the same conditions of analysis (30, 31).

Intermediate precision assesses the dependence of the method in conditions other than those in which that particular method was developed. The purpose of intermediate precision evaluation is to ensure that the method will lead to the same results, if samples are analyzed in the same laboratory using the same procedure under the same analytical conditions by different analysts using different equipment within a given time frame. It is expressed through the value of relative standard deviation (RSD), evaluated in the exact same conditions as the precision of the method (32, 33).

Reproducibility is defined as interlaboratory precision in collaborative studies. In other words, reproducibility depends on the conditions chosen for which the results are obtained using the same procedure, on identical samples, in different laboratories, using different equipment and reagents of different origin, by different operators.

Accuracy

Accuracy is a validation feature that evaluates how close the analytical results are to the true value. The accuracy usually assessed for HPLC assay methods for pharmaceutical substances by adding a known amount of analyte to a placebo solution with concentrations ranging from 80-120% or even 75-125% of the actual concentration in the pharmaceutical form (24, 30, 31).

Replicate samples are evaluated for each concentration level studied. Accuracy evaluation calculate the percentages based on the experimental results obtained. The interval in which the results of the recovery test are accepted is between 98 and 102% or 95 and 105% (23, 34-36).

Robustness and stability of the method

The robustness of an HPLC method is evaluated by measuring the ability of the method to remain unaffected by small, deliberate variations of some method parameters (mobile phase composition, column temperature, column age, etc.) or environmental factors (room temperature, air humidity, etc.), in other words, the stability

of the method. The stability of an analytical method is the degree of reproducibility of results obtained for the same sample under different conditions, such as different laboratories, different analysts, different apparatus, different reagent lots, different days (31-34, 37).

CONCLUSIONS

In conclusion, the validation of an HPLC method used for pharmaceutical analysis must be performed by each laboratory according to the method-specific tests, to ensure that the method exhibits accuracy, precision, specificity, reproducibility and stability over the entire concentration interval for the analysis of the analyte. Validation of the method must be performed prior to application and it is essential in all pharmaceutical research phases.

TECHNOLOGICAL PARTICULARITIES OF THE IMPLANT-SUPPORTED DENTAL PROSTHESES. CASE REPORT

TECHNOLOGICAL PARTICULARITIES OF THE IMPLANT-SUPPORTED DENTAL PROSTHESES. CASE REPORT (Abstract): Complete edentulous is a pathological condition characterized by the loss of all teeth and their supporting periodontal structures on one or both jaws, accompanied by functional consequences. The biggest challenge for both, dentist and patient, is the transition from dentate to completely edentate status. The indication for dental implant insertion to a totally edentate patient should be considered with a lot of discernment because it is usually addresses to elderly people, often presenting an associated general pathology, which may affect the final therapeutic success. The purpose of this article is to present the clinical and technological steps in the metal-ceramic bridges in a patient with bimaxillary complete edentulous. Prostheses were fixed on dental implants in order to achieve a complex oral rehabilitation. The precise knowledge of the algorithm and technological parameters of each step allows to avoid mistakes and to obtain the appropriate biologic and mechanical prosthetic constructions. **Keywords:** COMPLETE EDENTULOUS, COMPLETE DENTURE, DENTAL IMPLANTS.

Complete edentulous is the most serious mutilation of the dento-maxillary system. This disease can usually be treated by a removable restoration which is based on different clinical and biological criteria; sometimes this therapeutic variant is difficult due to the serious, progressive and irreversible alteration of residual tissue components and the decrease in adaptive natural mechanisms. By losing all the teeth, oral homeostasis is seriously affected, and morpho-functional recovery through prosthetic treatment requires the correlation of numerous factors that ultimately ensure the success of this treatment. Complete dentures are restorations which demand a high degree of knowledge and skill from the dental team. Each working step must yield the maximum result, the final goal being an increased quality of life for the patient (1). Currently, treatment of complete edentulous follows three main directions: the classical complete denture, (base on the residual elements of denture bearing area for retention, support and stabilization), removable partial denture supported by dental implants and fixed prostheses supported by dental implants (2, 3). The long-term success rate of full-arch, implant-supported restorations is one of the best in medicine. Clinical studies on the implant supported fixed prostheses have shown that long-term results are clearly superior to removable prostheses, due to the design

and the coating treatment of the implants.

In order to choose a prosthetic solution on implants, the following aspects should not be omitted from the assessment of the patient condition: informing patients about the benefits of implant insertion and possible associated risks, the medical history, evaluation of the general condition of the patient, evaluation of the oral status by performing a rigorous examination, determination of the number and position of future implants after careful radiological analysis. General contraindications for implants include major immune deficiencies, major heart diseases, severe hypertension, endocarditis, insulin-dependent diabetes, liver cirrhosis, chronic obstructive pulmonary disease, frequent illness requiring periodic or rhythmic use of steroidal anti-inflammatory drugs, cancer patients who had undergone, are undergoing or will undergo chemotherapy, uncontrollable endocrine diseases, psychotic disorders and drug use (4). Local contraindications include poor oral hygiene, oral mucosal disorders, local inflammatory processes, insufficient bone support, poor-quality of the bone, post-radiation therapy in the cervical-orofacial area. In general, local conditions are not an absolute contraindication, but only a timing of the implant solution.

The decision of choosing a fixed prosthetic construction supported on implants in complete edentulous should be determined with great discernment and attention because it is usually addressed to elderly people, who often have an associated pathology, that can affect the success of the prosthetic treatment, due to insufficient bone support or presence of absolute general contraindications.

CASE REPORT

We present the case of a 64-years-old patient with masticatory and physiognomic disturbances as a result of an extended bimaxillary partial edentulous.

Following clinical and radiological examination we established that the first step of the treatment should be the extraction of compromised teeth on both arches, transforming partial edentulous into complete one (fig. 1).

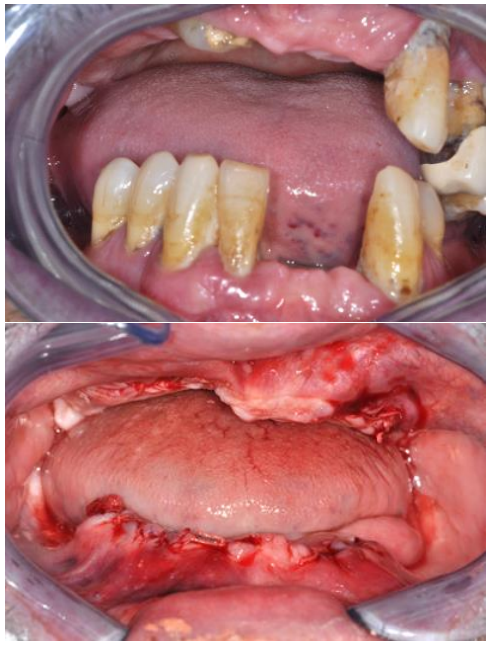

Fig. 1. Initial clinical situation and after teeth extraction

After complete cicatrization, bone capital was carefully analyzed again, performing a radiological examination by Cone-beam computed tomography (CBCT). This innovative technique for digital dental X-rays is commonly used in implantology, because it is more accurate than a panoramic dental X-ray and can target the area to be observed to avoid exposing other parts of the skull to X-ray. This examination explores the condition of the bones and the function of the temporomandibular joint.

The final therapeutic solution consisted in the insertion of 11 implants into the maxilla and 8 implants into the mandible, on which will be applied metal-ceramic bridges. The impression was taken using the indirect technique, with impression copings attached to the implant, which are removed together with the set impression. The analogues are attached to the impression copings while they are embedded in the impression tray (fig. 2).

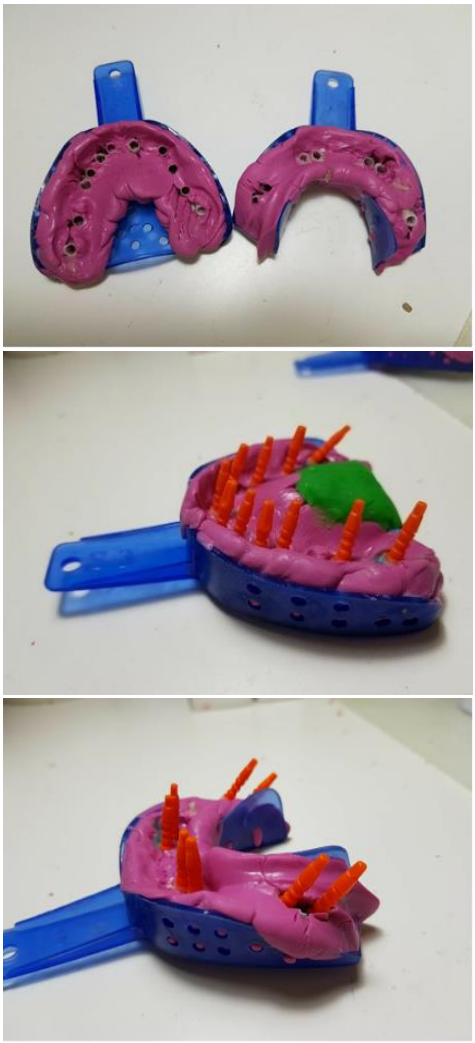

Fig. 2. The impressions

Dental impressions are checked and disinfected, and then sent to the dental laboratory, where the technician realize casts with removable dies for each impression, and then mount them into a dental simulator. The next step is the building metalic framework of metal-ceramic bridge. For the wax pattern a special blue inlay wax was used, and for metallic framework was used a cobalt-chrome dental alloy (Remanium CS/Dentaurum/Germany).

To enhance the bond between the metallic infrastructure and the aesthetic component, the framework was sandblasted with 50 μm Al_2O_3 particles. The ceramic layers were applied to the metallic framework and sintered at a preset temperature (960ºC for the opaque and dentine, in the vacuum condition, and 930ºC for glaze, in atmospheric conditions).

Fig. 3. Ceramic layers application

After completing all the steps, the prosthesis were verified on the die, then in the oral cavity, looking for adaption to the implant structures (fig. 4).

Fig. 4. The prosthesis on the die and in the oral cavity

DISCUSSION

Treating a completely edentulous patient with fixed prostheses implant-supported is a solution that has many advantages for the patient: much easier adjustment, immediate resumption of functions, superior esthetic appearance, and high mechanical strength. Prosthetic appliances involves treating dysfunctions, stimulating compensatory mechanisms, and achieving a new homeostasis balance between the elements of the oral system (5). Prosthetic treatment will not only aim to restore the dental arch continuity, but also the correct restoration of occlusion and of the fundamental mandibula-cranial relationships and mandibular dynamics. In order to achieve a correct and complete dental treatment, a clinical and paraclinical assessment of the initial situation is required. It is necessary to establish a correct diagnosis based on the clinical information and to develop a treatment plan based on the restoration of the balance between all the affected elements (6, 7). The treatment of complete edentulism should be the result of a comparative analysis of the benefits and disadvantages for each clinical case. The correct assessment of the initial clinical situation, preparation of the prosthetic area, preprosthetic and prosthetic treatments, and selection of the most appropriate therapeutic solution prevent failures and allow a good longevity of the restorations.

CONCLUSIONS

In order to achieve long-term therapeutic success in implant-supported oral rehabilitation some surgical, prosthetic, and periodontal aspects as well as the optimal timing of implant insertion must take into consideration. The selected implant type must provide mechanical strength, the implant material must be biocompatible, and its configuration must allow the aggregation of a suitable prosthetic superstructure and the transfer of the occlusal forces to the bone substrate, as physiologically as possible.

The prosthetic aspects should be considered from the very beginning before planning implant insertion. These aspects are essentials for the choice of implant system, number of implants to be inserted, their position, and insertion axis. In the fabrication of the prosthetic superstructure, the bio functional, gnathological and esthetic principles must be respected. The advantages of an implant-supported pros-

thesis is due to the fact that the patient gets easily accommodate to the artificial substitute, the comfort is superior, and the restoration of the functions is easily achieved.

The success of this solution is reached if the indication for implant therapy was correctly established and bridges were realized according to the clinical particularities of the case. These conditions are accomplished if there is a good collaboration between the implantologist, prosthetic specialist and dental technician.

NEWS

INCREASED INTEGRATION OF EXTRACELLULAR DNA IN THE ENVIRONMENTAL METAGENOME IN THE PRESENCE OF MUTAGENS LIKE BROMOACETIC ACID

A study by Mantilla-Calderon D *et al.* demonstrated that bromoacetic acid can increase transformation rates in microorganisms. Bromoacetic acid is a drinking water disinfection byproduct. Natural transformation allows for the uptake and integration of foreign DNA, which is a form of horizontal transfer of genes. This can be responsible for the acquisition of virulence and antibiotic resistance. The model microorganism used in the study was *Acinetobacter baylyi* ADP1. The transformation rate in this study was dependent on concentration of bromoacetic acid and its ability to cause DNA damage. Thus, transcription of recA gene was enhanced by 20 to 40%. This, in turn, facilitates the integration of extracellular DNA within the acceptor bacterial cell during DNA repair (Mantilla-Calderon D, Plewa MJ, Michoud G, Fodelianakis S, Daffonchio D, Hong P. Water disinfection byproducts increase natural transformation rates of environmental DNA in *Acinetobacter baylyi* ADP1. *Environ Sci Technol* 2019; 53(11): 6520-6528.

ELASTOGRAPHY, PROGRESSION FACTOR IN LIVER ULTRASOUND (ABSTRACT): Elastography is a method which,using ultrasound, obtains images and measurements of tissue elasticity when applying a force on it. As an imaging method it was developed to quantify objectively the pathological changes related to the presence of an abnormal tissue, compared to the surrounding tissues, giving information about the elasticity/stiffness of the examined tissue, the degree of fibrosis, the degree of stiffness compared to tumor free tissue. The tissue analysis can be done through a compression technology "*eSie touch* elasticity imaging" (with applications for the surface elastography) or *ARFI* technology – "acustic radiation force imaging" (the diffusion impulse of the acustic force). The *ARFI* method allows valid, accurate and flexible evaluation of liver stiffnessand it is correlates with the fibrosis stage. The liver elastosonography, through new technologies available, has reached the level of the fibroelastoscanner and magnetic resonance imaging. The ultrasound elastography application quickly advances, starting with the researches in this field. At present, it has analised the most various fields of application, from the breast, prostate, thyroid, pancreas imaging to the study of abdominal lymphnodes and peripheral vessels, gastrointestinal stromal tumors, primary and secundary liver tumors, the evaluation of uterine cervix, from cardiology to gastroenterology and urology, both in adults and in pediatrics. **Key words**: ELASTOGRAPHY, ULTRASOUND EVALUATION, IMAGING METHOD

The ultrasound evaluation is a non invasive, unpainful, repetitive investigation method which allows to have a good exploration of the tissues and organs, especially in children, where the patient's compliance is different from the adult's, often much lower.

Beside the simultaneous multichannel processing of information, the panoramic and harmonic ultrasound, the *elastography* is a new way of representing the ultrasonography information, a noninvasive evaluation concept of tissues nature (1,2). The method consists of applying a longitudinal pressure on a tissue and displacement measuring reflectance of the tissue nuclei. The representation of these displacements through colors, allows an information extract, which, in the end, facilitates the differentiation with high probability of benign from malignant tissue (2).

The method initially started and deve-

loped as applications on breast, but now it has applications in liver, prostate, thyroid, abdominal lymphnodes, peripheral vessels, myocardial and other directions of clinical application (3).

The ultrasound elastography reffers to ultrasound methods which can produce images or measurements of tissue elasticity - the ability to resist to deformation, deformations of tissues to the application on its strengths. The force applied to the tissue can be of several types (4) :

- the force applied by the ecografist's hand ;
- the force applied by an external mechanical device ;
- the force given by the physiological movements of the human body- breath, the cardiac activity, pulsed movements of large arteries ;
- the force applied by a certain ultrasound issued by the ultrasound probe which makes the exploration itself.

The response to the application of this force will vary according to the tissue elasticity.

The elastography as an imaging method was developed in order to objectively quantify the pathological changes related to the presence of an abnormal tissue, compared to the surrounding tissues (5). This new method of diagnosis gives informations related to the elasticity/stiffness of the examined tissue, degree of tissue fibrosis (eg. pre-stage liver cirrhosis), respectively the degree of stiffness of a tumor tissue compared to the free one, with promising results to differentiate between benign and malignant lesions or in assessing the tissue changes over time (4).

The manual palpation or the subjective "palpation" through ultrasounds was used for many years in order to give a qualitative assessment of the tissue stiffness, but the need to obtain a direct image led to the development of elastography (4).

The mechanical properties of the soft tissues which depend on their content, include elastic modulus (Young'modulus), Poisson's report and the shear properties of the tissue**.** These properties totally differ from the elastic modulus which governs the propagation of the ultrasounds. For example, the normal breast tissue is stiffer than the one made of fibroadenoma, and the breast cancers have shown how to shear up to seven times higher than in the normal tissue**.** The imaging potential resulted from this high contrast led to the development of some ultrasound investigation methods (4).

For these different approaches there have been developed :

1. The application of low frequency vibration energy and concomitant Doppler detection of the wave disturbance ;
2. Image of local response to a load applied to estimate the parameters by direct comparison between pre and post data compression ;
3. The calculation of these parameters.

This new ultrasonographic diagnosis method is not available using the conventional sonographic image and it represents the most important development in the ultrasounds technique since the appearance of the Doppler images. The information related to the tissue stiffness is complementary and independent of the information related to the acoustic impedance provided by the B--mode image (grayscale) and the one related to the vascular flow provided by the Doppler in age. Technically described since the last decade, the method was introduced just at the beginning of 2008, as an application of the latest ultrasound devices which include a wide range of analytical applications related to tissue strain or request and which allow visual qualitative and quantitative measurements of the tissue stiffness/ elasticity (6).

The extent of the tissue analysis can be done by two different technologies :

- Compression elastography "*eSie touch* elasticity imaging" (with applications

for the surface elastography – Real time exploration especially the breast. The aquisition of radiofrequency (RF) signals durind compression or because movements of inspiration/expiration, allows obtaining images generated by the tissue tension, which is proportional with its stiffness (4) ;

- An other example is *ARFI* – "acustic radiation force imaging" (the diffusion impulse of the acustic force)in which an acustic impulse is triggered in the tissue in order to assess/ interogate the mechanical properties of the tissue stiffness/ elasticity. The waves propagate like waves sideways when throwing a stone in the water. It has 2 possibilities of evaluation :

– *Virtual touch tissue imaging* – a method through which a diagram of the tissue stiffness is obtained, with a gray scale (reverse as the classical examination 2D) ;

– *Virtual touch tissue quantification* - through which it is appreciated the speed of the transverse propagation of the waves triggered, allowing the quantification of the tissue elasticity.

The *ARFI* method does not impose a certain degree of compression on the tissue, done by the examiner and which can vary (by hand fatigue), but it takes over the patient's respiratory movements, which means rhythmic and constant movements**.**

By means of the elastography using compression it can assess just the superficial tissues, while with the ARFI method the tissue elasticity can be assessed starting with a depth of 1.5 cm up to 8 cm.

Unlike the conventional sonography B--mode which gives us anatomical details based on differences in the acustic impedance, the Virtual Touch image describes properties reffering to the tissue stiffness . In this respect, the Virtual Touch image is closer to a tissue evaluation through a physical palpation than through the conventional ultrasound evaluation.

There are three steps in the process of Virtual touch acquisition :

- First an ultrasound image B-mode is obtained ;
- Then in a very short time (aproximatively 100 microseconds) a push impulse is given ;
- The issued impulse produces a displacement force, depending on the tissue's properties where it moves (so, in a soft tissue the waves move quickly, but in a stiff tissue it moves less or not at all). After the pushing pulse stops, the tissue relaxes and returns to its original shape. The captured ultrasound waves at a time are compared with the reference image, thus calculating the tissue displacements resulted from the pushing force (6).

VIRTUAL TOUCH TISSUE IMAGING (VIRTUAL TOUCH)

An image of the Virtual Touch soft-ware is actually a qualitative gray-scale map of the relative tissue stiffness (elastograma) for a user defined ROI (the region of interest). This information is calculated by examining the relative displacement of the tissue elements due to an acoustic pulse push. Thus, on elastograma the shining regions correspond to the tissue which is more elastic (less stiff) and the dark regions correspond to the stiff tissue.

If an image of the Virtual Touch soft--ware and a conventional image in B-mode are displayed together, the apparent limits of the tissue can differ, because the production of images is done through different mechanisms (6).

THE ADVANTAGES OF THE VIRTUAL TOUCH SOFT

The elastography methods previously available needed manual compression of the tissue or were based on the physiological needs of the body (cardiac activity, respiratory movements, and so on). These approaches

could limit the depth of the image location and easing the artifacts.

The application of the Virtual Touch soft allows an image by the independent combination of the multiple axial lines, obtained from the information of the tissue dislocation, starting with the left axial line within ROI, the tissue being described through a conventional ultrasound signal. Then, a push impulse is applied along this line, the captured conventional radiation being applied along the same line in order to obtain the signal of the dislocated tissue. Thus we can calculate the differences in tissue position every point along the axial line, between relaxation and compression (6).

The calculated differences are related to the maximum tested at a spatial location of tissue due to the tissues elastic properties in that area. The more elastic a tissue is, the bigger its dislocation is. The process above is repeated for each axial line within ROI as it is with a conventional B-mode scanning. Finally, all the calculated dislocations all over ROI are transformed in elastograma, describing the relatively tissue stiffness.

Generally, the stiffer the tissue is, the bigger the wave velocity is as it passes through this region. Overall, the measured speed of the wave is an intrinsic tissue property, which can be reproduced. The cut waves are generated and pass the tissue perpendicular, as some small waves resulted by throwhing a pebble in a pond. In contrast with the classical ultrasound waves axially oriented, the cut waves do not interact directly with the convertor. Besides this, unlike the conventional ultrasound waves, the cut waves are attenuated aproximately 10.000 times faster and thus needing a higher measurement sensitivity. Still, as the wave which is cut in front passes through the tissue, the generated dislocations are detectable, using ultrasound captive waves. Observing the front wave in more locations, and correlating these measurements with the past tense, the speed of the cut wave can be quantified (6).

VIRTUAL TOUCH TISSUE QUANTIFICATION

The *ARFI* technology can be used to measure a numerical value of the wave speed, by implementing the Virtual Touch tissue quantification.

For the Virtual Touch tissue quantification, first, it is identified an anatomical area using a ROI situated on a conventional image obtained through ultrasounds. An impulse of acoustic pushing is applied laterally, inducing a wave-cut which goes through ROI. The captured radiation, sensitive to more than 1/100 sound wave length, is applied adjacent to the push impulse. These radiations are continuously transmitted until the wave cut front is detected. The time between the cut-wave generation and the peak detection is used to calculate the speed of the cut wave. Multiple measurements are done for a given spatial location, for the reported value to ensure the quality measurement (6).

The tissue image and the Virtual Touch quantification is the first and the only implementation of the acoustic radiation image generated by the pulse force, which can be used with the conventional ultrasound in researches about the density and elasticity of the liver tissue. By this way, the previous elastography evaluations which were difficult and with variable results, become correct and practical (6).

It is important the fact that the technique of the Virtual Touch programme brings new information about the tissue, which can be used for diagnosis and in the therapeutic clinical applications.

CLINICAL APPLICATIONS OF THE ELASTOGRAPHY

The researches related to the ultrasound elastography quickly advances and the techniques utility too. At present, it is analised in the most various fields, from cardiology

to urology and gastroenterology, in adults and children too. Elastography begins trial in clinical practice and as a tool for cancer diagnosis (7).

Elastography was used in different studies to obtain images in vivo of the prostate and in the breast imaging, to view the elasticity of different tissues and to determine different degrees of stiffness, being able to distinguish the malignant tumor tissue from the benign tumor tissue. The researchers managed to classify correctly the lesion of the prostate using this technique (8,9).

The usefulness of this technique has been interes aroused also in the exploration of malignant tumors of the cervix and thyroid (10,11,12,13,14,15).

Elastography may be used in transvaginal ultrasound assessment of the female pelvis (16). There are only a few reports in the literature on the in-vivo use of real-time transvaginal elastosonography in the field of gynecology, being a promising tool that can provide detailed mapping and characterization of uterine fibroids, that could improve the gynecological ultrasound evaluation of size, volume and delineation of uterine fibroids before surgery or embolization (16,17).

The combination of elastography with highly sensitive conventional B-mode sonography has the potential to further improve the diagnosis of metastatic enlarged cervical lymphnodes (18).

Thyroid elastography is useful to make a correct differential diagnosis between malignant and benign thyroid nodules (10,11, 12,13,14,15).

This method of ultrasound exploration is used in the evaluation of superficial lymphnodes stiffness, too (10,11,12,13,14,15).

USING ELASTOGRAPHY IN HEPATOLOGY

Elastography of the liver through new technologies available, has become comparable to fibroelastoscanner (for assessing liver fibrosis) and to the nuclear magnetic resonance.

Normal liver tissue is soft and flexible. With inflammation, however, many of the cells die and are replaced by collagenous fibrils and the tissue gets stiffer. The process is often slow-extending over decades in many cases. Precise, noninvasive measurement of liver stiffness, a simple application of elastography, promises to be a safe, inexpensive method to monitor the progress of liver patients (19).

Real-time elastography is a noninvasive method based on use of ultrasounda promising in preoperative assessment of liver fibrosis in chronic hepatitis, in nonalcoholic fatty liver disease (NAFLD) and in cirrhosis (20,21).

Elastography imaging of the small liver nodules in cirrhosis might be used as a non-invasive tool for accurate diagnosis, as well as selection of patients for curative therapy, but not for screening. Its utility in patients with non-vascularised nodules, can help to eliminate the false negative diagnosis of contrast enhanced imaging of the liver and to improve their outcome. Real-time elastography is a promising sonography--based noninvasive method for the preoperative assessment of liver fibrosis both in liver diseases with considered fibrosis and in cirrhosis, having a highly sensitivity and specificity. It is considered fibrosis if the media of 3-5 successively determinations in the same area is over 2 (21,22).

Real-time elastography is a promising method for the non-invasive diagnosis of early hepatocarcinoma. Blue color at elastography and hypervascular aspects are independent predictors of hepatocarcinoma (22, 23).

THE ARFI ELASTHOGRAPHY METHOD IN HEPATHOLOGY

The new ultrasonographic method of *ARFI*

elastography allows valid, accurate and flexible evaluation of liver stiffness. Elastography of the left liver lobe is also possible which may be especially helpful in obese patients (24).

ARFI allows SWV quantification (SWV--shear wave velocity), in strong correlation with the fibrosis stage. Steatosis does not influence SWV (24,25). The maximal performance of the method consists of the prediction in severe fibrosis and cirrhosis. The diagnostic accuracy is strongly comparable to transient elastography only for the prediction of severe fibrosis and cirrhosis, whereas for earlier stages, TE performs better (25).

Both *ARFI* and TE have excellent predictive values in the presence of the cirrhosis, even if the liver elasticity determined by TE better correlates with the histological fibrosis in patients with chronic liver disease HCV and HBV (with hepatitis C, respectively B), compared to the values obtained through *ARFI* (26).

ARFI elastography has very good accuracy for the assessment of liver fibrosis and is superior to other noninvasive methods (APRI Index, FibroMax) for staging liver fibrosis (27).

Images obtained with ARFI elastography provided additional qualitative information regarding the stiffness and tumor margin of liver tumors. By measuring shear wave velocity, the quantification of stiffness was made possible and showed the potential to differentiate malignant hepatic tumors from hepatic hemangiomas (28).

CONCLUSION

Using conventional real-time ultrasound equipment with modified software (for example *virtual touch tissue imaging, virtual touch tissue quantification şi eSie touch elasticity imaging*), elastography has been reported to be useful for differentiation and characterization of various malignant tumors, such as breast, prostate, thyroid, pancreas, lymphnodes, gastrointestinal stromal tumors, primary and secundary liver tumors, the evaluation of uterine cervix (23).

DIGITAL DENTISTRY (Abstract): The age of full digital dentistry is a new concept, specific to the latest trends of aesthetics, providing superior innovation power in order to reach this goal. In today's world, technological advancements are far from being limited to specific fields. Oral diseases affect a large category of people physically and psychologically, influencing how they look chew, speak, integrate into the social life. Dentistry is witnessing phenomenal innovations, transforming people's smiles and lives in each and every way. Prosthodontic dentistry deals with the science and art of restoring teeth, both functionally and esthetically. The diversity of cases exposes the practitioners to a wide range of clinical situations and treatment solutions. The replacement of lost teeth with prosthetic appliances may sometimes be a problem for the clinicians, due to the esthetic requests. Among the multiple choices of techniques available for a suitable rehabilitation, the CAD/CAM techniques represent an ergonomic and minimal discomfort solution for the patient, representing a revolutionary method of oral rehabilitation. All stages of each dental treatment should benefit from the very latest technology and best products so the final result being characterized by efficiency and durability. **Keywords:** DIGITAL DENTISTRY, CAD/CAM TECHNOLOGIES, INTRA ORAL IMPRESSION.

Visionaries have long dreamed of digital intra oral impression, then sending the optical impression by e mail, and having their work designed and executed by a trained dental technician in his remote laboratory. The contribution of the dental team on treatment planning, managing the oral health and the interaction with the patient's demands will remain relevant regardless of technology changes. Professional exchanges are important for the advancement of digital dentistry. The CAD/CAM technologies, are constantly moving in new directions, to provide exciting, innovative products and systems, with the highest quality standards. Thanks to CAD/CAM technologies, perfect clinical restorations can be achieved, with no biocompatibility secondary reactions and excellent esthetic appearance, through a digital cooperation between dentists and dental labs. CAD/CAM technology allows the realization of a well-fitting, aesthetic, and durable prosthetic appliances. CAD/CAM complements earlier technologies used for these purposes by any combination of increasing the speed of design and creation; increasing the convenience or simplicity of the design, creation, and insertion processes; and making possible restorations and appliances that otherwise would have been infeasible. Other goals include reducing unit cost and making affordable restorations and appliances that

otherwise would have been prohibitively expensive. However, to date, chairside CAD/CAM often involves extra time on the part of the dentist, and the fee is often at least two times higher than for conventional restorative treatments using lab services. CAD/CAM is one of the highly competent dental lab technologies. CAD/CAM used in dentistry is based either on subtractive processes such as CEREC technology or additive processes, such as 3 D printing to produce restorations from 3d models to the final prosthetic substitute.

The 1980s represented the first use of CAD/CAM in dentistry. The technique was efficiently used in dental offices and dental laboratories. Chairside CAD/CAM restoration differs from conventional dentistry in that they are fixed in the same day, conventional prosthesis being cemented or bonded in place after a longer period of time. CAD/CAM systems use an optical camera to take a virtual impression, generating a digital cast. A 3D image is forwarded to a software program that can turn the captured images in order to produce and design the prosthesis.

Combining CAD/CAM software with 3D images from 3D imaging system means greater safety and security from any kind of intraoperative mistakes.

Typically, CAD/CAM dental restorations are milled from solid blocks of ceramic or composite resins or zirconia. If the CAD/CAM restorative material is Zirconia the restoration is “radio-opaque”, blocking X-rays. Only alumina, lithium disilicate materials are “radio-lucent” (1, 9). According to the used material, CAD/CAM pieces may have some aesthetic drawbacks, whether they are created at the dental practice or into a dental laboratory fabricating center. Depending on the dentist or technician, CAD/CAM restorations can be layered and baked or sintered in order to get a deeper more natural look.

Stains and glazes can be added to the surfaces of the milled ceramic crown or bridge to correct the otherwise monochromatic appearance of the restoration. The restoration is then adjusted in the patient’s mouth and fixed in place (2, 3).

CAD/CAM has improved the quality of prostheses in dentistry and found a way to standardize the production process. It has increased productivity and the chance to work with new materials with a high level of accuracy. It has also found a way to decrease chair time for the patient by the use of intra-oral scanning systems which allow the dentist to send electronic impressions to the lab. CAD/CAM requires a large initial investment. Despite the CAD/CAM being a major technological advancement, it is important that the dentists’ technique is suited to the methods of CAD/CAM and milling technology. This includes correct tooth preparations with a continuous preparation margin (which is easy registered by the scanner); avoiding the use of no shoulder preparations and parallel walls and the use of rounded incisor and occlusal edges to prevent the concentration of tension. Similar to the conventional restorations, CAD/CAM pieces present different aesthetic value, many presenting only one shade. In order to create a higher aesthetic appearance feldsphatic porcelain is fused to glass-infiltrated aluminum oxide (alumina) or zirconium-oxide (zirconia) (11). For the veneered crowns and bridges, the porcelain is layered onto a metal framework and often the color is influenced by the presence of the dark oxide lines related to the gum line. So, metal-free restorations are typically more aesthetically according to the patient expectations.

Fit accuracy varies according to the

CAD/CAD system utilized and from user to user. Some systems are designed to attain higher standards of accuracy than others and some users are more skilled than others (4).

There are different systems in use: the 3 Shape TRIOS reinvents the digital impression registration. Featuring color digital impressions, shade measurement and HD photos, TRIOS@ PACKS precision and speed into an easy to use, powder-free scanning solution. Enhanced detail capture makes it simple to identify preparation margins and evaluate the clinical situation, while shade measurement instantly identifies teeth shades as we scan. HD photos realize the documentation for each case, esthetic capture and visualize the solution for the patient. The 3 Shape Dental System offers technology-leading dental scanners for 3 D scanning of both physical impressions and gypsum models. The high-speed scanners have the capability to provide the accuracy and detail required for full-arch bridges and implant bars. The full integration with the design software ensures the optimal scan-to-design workflow. 3Shape Dental System™ is known throughout the dental industry as the most powerful CAD CAM design system in the world, supporting familiar workflows, providing the market's most comprehensive dental indication support (5, 6).

An important aspect is represented by the presence of the Sirona Connect portal, which links dentists and dental technicians in a very modern way, so they can exchange data conveniently and securely via the portal. The portal interface is integrated into the dentist's and technician's software, regardless of which software version is being used by either party, thus greatly facilitating workflow.

The 3D scanners and the CAD CAM software solutions are designed for the creation, processing, analysis and management of 3D data for application in complex manufacturing processes.

The benefits of CAD CAM systems are related to:

- the registration of a digital impression and ordering the restoration online, quickly and easily via the global portal as the Sirona one
- high cost-effectiveness of investment due to:
- extremely wide range of applications and material versatility
- maximum precision for all results combined with easy handling
- high flexibility and future security due to open CAD/CAM interfaces, a diversity of possibilities of integration and the possibility to process additional materials.

It is estimated that many new systems are expected to be present on the domain in the next few years. In the last decades the use of 3D printing techniques for medical and dental applications highly developed. Additive manufacturing is gaining rapid potential in nearly all dental fields It differs from formative and subtractive manufacturing as in the additive manufacturing process the object is "printed" by adding the building material layer by layer The application of the 3D printing in dentistry offers the possibility of individualized prosthetic appliances, savings on small scale productions, eased sharing and processing of patient image data and educational upgrading.

The entire process of additive manufacturing technology can basically be divided into four steps: creating a digital 3D model designed with a software or using intraoral scans or computed tomography data, processing and slicing of the 3D model into many two-dimensional layers, printing the 3D end product layer by layer, post-processing of the printed object. This basic

workflow can be applied for the different printing technologies, using a wide range of materials as polymers, metals or ceramics.

Advancement in digital workflow makes it possible to directly print the prosthesis from silicone providing acceptable esthetics and reducing the number of appointments for the patient at the same time.

Minimizing the treatment time and number of appointments is not only favorable for the patient but also precludes the complications and it is possible to achieve the preferred treatment outcomes with expedition of the whole procedure. Another advantage is represented by the leading of an excellent intraoral fit of the prosthetic appliance (7, 8).

Although clinical studies presented patient satisfaction using this technique, further groundwork is required with regards to the stability and comfortable design of the 3D-printed prosthetic restorations.

The importance of 3D documentation in prosthetic has been noticed since the last decade. Plaster models have now been replaced by digital information and data. This does not only solve the bulk storage problems often faced by clinicians, but also opens a new horizon of education and research. Rescuing the patient from repeated exposure to ionizing radiation, 3D-printed models have been used to establish new theorems and relationships between alveolar area and the remaining teeth. In the future it will be possible to use real patient additively manufactured dental models based on intraoral scans or cone beam computed tomography (CBCT) for training fixed and removable prosthetic to dental students (10).

Dental specialists should seek an entire ethical equilibrium of how to get and maintain optimal oral health, being open-minded, compassionate but also expecting the unexpected.

UNIQUE MONOBLOCK LUNG RIGHT-LEFT, UNIQUE PLEURAL CAVITY (Abstract): A 34 years old female with WPW syndrome has been under surgical treatment in our clinic with left basal chronic pleural empyema. During the surgical intervention multiple anatomical anomalies were detected, like unique pleural cavity, monoblock lung left-right, hypoplasic left lung, no scissures on the left side, no left pulmonary arteria with an aberrant arteria for the left lung derived from the right pulmonary arteria, the same for the bronchis. The pleural-pulmonary shelling proceeded without incidents and it has been finalized with the drainage of the whole pleural cavity. **Key words**: MONOBLOCK LUNG, UNIQUE PLEURA

EVALUATION OF ANTI-INFLAMMATORY ACTIVITY OF NITRO-L-ARGININE METHYL ESTER DERIVATIVES WITH THIAZOLIDIN-4-ONE SCAFFOLD

EVALUATION OF ANTI-INFLAMMATORY ACTIVITY OF NITRO-L-ARGININE METHYL ESTER DERIVATIVES WITH THIAZOLIDIN-4-ONE SCAFFOLD (Abstract): This paper is focused on the evaluation of the anti-inflammatory potential of some novel nitro-L-arginine methyl ester derivatives with thiazolidin-4-one structure, synthesized by our research group. **Materials and methods**: The evaluation of the anti-inflammatory potential was performed using *in vitro* assays: human red blood cell membrane stabilization (HRBC) and inhibiting bovine serum albumin denaturation (BSA) assays. **Results**: The obtained results showed that both stability of the erythrocyte membrane and inhibition of bovine serum albumin (BSA) denaturation, as parameters of anti-inflammatory effect evaluation, depend on the structure and concentration of the tested compounds. The most active derivatives were the compounds in which the aromatic ring from 2-position of thiazolidine-4-one scaffold is unsubstituted (**2a**) and halogen-substituted (with 4-chloro – **2c**, and 4-bromo– **2e**). **Conclusions**: The most favorable influence was obtained by the aromatic substitution with *chloro* and *bromo* in para position, the corresponding derivatives being the most active derivatives compared to diclofenac, used as anti-inflammatory standard. **Keywords**: L-ARGININE, THIAZOLIDINE-4-ONE, ANTI-INFLAMMATORY ACTIVITY, *IN VITRO* ASSAY.

INTRODUCTION

L-Arginine is considered as a semi-essential or conditionally essential amino acid depending on the stage of development and the individual's health (1). This amino acid is a precursor for polyamines, proline, glutamate, creatine, agmatine, and urea and, also functions as a precursor for protein synthesis and as substrate for several enzymes. It plays a critical role in several physiological processes, exerting antioxidant and anti-inflammatory effects and also serving as a precursor for nitric oxide (NO), a well-known vasodilator (2). Literature indicates that thiazolidin-4-one is a significant scaffold with medicinal relevance. Thiazolidin-4-one ring is susceptible for chemical modulations in positions 2, 3 and 5. Such modifications facilitate the search for novel compounds with desired activity (3). Upon modification

with various substituents, it exhibits a broad spectrum of biological activities, including antioxidant, antimicrobial, anticancer, and anti-inflammatory effects (4, 5).

Inflammation is the result of an oxidative stress that attacks the cells and prevents them from functioning normally and is a component of several types of diseases; therefore, the investigation of the anti-inflammatory action has an important role in the biological action assessment of different substances.

Based on these considerations, the aim of this paper was the evaluation of the anti-inflammatory properties of new compounds derived from the methyl ester of nitro-L-arginine (H_3C-OCO-Larg-NO_2), using *in vitro* assays, based on spectrophotometric methods.

MATERIALS AND METHODS

Nitro-L-arginine methyl ester (H_3C-OCO-Larg-NO_2) derivatives with thiazolidin-4-one scaffold (**2a-j**) (fig. 1) were synthesized by our research group (6). The standard reagents used for the anti-inflammatory activity tests: saline phosphate buffer pH 7.2, sodium chloride (NaCl), dimethylsulfoxide (DMSO), bovine serum albumin (BSA), sodium diclofenac, were purchased from Sigma Aldrich Company and Fluka Company, and they were used as received, without further purification. **Apparatus**: The absorbance measurements were read using microplate reader Tecan Austria GmbH Sunrise Remote with Magellan software and UV-Vis Spectrophotometer GBC Cintra 2020 V4166 with Cintra software.

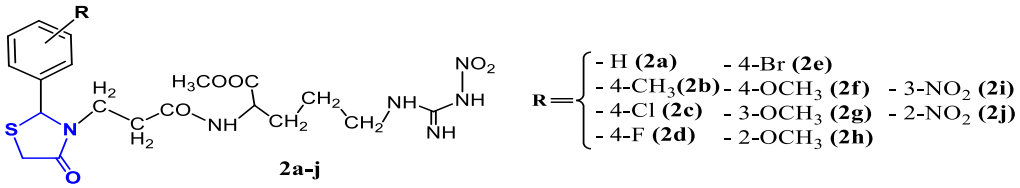

Fig. 1. Structure of H_3C-OCO-Larg-NO_2 derivatives with thiazolidin-4-one scaffold **(2a-j).**

1. Human red blood cell membrane stabilization (HRBC) assay. In order to obtain the erythrocyte suspension 10% (v/v) (HRBC suspension), blood from healthy volunteer was collected on citrate anticoagulant, and then washed (3 times) with 0,9% NaCl, centrifuged at 3000 rpm, followed by the removal of the supernatant. For each tested compound **(2a-j)** and reference drug (sodium diclofenac) a stock solution of 1 mg/mL was prepared by dissolving in DMSO. To prepare serial dilutions, from each stock solution different volumes (30 µL, 60 µL, 120 µL) were measured and 0.85% NaCl was added up to a volume of 1000 µL.

Finally, a volume of 250 µL from serial dilutions was measured, and added to a mixture of 500 µL phosphate buffer (pH = 7.4), 450 µL hyposaline solution (0.36% NaCl) and 300 µL HRBC solution (10% v/v). The hemolysis control sample was prepared by adding instead of 450 µL hyposaline solution (0.36% NaCl solution), 450 µL bi-distilled water, to which was added 250 µL 0.85% NaCl, 500 µL phosphate buffer (pH = 7.4) and 300 µL HRBC solution (10% v/v) - this representing the value of 100% hemolysis ($A_{\text{hemolysis control}}$) (7).

All samples (tested compounds - **2a-j**, reference – sodium diclofenac and hemolysis control) were incubated at 37°C for 30

min, and then centrifuged at 3000 rpm for 20 min. The absorbance of the supernatant was measured at 560 nm. The capacity of the tested compounds (**2a-j**) to maintain the stability of the erythrocyte membrane, expressed as a percentage of hemolysis inhibition (%), was calculated using the following formula (1):

% of hemolysis inhibition (% erythrocyte membrane stabilization) = $(A_{\text{hemolysis control}} - A_{\text{sample}}) / A_{\text{hemolysis control}} \times 100$ (9).

in which: $A_{\text{hemolysis control}}$ – absorbance of the hemolysis control;
A_{sample} – sample absorbance.

For each serial dilution a corresponding DMSO control was prepared using different volumes of DMSO (30 µL, 60 µL, 120µL) which were completed up to a volume of 1000 µL with 0.85% NaCl solution, then processed similarly to samples and which were used as a spectrophotometer reading blank for the samples. All determinations were performed in triplicate.

2. Bovine serum albumin denaturation (BSA) assay. For this assay a 1% (w/v) bovine serum albumin (BSA) solution in phosphate buffer (pH 7.2) was used. For tested derivatives (**2a-j**) as well as for the reference substance (sodium diclofenac) a stock solution of 1 mg/mL was prepared by dissolution in DMSO. To prepare serial dilutions, from each stock solution, different volumes (50 µL, 100 µL, 200 µL, 400 µL) were measured, and 0.85% NaCl solution was added up to a volume of 1000 µL.

Finally, a volume of 25 µL from serial dilution was measured, in a 96 well plates, and 225 µL of 1% BSA was added. A mixture of 25 µL 0.85% NaCl and 225 µL of 1% BSA was used as a control for albumin denaturation ($A_{\text{denaturation control}}$).

All samples (tested compounds **- 2a-j**, reference - sodium diclofenac and control) were incubated for 20 min at 37°C, then 5 min at 72°C, and finally cooled for 10 min. After that, the turbidity of each sample was read at 416 nm. The capacity of the tested compounds to inhibit the denaturation (precipitation) of serum albumin was calculated using the following formula (2):

% of inhibition of protein denaturation=$(A_{\text{denaturation control}} - A_{\text{sample}} / A_{\text{denaturation control}}) \times 100$ (8).

in which: $A_{\text{denaturation control}}$ – absorbance of the denaturation control;
A_{sample} – sample absorbance.

For each serial dilution a corresponding DMSO control was prepared using different volumes of DMSO (50 µL, 100 µL, 200 µL, 400 µL), which were completed up to a volume of 1000 µL with 0.85% NaCl solution, then processed similarly to samples and which were used as a spectrophotometer reading blank for the samples.

All determinations were performed in triplicate.

It was established that the lower absorbance, means a greater ability of the

sample to inhibit the thermally induced denaturation (precipitation) of proteins, respectively of BSA (11, 12).

RESULTS AND DISCUSSION

1. Human red blood cell membrane

2. stabilization test (HRBC assay)

The HRBC assay allow to evaluate the ability of the compounds to protect the erythrocyte membrane from lysis induced by hypotonicity (10). The effect of the tested compounds (**2a-j**) at different concentrations (5 µg/mL, 10 µg/mL, 20 µg/mL), on erythrocyte membrane stability, expressed as hemolysis inhibition (%), in reference with diclofenac, used as standard drug, are represented graphically in figure 2.

From the analysis of the obtained results it is observed that for all the studied compounds, the stability of the erythrocyte membrane increases with the concentration; the highest effect being reach at the concentration of 20 µg/mL. It was also noted that at concentration higher than 20 µg/mL, the stability of erythrocyte membrane slightly decreases. This could be explained in relation with the saturation degree of the permeability of erythrocyte membrane which can cause the lysis of the red blood cells' membrane. At 20 µg/mL the best results were obtained for compounds **2a**, **2c** and **2e**, for which the hemolysis inhibition (94.5% - **2a**, (93.46% - **2c**, 92.97% - **2e**) was similar with diclofenac sodium, at the same concentration (92.8%).

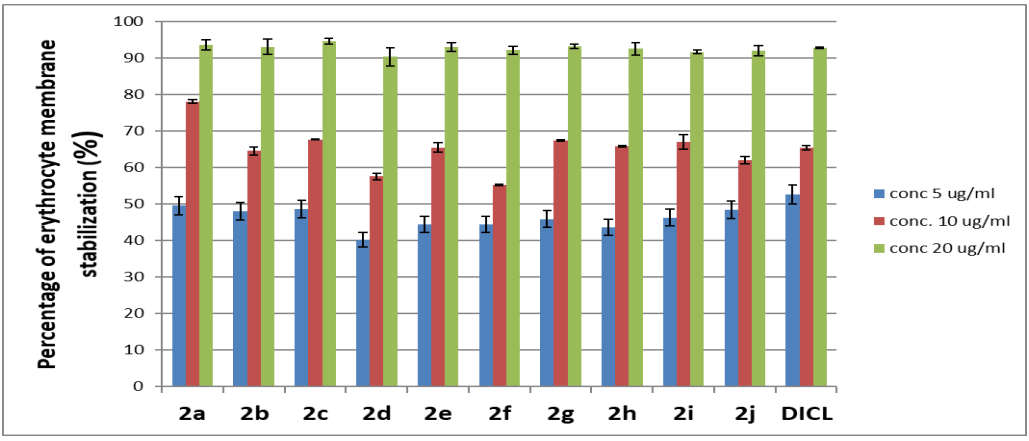

Fig. 2. Percentage of erythrocyte membrane stabilization of the compounds (**2a-j)** tested at different concentrations

3. *Bovine serum albumin denaturation (BSA) assay.*

Recent data suggest that tissue protein denaturation is among the causes of inflammatory and rheumatic diseases, through generation of autoantigens that can lead to *in vivo* protein denaturation. Upon heating, bovine serum albumin (BSA) undergoes a denaturation (precipitation) process with the release of antigens responsible for a number of hypersensitivity reactions. Thus, the agents that can prevent protein denaturation deserve to be studied later for the development of new anti-inflammatory agents (10). It is considered that any compound that has a percentage of protein denaturation inhibi-

tion of more than 60% can be further evaluated as a potential anti-inflammatory agent. A number of non-steroidal anti-inflammatory drugs, such as indomethacin, diclofenac, ibufenac, aspirin, flufenac acid, in addition to their ability to inhibit protaglandin synthesis in the inflammatory process (cyclooxygenase inhibition), have also shown appreciable ability to prevent BSA denaturation.

The inhibition percentage of BSA denaturation for tested compounds (**2a-j**) at different concentrations (5 μg/mL, 10 μg/ mL, 20 μg/mL, 40 μg/mL), in reference with sodium diclofenac, used as standard drug are represented graphically in figure 3.

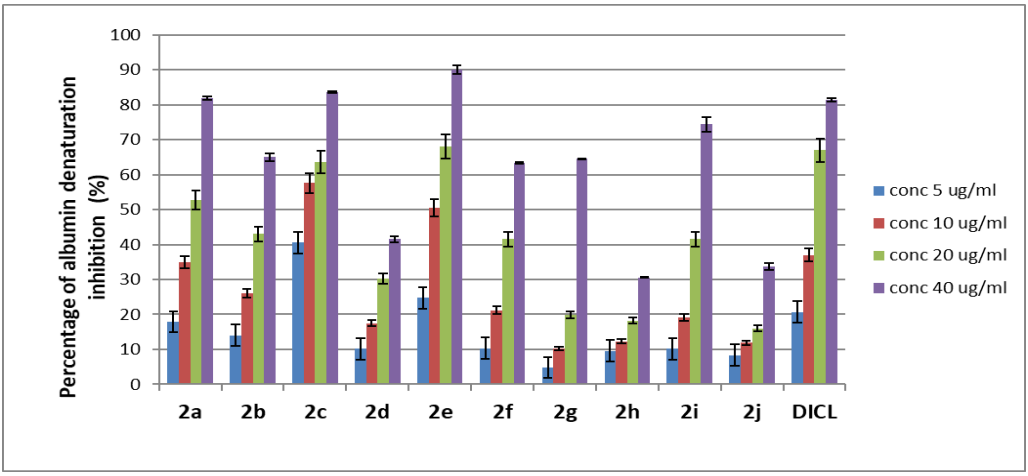

Fig. 3. The effect of the tested compounds (**2a-j**), at different concentrations, on inhibiting the BSA denaturation

From the analysis of the obtained results it is observed that for all studied compounds the inhibition of BSA denaturation increases with concentration, respectively the highest percentage of inhibition was obtained at the concentration of 40 μg/mL. At this concentration, the most active compounds were **2a**, **2c**, **2e**, for which the BSA inhibition (81.9% - **2a**, 83,65% - **2c**, 90.1% - **2e)** was higher than diclofenac (81.4%), used as a positive control at the same concentration of 40 μg/mL.

For both assays, HRBC assay and BSA denaturation assay, respectively, the 50% inhibitory concentration (IC_{50} μg/mL) was calculated from the dose response curve obtained by plotting percentage inhibition *versus* concentrations (tab. I).

The results confirmed that compounds **2a, 2c, 2d** which showed the best stability of the erythrocyte membrane and BSA inhibition denaturation, were slightly better than the positive control, sodium diclofenac. These results support that the compounds can prevent lysosomal membrane damage and thus impede tissue damage through hydrolytic enzymes provided by lysosomes. The lysosomal enzymes released during inflammatory condition produce a variety of disorders and they are related to acute or chronic inflammation. The anti-inflammatory agents act by either inhibiting the lysosomal enzymes or by stabilizing the lysosomal membranes (14, 15).

TABLE I.

IC_{50} value of tested compounds (2a-j) for in vitro anti-inflammatory effects.

No.	Compound	IC_{50} (µg/mL) – BSA assay	IC_{50} (µg/mL) – HRBC assay
1.	**2a**	12.21 ±0.34	4.17±0.18
2.	**2b**	26.36 ±0.41	6.23±0.54
3.	**2c**	9.22 ±0.22	4.05±0.11
4.	**2d**	55.4 ± 0.73	5.96±0.81
5.	**2e**	12.50±0.91	5.06±0.42

11.	**Diclofenac**	13.25±0.81	5.25±0.37

CONCLUSIONS

The anti-inflammatory potential of the new nitro-L-arginine methyl ester (H_3C-OCO-Larg-NO_2) derivatives with thiazolidin-4-one scaffold (**2a-j**) was evaluated by two *in vitro* methods - inhibition of BSA denaturation (BSA assay) and erythrocyte membrane stability (HRBC assay). The obtained results showed that both the inhibitory capacity of BSA denaturation and the stability of the erythrocyte membrane increase with concentration, respectively the best results were obtained at the concentration of 40 µg/mL in the BSA assay, respectively at the concentration of 20 µg/mL for the HRBC assay. The most active compounds were **2a, 2c, 2e**, which showed the best anti-inflammatory effect in comparation with sodium diclofenac, used as positive control.

CONFLICT OF INTEREST.

DIGESTIVE HEALTH AND FACTORS THAT IMPACT IT: AN OBSERVATIONAL CASE-STUDY OF THE PEDIATRIC PATIENTS HOSPITALIZED FOR GUT DISEASES AT A PEDIATRIC HOSPITAL FROM TIMISOARA, ROMANIA (Abstract): The **aim** of the study was to investigate whether personal, perinatal and early nutritional factors have an impact on digestive health. **Materials and methods:** An observational case-study was performed on a sample of 248 pediatric patients (51.2% males), admitted into a pediatric hospital over the course of two years. The gathered data (the prespecified gut diseases, personal, perinatal factors and early nutrition) from the patients` files were used to build a data base. Statistical analysis (binomial logistic regression) was performed with the aid of SPSS20 Program. Two statistically significant age-groups (0-3 years, 3-18 years) were considered. **Results:** Differences were revealed between the two significant age-groups: 0-3 years (predominance of: enterocolitis, gastroenteritis-GE, cow milk allergy-CMA, acute dehydration syndrome-ADS and bacterial diseases, females, caesarian section, breast feeding 0-2 months) and 3-18 years (predominance of: GE, ADS and parasitic diseases, males, natural birth, breast feeding over 12 months). The outcome variables were gut diseases (enterocolitis, GE, CMA, ADS), the independent variables were personal (gender, age, residence), perinatal (gestational age, delivery type), early nutrition (duration of breast feeding, milk formulas, diversification age). Statistically significant associations were demonstrated between: natural feeding 0-2 months (NF-2)-CMA (OR=13.51, p=0.007-entire sample, OR=7.48, p=0.002-age group 0-3 years), NF-2-enterocolitis (OR=5.47, p=0.005-age group 0-3 years), NF-2-GE (OR=0.185, p=0.009-age group 0-3 years). Age, residence and delivery type also related to gut diseases. **Conclusions:** There is an association between gut diseases as dependent variables and personal (age, residence), perinatal (type of birth) and early nutrition (NF-2) independent variables. **Keywords:** GUT DISEASES, PERSONAL FACTORS, EARLY NUTRITION, OBSERVATIONAL CASE-STUDY.

INTRODUCTION

Gut diseases are frequently found and they differentiate within the child population depending on etiology, localization and effects. In a study performed in The United States the results showed that two-

thirds of the surveyed Americans are burdened by gastrointestinal symptoms (1). There are gaps in our knowledge in understanding of infection/immunity throughout the human life cycle, focusing on focusing on early childhood growth (2). In the western region of Romania there is an increased burden of digestive pathology in pediatric patients, with an unknown area regarding factors that impact digestive health. In the performed study we aimed to investigate digestive health and factors that impact it in a population of pediatric patients hospitalized for gut diseases at a pediatric hospital in Timisoara, Romania, over the course of 2 years of study.

MATERIALS AND METHODS

The study was performed on a sample of 248 pediatric patients (51.2% males, aged between 1 day and 18 years) hospitalized at the "Pius Brinzeu" Clinical Emergency County Hospital Timisoara, Bega Clinic - Pediatric for gut diseases. The enrollment period was between January 1st, 2018 and December 31st, 2019. Each patient was hospitalized only once. It was a non-probability purposive sample, children with gut diseases being selected. Two age groups (0-3 years - 133 patients: 48.9% males), and 3-18 years - 115 patients: 53.9% males) and their recorded pathology gastroenteritis –(GE), enterocolitis, cow milk allergy (CMA), and acute dehydration syndrome (ADS) were considered in this analysis. The main inclusion criterion for the study sample was the hospitalized pediatric patients with diarrhea, vomiting or/and dehydration due to infectious or allergic disorders with location in the intestinal tract. Diagnoses of these intestinal diseases were collected from the children-patients` files. The exclusion criteria were: more than one admission and incomplete files.

The method consisted of an observational case-study (combined approach: cohort and cross-sectional) of the hospitalized pediatric patients for gut diseases during these two years of study. The primary medical records were gathered for this investigation. The gathered data (certain gut diseases, personal, perinatal factors and early nutrition) from these patients' files were used to build a data base. The agreement of the County Hospital Leadership was asked for and received in order to access primary medical records while I agreed to keep them confidential and to respect the personal data protection law. The medical data were already considered for medical and statistical purpose, with the requested and received individual consent of the patients. The agreement (no. 10/ 02.04.2019) of the "Victor Babes" University of Medicine and Pharmacy's Ethical Commission was requested and obtained for this statistical clinical study. All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments.

Statistical analysis was performed by the aid of software *SPSS version 20* (3). Binomial logistic regression used the dependent variable that consisted of only two nominal categories (absence/presence of one specific gut disease), and the independent nominal (categorical: personal - gender, age-groups according to developmental stages criterion and residence, peri-

natal factors - type of birth and gestational age, and early nutrition - duration of breast feeding, milk formulas and diversification age) variables that can be analyzed as possible predictors.

RESULTS

Gut diseases - by localization and etiology

Of the studied population 35% had enterocolitis and 29.9% gastroenteritis. At the age group *0-3 years* the most frequently were patients with enterocolitis (51.8%) and patients with GE (28.6%) and at the age group *3-18 years* the most frequently were patients with GE (31.3%).

Main gut diseases by *etiologies* were CMA (20.2%), bacterial (14.5% with: *E. coli* and *Helicobacter pylori*), parasitic (10.5% with: *Giardia lamblia, Toxocara canis and Enterobius vermicularis*) and viral (6.9% of patients with: Rotavirus and Adenovirus) diseases. At the age group *0-3 years* the most frequently met were CMA (34.6%) and bacterial diseases (15% of patients). At the age group *3-18 years* most frequently were found parasitic diseases (18.3%).

A generalized effect was ADS (31% of patients: 16.5% with gut diseases and 14.5% as result of other diseases). ADS was found in 27.8% patients aged 0-3 years, and in 34.8% patients aged 3-18 years.

Personal factors (gender, age-groups and residence)

The *gender* distribution in the two statistically significant samples chosen by *age groups* was: 0-3 years - 48.9% males, and 3-18 years - 53.9% males.

The most frequently admitted pediatric patients came from *urban* (58.9%), majorities of them living in Timisoara (50.4%). Patients who came from *rural* (38,7%) were less numerous and majorities of them came from Timis County (31%). Distribution on the statistically significant age groups of the pediatric patients considering urban/rural environment was: *0-3 years* (54.1% from urban, 48.9% living in Timisoara and 49.2% from rural environment, 38,3% living in Timis County) and *3-18 years* (64.3% from urban, 52.2% living in Timisoara and 33.9% from rural environment, 22.6% living in Timis County).

Perinatal factors (gestational age and delivery type)

Most frequently found *gestational ages* were 40 weeks (41.9% pediatric patients) and 38 weeks (20.6% pediatric patients). There was a high rate of caesarean *delivery* (41.5% pediatric patients). Distribution of the pediatric patients on the focused age-groups was as follows: *0-3 years* (natural delivery - 48.1%, caesarian - 48.1%, gestational age 38 weeks - 27,1%, gestational age 40 weeks - 34,6% patients), *3-18 years* (natural delivery - 53.9%, caesarian - 33.9%, gestational age 38 weeks - 13.9% and gestational age 40 weeks - 48.7%).

Early nutrition (duration of natural feeding, milk formula, diversification age)

Most frequent duration of the *breast feeding* was over 1 year (21.8%), 0-2 months (20.2%) and 2-6 months (19.8% of patients). Most used *milk formulas* were Nan, Aptamil and Humana (29.9%), followed by powder milk (15.3% of patients). Most frequently *diversification age* was at the 6th month (46.4%). Distribution of the pediatric pa-

tients considering *early nutrition* on the focused age groups was: *0-3 years* (breast feeding 0-2 months at 24.1% and breast feeding over 12 months at 20.3% of patients) and *3-18 years* (breast feeding over 12 months at 23.5% and between 2-6 months at 20%) for breast feeding.

Distribution of the pediatric patients for artificial feeding with *milk formulas* was: at age groups *0-3 years* - Nan, Aptamil, Humana (42.9%), powder milk (16.5%) and at age groups *3-18 years* - Nan, Aptamil, Humana (14.8%) and powder milk (13.9%).

Distribution of the pediatric patients considering *diversification* age was: at age group *0-3 years* (at the 6th month - 46.6%, at the 5th month 33.1% of patients) and at age *group 3-18 years* (at the 6th month - 46.1% and at the 5th month - 15.7% of patients).

High frequency (15% pediatric patients) of missing cases (no information) for early nutrition variables represents a limit of this study.

Prediction of gut diseases for entire sample

Residence resulted as a predictor for parasitic diseases with a decrease of these diseases in Timisoara (OR=0.11, p=0.001) and Timis County (OR=0.07, p=0.001). The model was 88.7% accurate.

A predictor for CMA was breast feeding with duration 0-2 months (OR=13.51, p=0.007, model - 84.2% accurate).

Prediction of gut diseases for age group 0-3 years

At the age group 0-3 years, binomial logistic regression indicated the breast-feeding duration 0-2 months as predictor for: GE (OR=0.185, p=0.009, model - 71.5% accurate), Enterocolitis (OR=5.476, p=0.005, model - 66.1% accurate) and CMA (OR=7.48, p=0.002, model - 67.9% accurate).

Association GE - gender (OR=3.619, p=0.019, model - 71.5% accurate) indicate a higher frequency of this disease at female than male patients. Associations of age with gut diseases indicate for Enterocolitis (OR=0.516, p=0.005, model - 62.3% accurate) and for CMA (OR=0.54, p=0.01, model - 66.2% accurate) a decrease with age increase.

Prediction of gut diseases for age group 3-18 years

At the age group 3-18 years delivery type was found as predictor for GE (OR=3.033, p=0.014, model - 68.1% accurate), which indicates an increase of GE for patients with natural delivery.

DISCUSSION

In the performed case-study a population of pediatric patients was investigated for gut diseases and factors that could impact them. First results indicated localization and etiology as being used in the diagnoses of this pathology. Therefore, enterocolitis, GE, CMA, microbial, viral and parasitic diseases were determined to be gut diseases. The highest frequencies of enterocolitis and CMA were found in pediatric patients aged between 0-3 years, and of GE in patients aged between 3-18 years. Previous studies have shown that Enterocolitis could be determined by sepsis or food allergies in infancy (4) and that the burden of acute gastroenteritis on children continues to be enormous (5). CMA is the most common food allergy,

especially in infancy (6). A generalized effect was ADS and predominated in patients aged between 3-18 years. In another study, most cases of ADS were clinically diagnosed (similar with our study) (7).

In the performed study, distribution of age-groups of the pediatric patients diagnosed with gut diseases was non-uniform when the information was collected from primary sources of evidence. More than half of the pediatric patients age was between 0 - 3 years. The necessity to adjust the investigation of GE to the age resulted in an empirical examination study of the 'pediatric gastroenteritis admission rate' indicator in Italy (8). In our study we considered age-groups (according to developmental stages criterion) when analyzed association with gut diseases for both samples.

The study involved a predominance of patients from an urban area for these two age groups. The loss of environmental biodiversity could be a public health threat as was concluded in another study (9). Caesarean delivery was more frequently (14%) at the age group 0-3years than at 3-18 years. Caesarean section is medically indicated. The concept of option arises from the fact that the regulations are more permissive in certain countries. The reasons why women opt for caesarean section were analyzed in another study and consisted of the fact that it is a pain-free method of birth and it is safe for both mother and baby (10). Early nutrition investigation of the pediatric patients in the performed study indicated natural (breast) and artificial feeding. Natural feeding duration was frequently found between 0-2 months for pediatric patients aged between 0-3 years, and over 1 year for pediatric patients aged between 3-18 years, suggesting a tendency to decrease the duration of breast feeding at 0-2 months. Human milk has potential effects on the infant, effects that will never be possible with the milk formula: it contains specific oligosaccharides that drive the growth of microbes within the gut (human microbiome), antimicrobial proteins/peptides that assure the immune protection (11). In the performed study, main milk formulas used for artificial nutrition were NAN, Aptamil, Humana and powder milk. These milk formulas predominated at the age groups 0-3 years and were used in the same measure with powder milk at the age group 3-18 years. Milk formulas proved to be useful against infections and to stimulate growth when they were symbiotic enriched (12).

In this study associations were found between gut diseases and certain personal (residence, age and gender), perinatal (delivery type) and early nutrition (breast feeding 0-2 months) factors. The most significant results of this study were obtained for association of gut diseases (GE, enterocolitis, CMA) with natural feeding duration (0-2 months) at the age group 0-3 years. Frequency of patients with GE decreases when frequency of patients with natural feeding duration (0-2 months) increases. On contrary, frequency of patients with Enterocolitis and CMA increase with frequency of patients with natural feeding duration (0-2 months) increase. Another study demonstrated that there are risks associated with all forms of infant feeding, including the breast feeding or use of manufactured milk formulas (13). CMA was proved to develop even when the child is breast feeding when the mother's diet con-

tains cow milk (14).

Other important predictors for gut diseases were age and residence. At the age group 0-3 years, Enterocolitis and CMA decrease with age increase. Residence was associated with parasitic diseases for entire sample, with a decrease of parasitic diseases in urban environment (9). Age proved to be an important factor in the study of digestive diseases in children (8). Delivery type was associated with GE, at the age group, 3-18 years, with an increase of GE for patients with natural delivery. Another study found that the mode of birth affects oral microbiota in infants, vaginally delivered infants having a higher number of taxa detected than infants delivered through caesarean section (15).

The discovered results were supported by research literature presented. A limit of this study is that it is an observational one.

CONCLUSIONS

The most frequently identified gut diseases in hospitalized pediatric patients are: enterocolitis, gastroenteritis and cow milk allergy. ADS is frequently found as a generalized effect of gut diseases. The most affected age group is 0-3 years. Personal factors (age and residence) are associated with gut diseases: age relates to enterocolitis and CMA. at the age group 0-3 years and residence relates to parasitic diseases for the entire sample. There is a weak association between delivery type and GE for age group 3-18 years. At the age group 0-3 years, there is a strong association between early nutrition factors (duration of breast feeding 0-2 months) and gut diseases: CMA, Enterocolitis and GE. As a general conclusion, there is an association between specific gut diseases and personal (age, residence), perinatal (delivery type) factors and early nutrition (natural feeding duration - 0-2 months).

PRINCIPLES OF OVERDENTURE ON ONE-PIECE NARROW DENTAL IMPLANTS IN PATIENTS WITH DIFFERENT PATTERNS OF MANDIBULAR RIDGE RESORPTION (Abstract). **Aim**: To highlight the particularities of mandibular overdenture on one-piece narrow dental implants in patients with two frequent and high-difficulty clinical situations, namely flat alveolar ridge (also known as severe ridge resorption, when mainly vertical bone resorption occurs) and narrow alveolar ridge (which in its most severe form has a knife-edge appearance, when mainly horizontal bone resorption occurs). Narrow implant overdenture is a treatment alternative that responds well to the most important reason of patient dissatisfaction with conventional denture, namely its instability, through a relatively minimally invasive surgical intervention followed by relatively simple prosthetic procedures. To obtain a good outcome, particularization according to patient features, such as the morphology of the alveolar ridge is recommended. Deciding upon implant type, number, site, and attachment system should be made in accordance with such factors as bone offer and morphology of the alveolar ridge, edentulous and prosthetic status in the maxilla, prosthetic space, and the need to improve denture stability and retention. **Keywords:** DENTURE, MINI DENTAL IMPLANT, MANDIBULAR EDENTULOUS, FLAT RIDGE, NARROW RIDGE.

Complete mandibular edentulism is frequently treated by complete dentures, treatment option that often does not ensure a good outcome in terms of proper prosthesis stability and retention, and patient satisfaction. This is linked to objective factors, such as increased treatment difficulty due to the loss of all teeth and consequent ridge resorption, and subjective factors, as psychologically rejection of conventional complete denture due to associating it with aging and limitation of social functioning. According to current perspective, the new minimal treatment standard for mandibular complete edentulism is stated to be the two-conventional implant overdenture, treatment alternative that addresses the main deficiencies of complete denture (1-3). The usage of the narrow dental implants is beneficial especially in the aged edentulous patients, with unfavorable morphological conditions for the conventional or implant prosthetic rehabilitation (4, 5). This treatment option is well-adapted to the

older patients' needs, as it addresses the main reason of dissatisfaction (increases prosthesis retention and stability), at moderate biological, financial and time costs, having also rather simple maintenance procedures and means of addressing possible complications (6).

The aim of this article was to highlight the particularities of mandibular overdenture on one-piece narrow dental implants in patients with two frequent and high-difficulty clinical situations, namely flat alveolar ridge (known also as severe ridge resorption, when mainly vertical bone resorption occurs) and narrow alveolar ridge (that in its most severe form has a knife-edge appearance, when mainly horizontal bone resorption occurs).

General coordinates of treatment planning and conduct

The following aspects are to be considered when planning for mandibular implant overdentures: accurate patient assessment, through anamnesis, clinical evaluation, panoramic radiographs, supplemented sometimes by lateral cephalometric radiographs and other investigations (7, 8); the number of narrow dental implants to be used, which vary, usually 2 to 4 implants being sufficient, a higher number being chosen when teeth or implant prosthesis are found in the maxilla, in younger patients (under 60 years), in those with a harder food diet, bruxism and a more obvious tendency to ridge resorption (fig.1); narrow dental implants sites, usually implants being placed in the interforaminal area, upon considering the bone density, width and height, and the prosthetic needs (a surgical template can be used for a more accurate localization of implant placement site); surgical technique of implant placement, by the usage of a flap technique (advantageous by the possibility to accurately evaluate bone width through direct assessment), or flapless technique (advantageous by the reduced invasiveness of the surgical procedure) (4, 9); loading protocol, which can be either an immediate loading protocol (i.e., immediate fixation of the metal rings in the overdenture base) or progressive loading protocol (i.e., soft lining materials were used as soft matrices during the osseointegration period); type of attachment system, which for one-piece narrow implants is usually O-Ring (e.g., miniSKY1 dental implants, Bredent; mini dental implants, IMTEC, later 3MESPE), some other variants being available (e. g., Locator, LODI implant system, Zest Anchors; magnet, Magfit, Aichi Steel Corporation)(10,11); overdenture design, which should aim to ensure adequate support, retention and stability, a complete coverage of the support area, in correspondence with the anatomical and functional borders, being usually preferred (a), should not exert pressure on the dental implants, when they are used only to increase retention, not for support (b), and should be made at correct intermaxillary relationship, providing a stable occlusion (c); previously made complete dentures can be either kept and transformed into overdentures (when considered satisfactory, this promoting a faster adjustment with the new treatment, aspect that should be considered especially in the elderly, known to have difficulty adapting to change, either preserved as interim prosthesis during the healing phase (when considered unsatisfactory, but not having severe deficiencies that may be risk factors for implant failure), either replaced before implant placement.

Fig. 1. Implant number varied according to the dentate status in the maxilla

One-piece narrow-dental implants for edentulous patient

Various types of dental implants can be used for implant overdenture, e.g. conventional or narrow, one-piece or two-piece design, for which different types of attachment systems are available. The one-piece narrow dental implants are mainly used in the completely edentulous elderly patients. Their narrow diameter is usually well-suited for them because of the severe bone loss and requiring minimally invasive surgical procedures. In this context, it should be mentioned that there isn't a well-defined cut-off point for differentiating the mini-, from narrow-, from conventional-diameter dental implants. Generally, there are considered narrow implants those with a diameter below 3.75mm. Therefore, the 2.8 mm dental implants, as mini SKY 1, are included in either mini-, narrow-, or hybrid-dental implant category. The narrow dental implants are generally manufactured in different lengths (e.g., miniSKY1 is available in lengths of 10 mm, 12 mm and 14 mm, and MDI form 3M ESPE in lengths of 10 mm, 13 mm, 15 mm and 18 mm), suiting both vertical and horizontal ridge resorption. The one-piece design, usually encountered, has some advantages, among which is the possibility to verify the primary stability of the implants through horizontal percussion, or to easily address implant loss by placing another implant (not requiring major interventions or replacing the prosthesis). Also, the use of O-ring attachment system has the benefit to allow an implant divergence, less of 30 degrees. The usage of the implants mainly targets increasing prostheses' retention and stability, and generally are not to be used for support.

Particularities of treatment conduct in patients with flat alveolar ridge

These patients usually have wider alveolar ridges that allow placement of larger diameter dental implants, but have a reduced bone height, which associates the need of use of shorter dental implants. This clinical situation is encountered more frequently in patients with the following characteristics: often old patients, with expectations mainly related to a solution for improving prosthesis retention by interventions that required minimal surgery, at moderate costs; patients complaining of poor denture retention and stability, and occasionally pain described as appearing under the dentures, main reason of dissatisfaction with conventional denture; many of them are long-time mandibular denture wearers, some of them having teeth or

fixed conventional or implant prosthesis in the maxilla (these being risk factors for severe ridge resorption);usually eating a soft diet, motivated by the masticatory deficiencies related to the ill-fitting dentures; the attached mucosa occasionally presents alterations related to the long-period of denture wearing, as reduced thickness, it becoming painful under the pressure exerted by the denture; soft peripheral tissue may exhibit changes that increase treatment difficulty, such as: herniation of sublingual glands; displacement of muscle and ligaments attachments closely to the ridge crest; posterior position of tongue during rest position; tongue hyperactivity (that is related to patient's functional particularities, prolonged wearing of ill-fitting dentures or involution phenomena); hypertonia and shortening of the lower lip *orbicularis oris* muscle that enhances mandibular denture instability; there can be encountered abnormal sagittal and horizontal ridge relationships, that can be related to factors such as the skeletal class, the pattern of the bone resorption of the jaws (centripetal in the maxilla, respectively centrifugal in the mandible) and the anterior hyperfunction syndrome (combination syndrome), all contributing to the facial appearance known as pseudo-skeletal class III facial appearance or the old man's prognathism (12); these patients generally have oral conditions unfavorable to obtain a good denture retention, support and stability, with a high degree of treatment difficulty according to Prosthodontic Diagnostic Index (PDI) classification System of American College of Prosthodontists (ACP) (13), the usage of dental implants being considered appropriate in order to ensure an adequate functionality with the prosthesis.

Planning and conducting he treatment in these patients by narrow dental implant overdenture, without bone augmentation procedures, usually has the following pattern: a number between 2 and 4 narrow dental implants is usually sufficient; shorter dental implants of less than 12mm or 10 mm are frequently needed (14); dental implant placement site is in the inter foraminal region; in cases with severe ridge resorption, sometimes adequate bone quantity is found only nearby the mental symphysis, in these cases without bone augmentation the implant number being limited to 2 implants, placed in the most anterior part of the mandible (fig. 2); dental implants can be usually placed by a flapless technique; generally the bone density is assessed as being favorable in regard to ensuring a good primary stability for immediate implant loading; the vertical prosthetic space is generally sufficient for O-Ring attachment system, difficulties in this respect being encountered in patients with a hypodivergent class II skeletal pattern, in the context of the counter clock wise rotation of the mandible, that occurs in edentulous patients.

Fig. 2. In patients with severe ridge resorption, implants are placed more frequently closer to the mental symphysis

Particularities of treatment conduct in patients with narrow alveolar ridge

These patients usually have unfavorable conditions for conventional denture and implant placement, due to the reduced width of alveolar bone and sometimes the sharp ridge crest, covered by a painful mucosa. Narrow dental implants are indicated especially in cases with narrow-ridges, considering their diameter is well suited to bone width (at least 4 mm width). Narrow alveolar ridges are encountered more frequently in patients with the following characteristics: have more frequently a class II hypodivergent skeletal pattern, which associates tongue and lip muscle hyperactivity; are usually recent edentulous patients with low-density trabecular bone, and first time denture wearers; present to the dentist usually dissatisfied with denture instability and complaining about pain related to denture pressure; alveolar ridge morphology is usually high and thin, with a greater depth of the vestibular sulcus; different morphological aspects of the alveolar ridge are observed, characterized by the relatively frequent presence of cortical bone irregularities, such as exostosis, covered by thin mucosa, painful under pressure, which are linked to intolerance of conventional dentures; in previous wearers of ill-fitting dentures in which tooth loss is mainly linked to periodontal disease, there was rather often encountered flabby ridges and mucosal hyperplasia (12).

Planning and conducting edentulism rehabilitation in these patients by narrow dental implant overdenture has usually the following pattern: the number of implants is generally between 2 and 4 narrow dental implants, according to bone offer, the degree of overdenture retention needed and clinical situation on the opposite jaw (fig. 3); if the clinical situation requires, the number of implants can be increased later, after the stabilization of bone level after

Fig. 3. Patient with narrow mandibular ridge, with two implants placed for increasing denture's retention

tooth extraction; implant scan usually have higher length, of more than 12 mm or 14 mm; implant diameter is usually smaller, corresponding to ridge width; more frequently the implants are placed by a flap technique, chosen in order to correct bone and mucosa alterations, and to adequately assess bone offer and the limits of implant placement (to prevent cortical perforation); progressive implant loading is usually preferred due to rather frequently encountered reduced bone density, for which soft silicone or acrylic materials may be used during the osseointegration period for amortization of occlusal forces or peri-implant soft tissue conditioning; the healing process is slower compared to the one of the patients with flat ridge considering that in these patients usually a flap technique is used for implant placement; the vertical prosthetic space may be decreased, in relation to the skeletal class, therefore implants with other type of attachment system (e.g., magnets) can be used; overdenture risk fracture is higher because of the reduced width and thickness of overdenture base, especially when there are placed more than

two implants; dental implants are especially beneficial in recent edentulous patients with narrow-ridges, through minimizing the bone resorption, which has the highest rate after tooth loss and is enhanced by ill-fitting dentures.

In both clinical situations, rehabilitation by recreating the correct intermaxillary relationship, with a stable occlusion, correct relationship of the implant with the overdenture base which should not exert pressure on the dental implants, as well as compliance with the recommendations after implant placement (as having a soft diet for the next following days, and maintain a good oral hygiene) are required.

CONCLUSIONS

We can conclude that narrow implant overdenture is as a treatment alternative that responds well to the most important reason of patient dissatisfaction with conventional prosthesis, namely the mandibular denture instability, through a relative minimal invasive surgical intervention followed by relatively simple prosthetic procedures. Aspects as accurate selection of narrow implant number and placement sites, correctness of overdenture execution, proper maintenance and monitoring are important prognostic factors. To obtain a good outcome, particularization according to patient features, such as the morphology of the alveolar ridge, is recommended. Deciding upon implant type, number, site, and attachment system should be made in accordance with factors as bone offer and morphology of the alveolar ridge, edentulous and prosthetic status in the maxilla, prosthetic space, and the need to improve denture's stability. Prospective studies must be implemented to gain knowledge on best treatment coordinates for different clinical situations.

NEWS

COULD CALCIUM HOLD THE KEY TO FIGHTING A DANGEROUS HOSPITAL INFECTION?

Clostridium difficile (*C. difficile*) is an anaerobic gram-positive pathogen that is the leading cause of nosocomial bacterial infection globally. *C. difficile* infection (CDI) typically occurs after ingestion of infectious spores by a patient that has been treated with broad-spectrum antibiotics. While CDI is a toxin-mediated disease, transmission and pathogenesis are dependent on the ability to produce viable spores. These spores must become metabolically active (germinate) in order to cause disease. *C. difficile* spore germination occurs when spores encounter bile salts and other co-germinants within the small intestine, however, the germination signaling cascade is unclear. Here we describe a signaling role for Ca^{2+} during *C. difficile* spore germination and provide direct evidence that intestinal Ca^{2+} coordinates with bile salts to stimulate germination. Endogenous Ca^{2+} (released from within the spore) and a putative AAA+ ATPase, encoded by *Cd630_32980*, are both essential for taurocholate-glycine induced germination in the absence of exogenous Ca^{2+}. However, environmental Ca^{2+} replaces glycine as a co-germinant and circumvents the need for endogenous Ca^{2+} fluxes. *Cd630_32980* is dispensable for colonization in a murine model of *C. difficile* infection and *ex vivo* germination in mouse ileal contents. Calcium-depletion of the ileal contents prevented mutant spore germination and reduced WT spore germination by 90%, indicating that Ca^{2+} present within the gastrointestinal tract plays a critical role in *C. difficile* germination, colonization, and pathogenesis. These data provide a biological mechanism that may explain why individuals with inefficient intestinal calcium absorption (*e.g.*, vitamin D deficiency, proton pump inhibitor use) are more prone to CDI and suggest that modulating free intestinal calcium is a potential strategy to curb the incidence of CDI (Travis J. Kochan, Madeline J. Somers, Alyssa M. Kaiser *et al.* Intestinal calcium and bile salts facilitate germination of Clostridium difficile spores. *PLOS Pathogens* 2017; 13(7): e1006443 DOI: 10.1371/ journal.ppat.1006443).

THE ASSESSMENT OF THE RISK FACTORS FOR ATHEROSCLEROSIS AMONG POPULATION FROM THE NORTH-EASTERN REGION OF ROMANIA (Abstract): **Aim**: This study investigates the factors that influence the risk of atherosclerosis for the population included in the research and to assess the relationship between these factors and atherosclerosis. **Material and methods**: A case-control study was conducted on cardiovascular risk factors that contribute to the occurrence of atherosclerosis which included a number of 207 patients of both sexes, selected from urban and rural areas, with permanent residence in the county of Iasi, aged between 20 and 80 years, during the period April-June 2014. **Results:** Analyzing the risk factors there was found a statistical significance for the values of the total cholesterol and triglycerides, as well as for other risk factors such as obesity (assessed by body mass index), blood pressure, smoking and physical inactivity. For other risk factors involved in the occurrence of atherosclerosis, such as: ischemic personal history, family history of coronary heart disease, diabetes, type of diet, history of infection with *Chlamydia pneumoniae*, *Cytomegalovirus*, *Helicobacter pylori* there were obtained insignificant statistical values. **Conclusions:** The results of this study provide information with practical implications that can be used by clinicians when they faced people with cardiovascular risk factors. **Keywords**: CARDIOVASCULAR DISEASES, ATHEROSCLEROSIS, RISK FACTORS, ROMANIA, PREVALENCE.

Atherosclerotic cardiovascular diseases are the leading cause of death worldwide (1). Atherosclerosis (ATS) is considered a chronic inflammatory disease related to age, with a long and slow asymptomatic phase. Recent data shows that it begins to develop early in life and presents clinical manifestation in many patients in a relatively advanced stage. The consequences of ATS responsible for the occurrence of cardiovascular diseases are among the leading causes of morbidity and mortality worldwide. It should also be noted that the coronary heart disease due to ATS is increasing. The diag-

nosis and treatment are a priority partly because the sudden death is a consequence of primary coronary artery disease in 50% of men and 64% of women (2).

Increased susceptibility to atherosclerosis is conditioned by the accumulation of the risk factors (RF): hypercholesterolemia, hypertension smoking (3).

The risk factors for atherosclerotic cardiovascular diseases includes (4, 5): *individual characteristics* (unchangeable = non-modifiable RF): age, sex, family history of atherosclerosis at a young age (for women < 65 years, for men < 55 years), previous personal history of atherosclerosis; *the biochemical/physiological factors*: hyper-LDL-cholesterol, hypo-HDL-cholesterol, hyper-triglycerides, high blood pressure (HBP), diabetes mellitus (DM) or impaired glucose tolerance, obesity, thrombogenic factors; *lifestyle characteristics*: diet rich in saturated fats, smoking, alcohol, physical inactivity (6).

The aim of this study was to investigate the factors that influence the risk of atherosclerosis for the population included in the research and to assess the relationship between these factors and atherosclerosis.

MATERIAL AND METHODS

A case-control study was developed to assess the risk of various factors among the study population. The case-control study on cardiovascular risk factors that contribute to the occurrence of ATS included a number of 207 patients of both sexes, selected from urban and rural areas, with permanent residence in the county of Iasi, aged between 20 and 80 years, during the period April – June 2014. Patients were divided into two groups, the group of cases which included 78 patients with ATS, recruited from people who visited the family doctor office, and the control group, which included a total of 129 persons selected from the subjects who were present in the Ambulatory of the "Dr. I. Czihac" Emergency Army Hospital from Iasi. The inclusion criteria were: age over 20 years, and the diagnosis of ATS confirmed by angiography or computed tomography. During the visit to the family doctor for each patient enrolled in the study was filled up a questionnaire with the following data: date of birth, age, gender, ethnicity, residence, education level, economic situation perceived by the patient, personal history, lipid profile (the total cholesterol value, the amount of LDL and HDL cholesterol and the amount of triglycerides), body weight, height, blood pressure value, the presence of diabetes, smoking, physical activity, type of food, the inflammatory markers C-Reactive Protein (CRP), evidences of the medical history of infections with *Chlamydia pneumonia*, *Cytomegalovirus*, and *Helicobacter pylori*.

A pilot study was conducted to validate the questionnaire used for the assessment of the risk factors for ATS. A number of 40 subjects were included in the study: 20 cases, recruited from people who visited the family doctor office and 20 controls, chosen from the subjects who were present in the Ambulatory of the "Dr. I. Czihac" Emergency Army Hospital from Iasi, during a period of 3 months, between January and March 2014.

In both studies, the information was collected using a questionnaire specially designed for this purpose, and then were included in an Excel database that has been further processed using Excel and Epi Info 7 programs. The variables under the study were analyzed and the values within the statistical confidence interval (CI) 95% ($p < 0.05$) were considered values with statistical significance.

RESULTS

Characteristics of the subjects under the study. The study included a number of 207 participants of which 78 cases (37.68%) were cases with ATS and 129 (62.31%) were controls without a disease with clinical confirmation. Regarding the gender distribution, was found a preponderant presence of the disease in males (51.28%), because they have a higher risk of getting the disease.

The most affected patients were within the age group of 70-79 years (41.02%), followed by those aged 60-69 years (28.21%) (fig. 1).

Most of the cases were from urban areas (55.13%) compared with 44.97% from rural areas. A possible explanation could be that people in rural areas have a higher addressability to the doctor and an easier access to specialized medical services.

If we refer to the level of training, the cases with secondary education have been recorded in more than a half of the cases (51.28%), followed by those with higher level of training (28.21%) and those with primary education (20.51%).

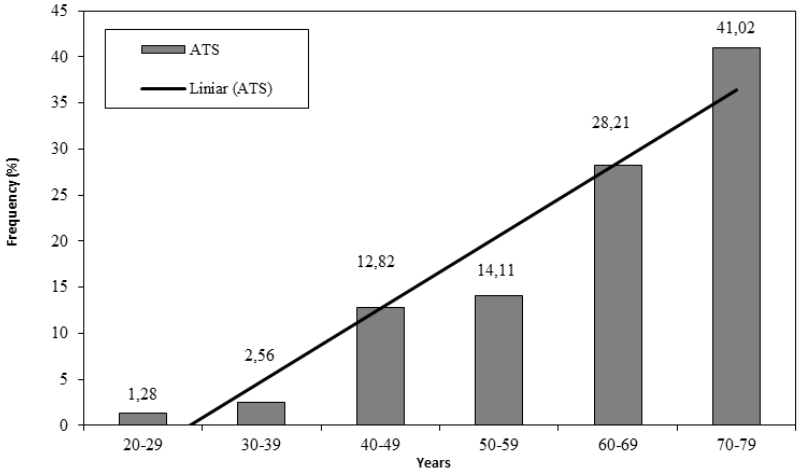

Fig. 1. The prevalence of atherosclerosis, according to different age groups

The assessment of the relationship between different risk factors and ATS. The following risk factors were studied: personal history of ischemic heart disease, family history of coronary heart disease, the amount of LDL cholesterol, HDL cholesterol, triglycerides, body mass index, blood pressure, diabetes, smoking, sedentary lifestyle, type of diet, C Reactive Protein (CRP), history of infections with *Chlamydia pneumoniae*, *Cytomegalovirus*, *Helicobacter pylori.*

Analyzing the risk factors there was found a statistical significance for the values of the total cholesterol (TC) and triglycerides, as well as for other risk factors such as obesity (assessed by body mass index), blood pressure, smoking and physical inactivity. For other risk factors involved in the occurrence of ATS, such as: ischemic personal history, family history of coronary heart disease, diabetes, type of diet, history of infection with *Chlamydia pneumoniae*, *Cytomegalovirus*, *Helicobacter pylori* there were obtained insignificant statistical values (tab. I).

TABLE I

The relation between the risk factors and the atherosclerosis among the population under the study

The studied factor	Cases		Controls		OR	X^2	p	Statistical significance
	No.	%	No.	%				
Obesity	67	85.9	54	41.9	2.8	13.5	0.01×10^{-2}	SS
High cholesterol	60	76.9	49	37.9	5.5	31.1	$<0.01\times10^{-5}$	SS
High LDL-cholesterol	57	72.2	42	32.6	5.2	30.5	$<0.01\times10^{-5}$	SS
Smoking	57	67.1	58	44.9	0.6	3.0	0.04	SS
High triglycerides	50	64.1	29	22.5	6.3	35.9	$<0.08\times10^{-5}$	SS
High Blood Pressure	48	61.5	41	31.8	3.5	18.0	0.01×10^{-3}	SS
Sedentarism	43	55.7	52	40.3	1.8	4.5	0.01	SS
Low HDL- cholesterol	34	43.6	103	79.8	0.2	28.9	$<0.01\times10^{-4}$	SS
Poor economic situation	34	43.6	30	23.2	2.6	9.6	0.001	SS
Type of food	42	53.9	59	45.7	1.4	1.6	0.1	NS
Infections with *Ch. Pneumoniae, Cytomegalovirus, H. pylori*	29	36.7	43	33.3	1.2	0.4	0.3	NS
Family history of ischemic heart disease	23	29.5	33	25.6	1.2	0.4	0.26	NS
Personal history of ischemic heart disease	17	21.8	26	20.2	1.1	1.1	0.36	NS
Diabetes	14	17.9	29	22.4	0.7	0.5	0.24	NS
CRP	4	5.1	4	3.1	1.7	0.5	0.24	NS

For the subjects included in the study, it was observed an average of the cholesterol value above the normal value, as well as for the other biochemical indicators (LDL-cholesterol and triglycerides). Regarding the variation coefficient, which shows us the scatter of the value series, the lower the value (as is the case with cholesterol) the closer it is to the average (tab. II).

TABLE II

Biochemical investigations among subjects included in the study

	Mean	Standard Deviation	Variation coefficient (%)
Total cholesterol	211.19	42.15	10.96
LDL-cholesterol	126.68	50.07	39.52
HDL-cholesterol	61.06	15.44	25.28
Triglycerides	137.34	69.47	50.58
Body Mass Index	26.71	5.4	20.21

Retrospective and prospective epidemiological research regarding the risk factors among the studied subjects. Of the total number of ATS cases included in our study, it was observed that the most patients had high total cholesterol levels (76.92%), followed by increased LDL-cholesterol values (72.15%) and low HDL-cholesterol levels (56.41%). The most affected age group by the increased values of the cholesterol, triglycerides and LDL-cholesterol was 70-79 years of age, and the

least affected was 20-29 years (fig. 2).

Another risk factor involved in the occurrence of ATS is the high triglyceride levels (normal values being between 50-150mg/dL). Laboratory investigations found that the most patients diagnosed with ATS had elevated triglycerides levels (>150mg/dL) (64.11%).

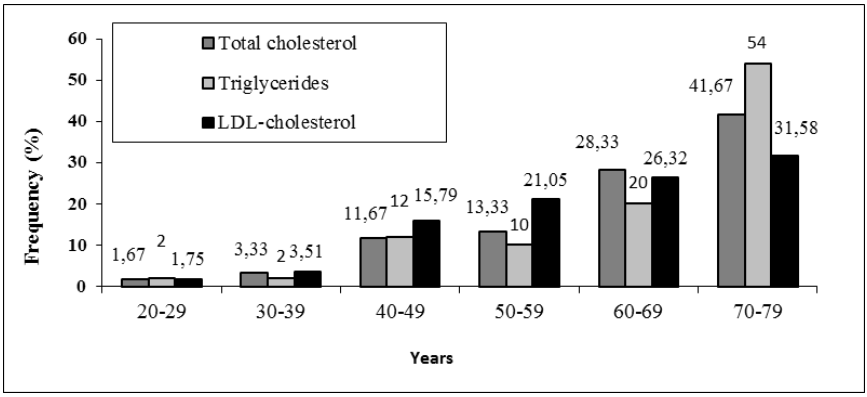

Fig. 2 The distribution of atherosclerosis cases with high values for the total cholesterol, LDL-cholesterol and triglycerides according to age groups

To assess the obesity as a risk factor for ATS, we calculated the Body Mass Index (BMI) for all patients included in the study. The most common classes of obesity were II degree, corresponding to a BMI values between 35.00 and 39.99 Kg/m2 (37.44%) and I degree (BMI between 30.00 and 34.99) (22.82%). Following the analysis of ATS cases, the obesity has been found to affect most the age groups 70-79 years and 60-69 years, and then decreases with age (fig. 3).

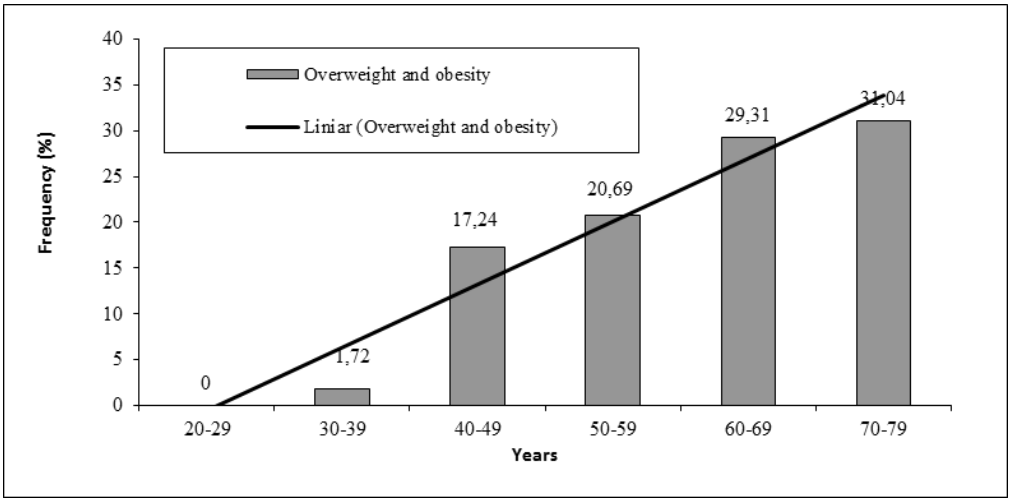

Fig. 3 The distribution of atherosclerosis cases among overweight and obese according to the age groups

Assessing another risk factor for ATS, namely high blood pressure (HBP), it was found to be present in most of the cases (61.54%). The most affected by hypertension among the atherosclerosis cases included in the study were those in the 70-79 age group (39.58%), followed by the age group 60-69 years (31.25%) (fig. 4).

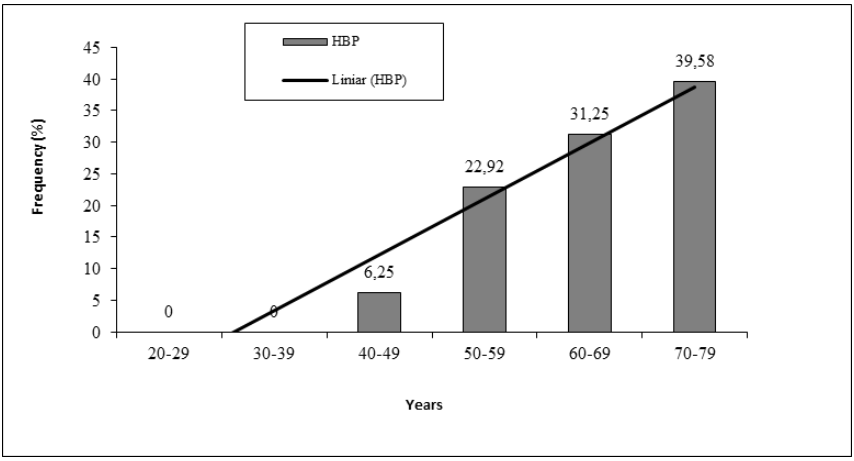

Fig. 4. The distribution of subjects with atherosclerosis and HBP according to the age groups

Smoking, another risk factor for ATS, was present in 67.09% of the investigated cases, the most frequently affecting the age group of 40-49 years (40.35%) and the age group of 50-59 years (35.09%) (fig. 5).

Another risk factor involved in the occurrence of ATS is the sedentarism. In the current study, it was observed that more than a half of the patients (55.7%) were sedentary (walking <30 min/day), more frequently within the 70-79 age group (30.23%) (fig. 6).

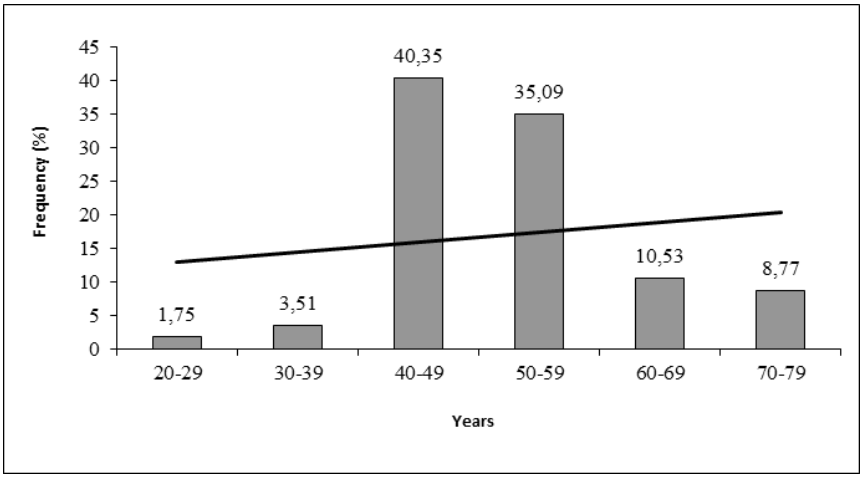

Fig. 5 The distribution of atherosclerosis among smokers according to the age groups

DISCUSSION

It has been noted that infectious factors play an important role in the development and progression of ATS, leading to chronic infections and persistent inflammatory process. Both the acute and chronic inflammation causes endothelial dysfunction. The main microorganisms that have been studied were *Chlamydia pneumoniae*, *Cytomegalovirus* and *Helicobacter pylori* (7). Also, some studies have reported that seropositive to *Chlamydia pneumoniae*, *Cytomegalovirus* and *Helicobacter pylori* is associated with coronary artery disease (8, 9). Infectious agents are considered risk factors or enhancers of other factors contributing to the occurrence of ATS (10).

In a study of the rural Chinese population, it was found that the most common risk factors involved in the occurrence of peripheral cardiovascular disease, more precisely in atherosclerosis, were high blood pressure and increased LDL-cholesterol / HDL-cholesterol ratio (11). Our data were similar to those found by Liang et al, the high blood pressure and high cholesterol levels being identified as risk factors with statistical significance.

There are several cohort studies that support a strong correlation between HDL-cholesterol and coronary risk. Some US epidemiologic studies involving many subjects (like the Framingham Heart Study, the Lipid Research Clinics Primary Prevention Trial) showed that low HDL-cholesterol levels increase the risk of coronary heart disease and argue that every 1 mg/dL increase in HDL-cholesterol level reduces the risk of coronary heart disease by 2% in men and 3% in women. The Framingham Heart Study supported the role of HDL-cholesterol as an independent factor for the coronary artery disease. The main mechanism by which HDL-cholesterol is considered to reduce the cardiovascular risk consists in the reverse transport of cholesterol, a way to remove the free cholesterol from macrophages into the arterial wall and to return to the liver for bile excretion (12). Our study did not found an increased risk for atherosclerosis when low values of HDL-cholesterol were registered ($OR = 0.2$, $p < 0.01 \times 10^{-4}$).

Various epidemiological studies have shown that around 25% of US adults are estimated to have high levels of triglycerides (> 150mg/dL), leading to an increased risk of cardiovascular disease. It is well known that lowering the high level of low-density lipoprotein (LDL-cholesterol) remains the primary target of treatment to reduce the

risk of cardiovascular diseases. Also, a series of epidemiological studies including many subjects have shown that increased levels of triglycerides are associated independently with an increased incidence of cardiovascular events, even in patients treated with appropriate statins (13, 14). This fact was observed in the current study, which found that subjects diagnosed with ATS had elevated levels of both triglycerides and LDL-cholesterol. The same aspect was identified by Fukuda N et al. during an experimental trial conducted in 2013 involving 15 rabbits. The postprandial hypertriglyceridemia was found to be a risk factor in promoting the ATS (15).

The early measurements of BMI, cholesterol, triglycerides and the blood pressure were found to be more strongly associated with the presence and severity of coronary calcifications (16). In the current research obesity has been shown to be a risk factor in the development of atherosclerosis. Also, there are researchers shown that obesity induces a pro-inflammatory state due to the secretion of adipokines that are an essential event in the occurrence of cardiovascular disease (17). The risk factors for ATS and diabetes are based on inflammatory and genetic backgrounds that can be accounted for by the excess of fat. Longevity has increased in last past years and is related to a pro-inflammatory response with cardiovascular consequences. If lifestyle would include an increase in physical activity as well as a calories restricted diet, the low degree of obesity would have a limited effect on chronic inflammation, and the risk of atherosclerosis and diabetes mellitus could be reduced (17).

In a study of the prevalence of risk factors for atherosclerosis among the adults from the Philippines, which was conducted in 2008, the following results were obtained analyzing the 7,700 eligible subjects who participated in the study: the prevalence of dyslipidemia - 72%, high blood pressure - 24.6%, diabetes mellitus - 3.9%, obesity - 4.9%, smoking - 31%, and a history of coronary, cerebrovascular and peripheral disease - 1.1%, 0.9% and 1.0%, respectively. Following this comparative study, it was found that the prevalence of the risk factors for ATS was higher in 2008 than in 2003, indicating a need for active collaboration intervention with all government agencies and medical societies in the Philippines in order to prevent or control the action of these factors (18). A similar situation was found in our study, which showed that the economic situation of patients, high level of cholesterol, triglycerides, blood pressure, smoking, and sedentarism can influence the development of ATS.

Smoking is another risk factor with a major contribution in the development of cardiovascular and atherosclerotic diseases, but our study did not identified smoking as a risk factor for ATS ($OR = 0.06$, $p = 0.04$). Another research involving 299 subjects, from which 34 (11%) smokers, 73 (24%) former smokers and 192 (4%) who never smoked showed that smoking was associated with subclinical atherosclerosis in diabetic persons and was influenced by the duration of diabetes to promote the progression of ATS (19).

CONCLUSIONS

The actual research identified as risk factors with statistical significance for ATS the following conditions: obesity, high cholesterol, high LDL cholesterol, high triglycerides levels, high blood pressure, sedentarism, and poor economic situation. The findings of this study provide information with practical implications that can be used by clinicians when they faced with people with risk factors.

Most of the cases come from urban are-

as. One possible explanation might be that the urban population has a greater addressability to the doctor and easier access to the specialist medical services. So, the future cardiovascular preventive strategies should address this issue.

This study showed that patients with high blood pressure have an increased risk of developing ATS due to hyperreactivity to risk factors. Although sometimes it is difficult to manage the systolic blood pressure in the elderly, the total cardiovascular risk can be reduced by action on other risk factors such as smoking, obesity, sedentarism, and high cholesterol levels. If the lifestyle would include an increase in physical activity as well as a calorie restricted diet and a diet rich in fruits, vegetables and fish, the low degree of obesity could have a limited effect on chronic inflammation and the risk of ATS and consequently the risk of cardiovascular disease may be reduced.

The measures used to prevent cardiovascular events in patients with coronary artery disease involve a multifactorial approach including the management of all the modifiable risk factors (especially high cholesterol, high LDL-cholesterol, high triglycerides levels, obesity, and high blood pressure). Prevention of cardiovascular disease should be a priority not only in research but also in clinical practice, especially in preventive medicine.

ACKNOWLEDGEMENTS

We would like to acknowledge Niculina Alexandru, family doctor specialist (GP) and the Microbiology Laboratory Team of the "Dr. I. Czihac" Emergency Army Hospital from Iasi for their sustained help and support providing and analyzing the samples from subjects included in the control group.

NEWS

RISK OF ACUTE MYOCARDIAL INFARCTION WITH NSAIDS IN REAL WORLD USE: BAYESIAN META-ANALYSIS OF INDIVIDUAL PATIENT DATA

Michèle Bally (epidemiologist in the Department of Pharmacy and Research Center, Centre hospitalier de l'Université de Montréal, Quebec, Canada) and her research team conducted a systematic review followed by a one stage bayesian individual patient data meta-analysis which shows that the use of nonsteroidal anti-inflammatory drugs (NSAIDs) is associated with a significantly increased risk for myocardial infarction (MI). A cohort of 446,763 individuals (61,460 with acute myocardial infarction) was included in the study. The results highlighted that taking any dose of NSAIDs for one week, one month, or more than a month was associated with an increased risk of MI. If the subject used the NSAIDs for one to seven days the probability of increased MI risk was 92% for celecoxib, 97% for ibuprofen, and 99% for diclofenac, naproxen, and rofecoxib. The corresponding odds ratios (95% confidence intervals) were 1.24 (0.91 - 1.82) for celecoxib, 1.48 (1.00 - 2.26) for ibuprofen, 1.50 (1.06 - 2.04) for diclofenac, 1.53 (1.07 - 2.33) for naproxen, and 1.58 (1.07 - 2.17) for rofecoxib. A greater risk of MI was reported for higher dose of NSAIDs, but the use for longer than one month, did not appear to exceed the risks associated with shorter durations. The study concluded that all NSAIDs, including naproxen, considered by some as one of the safest drugs in this class, were found to be associated with an increased risk of acute MI. The risk of MI with celecoxib was comparable to that of traditional NSAIDs and was lower than for rofecoxib. Also, the risk was greatest during the first month of NSAIDs use and with higher doses. (Bally M, Dendukuri N, Rich B, Nadeau L, Helin-Salmivaara A, Garbe E et al. Risk of acute myocardial infarction with NSAIDs in real world use: bayesian meta-analysis of individual patient data. *BMJ* 2017; 357 : j1909. doi.org/10.1136/bmj.j1909).

THE RISK OF ITERATIVE FRACTURES IN PATIENTS WITH OSTEOGENESIS IMPERFECTA-CASE REPORT (Abstract): *Osteogenesis imperfecta* is characterized by connective tissue involvement and is due to quantitative and qualitative changes of collagen type I. The curative treatment is not possible, but the introduction of antiresorptive bisphosphonate therapy and multidisciplinary approach of this pathology has allowed a considerable improvement in quality of life for these patients. The case presented is of a patient who inherited the disease from the paternal side and has a very rich medical history represented by the existence of 18 fractures. Leg fracture occurred at the age of 20 years has not been treated with centromedullary implants due to the accentuated tibial curves and tibial medullary canal obliteration, so osteosynthesis with plate was don. Removal of osteosynthesis material 18 months postoperatively resulted in the emergence of iterative fracture after 3 months, necessitating a reintervention by the same technique with bone consolidation. **Keywords**: BLUE SCLERA, COLLAGEN, BONE FRAGILITY, OSTEOSYNTHESIS.

Osteogenesis imperfecta (O.I.) is a hereditary disease which involves the connective tissue and is due to quantitative and qualitative changes of collagen type I. The clinical expression of this alteration of connective tissue can be various, but manifests most commonly by fragility of the bone associated with multiple fractures and deformities of anatomical segments, blue stained sclera, impairment of the internal ear segment with disturbing of hearing to complete extinction, developmental abnormalities of the teeth. The disease was detected beginning with the 17th century and was originally classified by Silence (1), based on clinical and radiological modifications, in four types and later, with the introduction of molecular genetics techniques, classification has been extended to 8 main types. The most frequently encountered are the type I and IV. Type I is characterized by the mildest clinical manifestation. The transmission of the disease is usually autosomal dominant (80-90%) but an autosomal recessive transmission is also possible, even an appearance of a spontaneous mutations that make possible its emergence in the absence of a family history.

Prenatal diagnosis is possible in case of risk pregnancies in the weeks 10-12, by analyzing the collagen produced by fetal cells, interruption of pregnancy being a

good option in this case, considering the poor prognosis of these children. The fetal ultrasound is the second diagnostic method, as it can visualize the fractures already established (2).

Clinical manifestations can vary from simple osteopenia to fractures in utero and are those who raise the suspicion diagnosis, the genetic analysis being the diagnosis of certainty. Most patients fall into type I and most often the stature is normal, distortions are minimal and the intellect is unaffected. Type II is a form that is manifested soon after birth and often incompatible with life. Type III and IV have a more severe clinical expression than type I and are characterized by triangular faces, short stature and important bony deformities. The peculiarity specific for type V is represented by the interosseous membrane calcification in forearm and fractures healing by hypertrophic calluses. The disease affects both sexes in equal proportions, all races and ethnic groups being exposed (3), and has an estimated incidence of 6-7 cases per 100,000 people worldwide (4) of which about half are affected with OI type I or IV (5). The first 4 types of the disease are due to mutations of collagen type I alpha 1 chain (COL1A1) and collagen type I alpha 2 chain (COL1A2). Bone fragility is due to decreased amount of collagen type I. Patients of types V to IX show mutations in cartilage associated protein gene (CRTAP), prolyl 3-hydroxylase 1 (LEPRE1), peptidylprolyl isomerase B (PPIB) and FK506 binding protein 10 (FKBP10) genes. Although curative treatment is not possible, multidisciplinary approach of this pathology has allowed a considerable improvement in quality of life. The introduction of antiresorptive bisphosphonate therapy resulted in a considerable reduction in the number of fractures and their further complications (6). The correction of deformities by orthopedic techniques, the maintenance of joint mobility through physical therapy, introducing modern analgesic medication, are other important therapeutic resources (7).

CASE REPORT

The patient, female aged 20 years is taken in our evidence starting with July 2014, when she was presented after a minor right leg injury. Radiological examination revealed a fracture of both bones of the right leg in the distal part and a particular aspect of them represented by a thin structure of both tibia and fibula, deformation of skeletal parts by accentuated curves and post fracture sequels, disappearance of spinal peroneal canal and narrowing until the obliteration of the tibial canal, a marked osteoporosis especially in the ankle and foot (fig. 1).

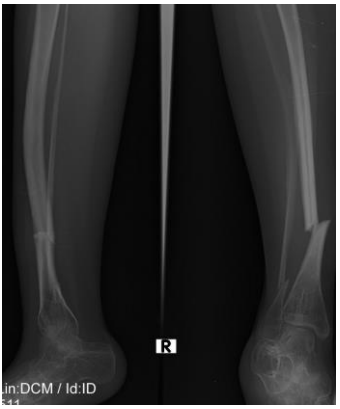

Fig. 1. Fracture in distal part of right leg

The patient's *medical history* included a total of 18 fractures, with onset around the age of 1 year, when the first fracture of the lower limbs occurred and was suspected of *osteogenesis imperfecta*, diagnosis made in the context of a family history. The disease

had a paternal transmission, patient's grandfather experiencing a mild form of the disease and presenting a normal waist without having suffered any fractures, and who, besides the existence blue whites, installed hearing problems after the age 40 years. In her father's case, the disease evolved more aggressively, due to the emergence of 6 fractures before puberty and their end after the age of 14. He also has been affected by hearing disorders occurred after age 23 years. In the father's family, the disease manifested in a different form in his sister also, who developed hearing impairment around the age of 20 years, while fractures occurred in adulthood, after 35 years. The patient's sister also presents the characteristics of the disease, but in a mild form, suffering only one fracture until now.

Physical examination reveals a waist of 146 cm and a weight of 39 kg. The patient presents blue sclera and slight modifications of the dentition. Musculoskeletal examination shows the hyperlaxity of articulations in both upper and lower limbs as well as an inequity of 4 cm length between the lower limbs due to underdevelopment of the left femur that was installed after its fracture at the age of 9 years, probably by affecting the cartilage of growth. Thorax examination reveals the presence of kyphoscoliosis, without generating breathing difficulties or auscultation pathological phenomena, the patient maintaining her muscle tone through daily exercise using treadmill.

Cardiological evaluation revealed no pathological elements and neurological examination was normal, the patient not showing any hearing changes at that moment. Bone Mineral Density (BMD) was measured via dual energy X-ray absorptiometry, and indicated a T score value of -2.8 and a Z score f-2.6, indicating the presence of osteoporosis even under chronic treatment with antiresorptive medication from the age of 9 years. At the moment of presentation, the regimen for increasing the bone mineral density contained Ibandroic acid 150 mg / month, Alpha D_3 0.5µg / day and Coral D 1cp / day.

Thoracic radiograph confirms the presence of moderate kyphoscoliosis, normal ribs and no post fractural changes (fig.2), pelvic radiograph captures bilateral *coxa valga* with cervical shaft angle of 160 degrees (fig. 3) and radiographs of the limbs identify deformities and osteoporosis in all skeletal parts (fig. 4). On the basis of the clinical and radiological changes captured, the patient has been included in the osteogenesis imperfecta type I.

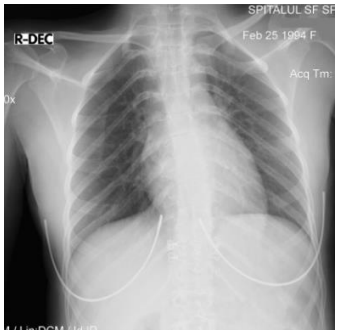

Fig. 2. Thoracic radiograph

Fig. 3. Pelvic radiograph

Fig. 4. Left femur deformation

Laboratory tests being totally normal, it was opted for the surgical treatment of the fractured leg, which was implemented in the second day posttraumatic, under general anesthesia, spinal being a difficult choice in the context of existing changes in the lumbar spine. The tibial intramedullary canal extremely narrow and even disappeared in the distal portion, made intramedullary osteosynthesis impossible and an open reduction of the fracture by anterolateral approach and osteosynthesis with dynamic compression plate (DCP) placed on the lateral side of the distal tibia were practiced.

The postoperative radiological control showed anatomical reduction of the fracture and correct positioning of the implant (fig. 5)

Fig. 5. Postoperative result

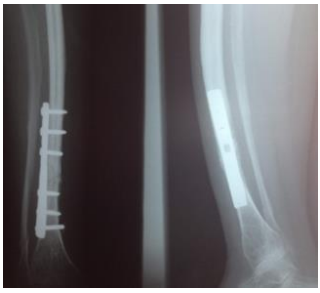

Fig. 6. Result after 12 weeks postoperative

Postoperative evolution was favorable, it was applied a splint for 3 weeks, the partial support being resumed in 8 weeks postoperatively and the integral support in 12 weeks postoperatively, after radiological assessment confirmed the fracture healing (fig. 6)

Clinical and radiological periodic reassessments have captured a favorable evolution with consolidation of the fracture, so that after 18 months postoperatively was chosen the ablation of the plate, followed by avoiding any support for 4 weeks. The patient returned to our service following a minor injury occurred 3 months after the removal of the plate, when she was diagnosed with an iterative fracture in the right leg and the therapeutic approach was represented by the resuming the osteosynthesis with DCP plate and healing of the bone (fig. 7).

Fig. 7. Iterative fracture of the right leg and osteosyntesis with DCP plate

DISCUSSION

Osteogenesis imperfecta type I is the mildest clinical expression of this disease and fortunately has the maximum prevalence. In most cases, this version has family history and autosomal dominant mode of transmission, but the possibility of this form of the disease to be a consequence of a de novo genetic mutation has also been demonstrated. In the mild forms of the disease, the fragility of bone system and joints hyperlaxity are due to an insufficient amount of collagen and the number of fractures in patients who have the mutation is 15 times higher compared with healthy children, existing the risk of being confused with a parental abuse (8).

Exceeding the period of puberty makes the fractures frequency decrease. The longevity of these patients is not directly influenced by genetic mutation, but recurrent fractures and their complications can alter life expectancy. Serious forms that occur when collagen is not only insufficient, but also nonfunctional, can be diagnosed prenatally by specialized monitoring of risk pregnancies and fetal's DNA-analysis.

Regarding the case presented with osteogenesis imperfecta type I, the patient has a consistent family history and the transmission was autosomal dominant. If one parent is affected by this genetic mutation, each child has a 50% chance to be born with this disease but the clinical expression may be totally different from that of their parents (9). The diagnosis was a clinical one and was suspected initially because of the modified color of sclera, later confirmed with the appearance of early fractures (starting from one year), of joints and skin hyperlaxity and bone deformities. No complex investigations such as quantitative and qualitative analysis of type I procollagen molecules obtained by biopsies from cultured skin fibroblasts or identification of genetic mutations in the blood cells DNA were conducted. According to studies, false negative results are obtained in 13.6% of cases. In the present case, the patient had multiple fractures, occurred starting with one year of age and produced by minor trauma. Administration of calcium preparations during childhood had not the desired favorable effect and the frequency of fractures decreased only after overcoming puberty.

Clinical examination reveals the existence of a triangular face, blue sclera, joints hypermobility and no hearing damage. Radiological investigations confirm the presence of osteoporosis in all skeletal parts, including the spine, where was an evidence of a moderate scoliosis caused by unequal legs. The patient reported no history of rib fractures and thoracic radiographs confirmed the normal appearance of the ribs. The actual therapeutically management makes possible to achieve a quality of life close to normal, addressing osteogenesis imperfecta type I in multidisciplinary team: antiresorptive medication administration (bisphosphonates orally and intravenously) under the supervision of the endocrinologist, correction of deformities and treatment of fractures by orthopedic surgery, physiotherapist and physician's intervention of recovery to preserve joint mobility and maximizing physical performance. Bisphosphonate therapy was administered with caution in children at first, because it was considered a risk to disrupt the processes of mineralization and bone growth, emphasizing such deformities.

Research published by Bianchi ML showed that administration of alendronate to children affected by osteogenesis imperfecta does not interfere with normal bone growth (10).

CONCLUSIONS

Our case is very suggestive for osteogenesis imperfecta type I, starting from the rich family history and especially the clinical manifestations and radiological evaluations. Insufficient amount of type I collagen is responsible for the existence of bone fragility and increased risk of fractures fallowing minimal trauma. Antiresorptive bisphosphonate therapy is effective for increasing bone strength, DNA tests conducted in patients who stopped the medication period indicate decreased bone mineral density. Stabilization of fractures in these patients is difficult due to the poor quality of bone tissue and to the atypical form of the skeletal parts because the long bones of patients are thin for their length and body weight and this condition tend to be more severe with age (11). Osteosynthesis with plates and screw provides a low resistance because of the failure of each screw and because of the stress riser effect at the plate ends (12).

Although the centromedullar implant would have represented the ideal solution for stabilizing a fracture occurred on a bone with little resistance, we had to use plates that we could adapt intraoperatively to the tibial shape, because the small size and conformation of tibial canal did not allow the placement of a nail. Even if the radiological image showed normal aspect of consolidation and tibial cortices, removal of osteosynthesis material 18 months after implantation favored the reappearance of fracture in the old fracture place, with its recurrence 3 months after the ablation of the plate. Multidisciplinary approach of the patient with osteogenesis imperfecta significantly improves patient's quality of life.

FRAILTY DETECTION AND PREVENTION IN INDEPENDENT LIVING PRE-ELDERLY AND ELDERLY IN NORTHEASTERN ROMANIA (Abstract): Frailty is the central feature of old age, a new concept in medicine, being the leading cause of decreased quality of life, dependency and death in elderly people. The older we get, the more fragile the basic balance, and increasingly lower aggression can be sufficient to disrupt this balance. **Aim:** To identify frailty through the Romanian version of the Groningen fragility indicator (GFI) questionnaire among the independently living elderly in the northeastern region of Romania. **Material and Methods:** GFI questionnaire was applied to 60 persons aged 65 to 95 years, randomly selected from general practices in Iasi town and Iasi country in the interval March-April 2014. **Results**: A significant percentage of the subjects were considered frail, particularly women, and divorced or widowed. According to the general practitioners, 65% of the older persons were frail without significant gender and marital status-related differences, with a significantly higher degree of frailty in those the those aged over 75. **Conclusions**: These findings are a red flag to the health system, and given the major social impact the detection of frailty and early intervention should be a priority. **Keyword:** FRAILTY, ELDERLY POPULATION, PREVENTION, STATE OF VULNERABILITY, SARCOPENIA.

Frailty is a clinical state of increased vulnerability and decreased ability to maintain the homeostasis, which is characterized by a decline in physiologic reserve and function across multiple organ systems. Currently, a consensus was reached regarding the description of frail elderly person, which includes: weight loss, decreased muscle mass and strength, impaired balance and mobility, physical inactivity and cognitive impairment (1). In the clinical picture, sarcopenia is considered a key element of frailty.

Several studies have proposed different tools for measuring fragility. Some are complex, others are simple (2). The frailty index seems to be the most appropriate instrument to measure frailty, but this instrument is complex, the psychometric properties need to be explored more extensively and they were not validated in a primary healthcare setting.

Therefore, it is difficult to determine which the best screening instrument is, and

that is why there is an attempt to establish a frailty detection protocol including the assessment of all systems involved, which to be easy to implement, reproduce, and whose validity could not be challenged. Such an instrument does not currently exist, and the numerous questionnaires and even laboratory assessments of the musculoskeletal, neuro-endocrine, immune, and inflammatory systems did not prove to meet all these criteria; frailty is best detected through comprehensive geriatric assessment. Additionally, multiple studies have shown the importance of assessing frailty in the primary care system (3-5).

In Romania frailty is detected since 2013 following a training course delivered by Professor Heuvel and the initiation of a pilot project in a community of independent elderly (6). The results of the study showed that the Romanian version of the Groningen frailty indicator (GFI) is a valid and feasible instrument for assess in frailty. The present study implements the detection of frailty by the Romanian version of GFI in the independently living older persons in northeastern Romania.

MATERIAL AND METHODS

The study was conducted in March-April 2014. The data were collected by using the Romanian version of GFI questionnaire (fig.1) in a group of 60 persons aged 65 to 90, randomly selected from the general practices in Iasi town and Iasi country. Informed consent was obtained from all study subjects in the general practice waiting room or at home. At the same time, the GPs were asked to rate the subjects as fragile or robust based on clinical judgement without having access to the questionnaire data. The obtained data were statistically analyzed using *SPSS 13.0* software.

RESULTS

Data on patients' age did not reveal significant gender differences. In women, the age ranged from 65 to 95 years, mean age 74.29 ± 7.74 years.

The distribution by marital status showed a slightly higher percentage of married persons (65%).

The questionnaire consisted of 15 questions related to different functions: physical (questions 1-4), sensory (questions 6-9), cognitive (questions 5, 10), social (11-13) and psycho-affective (questions 14, 15).

The items can be grouped into three subscales that define daily physical activities (questions 1-4), health-related problems (questions 5-10) and psychosocial activities (questions 11-15).

A percentage of 63.3% of the subjects responded affirmatively to question number 1, without significant percentage gender and marital status differences, but only 50% of the subjects aged over 75 could do the shopping themselves ($p=0.046$). The percentage of subjects who could walk independently was 83.3% with no significant percentage differences between sexes, age groups or marital status (tab. I).

In terms of sensory functions, 48.3% of the subjects experienced difficulties in their activities of daily living due hearing impairment, significantly more common in men and in subjects over 75 years ($p=0.004$; $p=0.010$);

Only 15% of the respondents mentioned unintentional weight loss in the last 6 month, most of them being older than 75 years or unmarried ($p=0.049$; $p=0.040$), most likely suffering from depression due to the absence of a life partner.

Sixty-one-point seven percent of the subjects were taking 4 or more drugs, but statistically there were no significant differences by gender, age group or marital status (tab. II).

Question 9	37 (61.7)	F 62.9% M 60.0%	0.861	<75 62.5% ≥75 60.7%	0.901	C 56.4% NC 71.4%	0.388

The mean values for self-rated physical activity on a scale of 2 to 9 indicated a moderate level of physical activities, no significant differences by gender, age groups and marital status being recorded.

Only 23.3% of the subjects reported memory impairment and 50% occasional memory problems, statistically insignificant.

Both men and women aged under 75 years reported an active social life regardless of marital status (p=0.050). The respondents believed they would receive help from their entourage when they need it, without percentage differences by gender or marital status, but with a significantly increased frequency in subjects aged under 75.

About the psycho-affective component, the divorced or widowed subjects felt sad or discouraged in the last 4 weeks more frequently than the married ones, aspect which is not significantly influenced by on gender or age group (tab. III).

TABLE III

Statistical significance of responses related to the affective component

Question 14	Female		Male		< 75 yrs		≥75 yrs		Married		Divorced/ widower	
	n	%	n	%	n	%	n	%	n	%	n	%
Never	4	11.4%	3	12.0%	5	15.6%	2	7.1%	7	17.9%	-	-
Rarely	4	11.4%	3	12.0%	6	18.8%	1	3.6%	5	12.8%	2	9.5%
Sometimes	15	42.9%	8	32.0%	9	28.1%	14	50.0%	12	30.8%	11	52.4%
Often	7	20.0%	9	36.0%	8	25.0%	8	28.6%	13	33.3%	3	14.3%
Very often	3	8.6%	-	-	1	3.1%	2	7.1%	-	-	3	14.3%
Always	2	5.7%	2	8.0%	3	9.4%	1	3.6%	2	5.1%	2	9.5%
p	0.533				0.218				**0.020**			

Per the general practitioners, 65% of the subjects were frail, without significant percentage differences by gender or marital status, but significantly more frail were the patients aged over 75.

The results obtained by processing the questionnaire responses show that 80% of the subjects were frail, higher percentages being recorded in females than in males (82.9% *vs* 76%), but the percentage distri-

bution is not statistically significant (p=0.294).

There is slightly higher frequency of frailty among people aged over 75 years under 75 years (92.9% *vs* 68.8%) (p=0.045), with a significantly higher percentage in the divorced or widowers (95.2% *vs* 71.8%) (p=0.028) (tab. IV) (8).

TABLE IV
Statistical significance of the questionnaire results and GP rating by age group, gender and marital status

Demographic structure	GP Review			Questionnaire results			GP rating *versus* Questionnaire results
	fragile	robust	p	fragile	robust	p	
Female	65.7%	34.3%	0.891	82.9%	17.1%	0.294	0.172
Male	64.0%	36.0%		76.0%	24.0%		0.537
< 75 yrs.	50.0%	50.0%	**0.020**	68.8%	31.3%	**0.045**	0.203
≥75 yrs.	82.1%	17.9%		92.9%	7.1%		0.419
Married	59.0%	41.0%	0.294	71.8%	28.2%	**0.028**	0.341
Single	76.2%	23.8%		95.2%	4.8%		0.186

DISCUSSION

The use of these subscales allowed a more accurate identification of the needs of the elderly (social, medical, emotional) by categorizing them as frail or robust.

Based on a descriptive analysis of daily activities, in our study 50% of the elderly aged over 75 years could do the shopping themselves, with no differences by gender or marital status, and maintained an optimal level of autonomy.

Compared to GP's ratings, the questionnaire revealed a higher frequency of frailty in the studied population, but the ratio between sexes, age groups and marital status was similar (6). We believe that these results do not reflect reality, because the methodology for completing the questionnaire did not comply with the rules necessary for completing close to the truth (questionnaires filled out with the help of qualified personnel, which does not manipulate the response, under stress conditions, in limited time).

In agreement with the literature, the two subscales that define the daily physical activity and psychosocial component proved to have good internal consistency, meeting the criteria for validation (Cronbach's alpha value = 0.778, respectively 0.630) (7).

The research based on questionnaire can never be completely objective. Both the researchers and the respondents are human beings, with different psychological, emotional and social needs. Thus, the participants must have the feeling that they are collaborators to the study, without being subjected to psychological abuse.

CONCLUSIONS

In our study the percentage of subjects identified as frail with the help of the used questionnaire was high. Based on the obtained results, it could be stated this instrument of research is a valid one, and that it could be applied on larger population group, even at national level.

Another focus is on the development of appropriate method for administering the

questionnaire, to prevent potential false positive or false negative results.

Therefore, identifying the frailty status through the questionnaire among elderly in primary care requires complex geriatric evaluation in the geriatrics ambulatory.

NEWS

REVERSING THE NON-VITAMIN K DEPENDING ANTICOAGULANTS: A NEW ANTIDOTE ON THE HORIZON?

The newer non-vitamin K dependent anticoagulants (NOACs) have provided a new tool in the armamentarium of physicians treating nonvalvular atrial fibrillation and thromboembolism. The major limiting factor and the concern that precluded their use was lack of reversal in emergent situations. Andexanet alfa is a modified factor Xa molecule which reverses the anticoagulant effect of both direct and indirect factor Xa inhibitors. A recent multicenter, prospective study showed that an initial bolus and subsequent 2-hour infusion of andexanet substantially reduced anti–factor Xa activity in patients with acute major bleeding, gastrointestinal or intracranial, associated with factor Xa inhibitors, with effective hemostasis occurring in 79% (Stuart J. Connolly, Truman J. Milling, Jr., John W. Eikelboom, M.D., et al , *Andexanet Alfa for Acute Major Bleeding Associated with Factor Xa Inhibitors*, *N Engl J Med* 2016; 375:1131-1141September 22, 2016DOI: 10.1056/NEJMoa1607887).

BILATERAL SYNCHRONOUS MALE BREAST CANCER OF RARE HISTOLOGIC TYPE. CASE REPORT (Abstract). The particularity of the presented case is bilateral synchronous male breast cancer of uncommon histologic type – invasive cribriform carcinoma. In the practice of our surgical unit it is the first and only case of synchronous bilateral male breast cancer. The patient was followed up regularly for the last 4 years after a modified radical bilateral mastectomy with axillary lymph node clearance followed by adjuvant chemotherapy and endocrine therapy and he showed no signs of local recurrence or metastatic disease. **Keywords:** MALE BREAST CANCER, SYNCHRONOUS CANCERS, INVASIVE CRIBRIFORM BREAST CANCER, MORBIDITY.

Male breast cancer (MBC) is a rare disease (0.5-1% of all breast cancers (1)). Only 2% of all reported cases of MBC are bilateral (2). Men diagnosed with breast cancer are older (mean age at diagnosis is 67 years) than women with this disease, and have a poorer survival rate (5-year-survival - 67%). Klinefelter syndrome is found in approximately 7.5% of men with breast cancer. The risk of breast cancer in individuals with Klinefelter syndrome is up to 20–50 times higher compared to men with normal karyotype. BRCA2 mutation carriers have an 80–100 times higher lifetime risk of MBC. Up to 20% of men with MBC have a positive family history of breast cancer (3). Conditions such as hyperestrogenism, hyperprolactinemia, alcohol intake and tobacco smoking, occupational risks (especially working in hot environments) are slightly increasing the risk of MBC (4). Gynecomastia, a very common disorder in young men, does not increase the risk for MBC (5). First described by Page et al. in 1983, invasive cribriform carcinoma (ICC) has a low incidence (0.3% to 3.5% of all invasive breast carcinomas) (6,7). There are 3 forms of ICC of the breast - pure, classical, and mixed. ICC usually presents as a slowly growing, frequently occult tumor mass, often difficult to detect on conventional examinations. Most of these tumors have positive estrogen and progesterone receptors (8). Metastatic disease in patients with ICC is rarely reported (7). Five-year survival rate is

nearly 100% for pure and classical types (⩾50% ICC), 88% for mixed types (<50% ICC), and 78.3% for the infiltrating duct carcinoma controls (8).

CASE PRESENTATION

A 61-year-old male presented to our unit with an unpainful, insidiously growing left breast mass and a bloody discharge from the right nipple that occurred 2 months ago. His past personal medical and family history was unremarkable, except for rheumatic fever (in childhood). He had no pertinent occupational exposure. No liver dysfunction or testicular failure was found. Routine laboratory data showed no pathologic changes. Tumor marker CA15.3 was within normal range. The levels of other tumor markers (α-fetoprotein=1,26 ng/ml, PSA=1,81 ng/ml, Prolactin=310.9 µUI/ml) were also normal. Physical examination of the right breast revealed no palpable masses and clinically negative right axilla. Palpation of the left breast revealed a 3 cm irregular, solid lump in the central quadrant, fixed to the subjacent tissues. Left axilla was also clinically negative. Other physical assessments were normal. No genetic tests were performed.

Fig. 1. Right breast ultrasound appearance.

Breast ultrasound revealed in the right breast (fig.1) two nodular, retro areolar, well defined hyperechoic masses of 1.1 x 0.9 cm and 0.74 x 0.65 cm, respectively and possibly another 0.37 x 0.34 cm mass adhering to the subjacent muscular structures, absence of axillary lymph nodes. The left breast (fig. 2): retro areolar and external 2.6/2.1 cm mixed lump with the presence of a 1.9 x 1.7 cm solid mass with Doppler signal present; left axilla contained no detectable lymph nodes. Mammography showed: in the right breast a 0.7 x 0.6 cm homogeneous opacity with precise contour; in the left breast a 3 x 3.1 cm solid mass, which contained on the lateral wall a 1.4 x 1.4 cm solid irregular mass adherent to the subjacent pectoral muscle. No distant metastases were identified (thoracic radiography and abdominal ultrasonography).

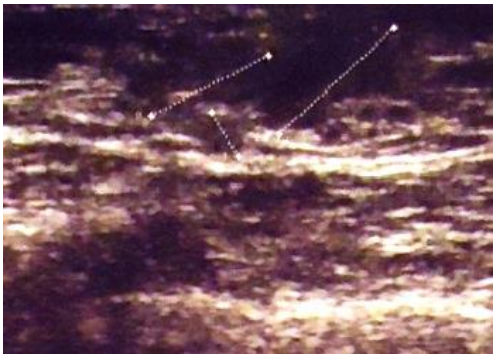

Fig. 2. Left breast ultrasound appearance.

After adequate preoperative preparation, an excisional biopsy the of breast tumors was performed. Extemporaneous analysis of the specimens revealed a bilateral invasive ductal carcinoma. A bilateral Madden-type modified radical mastectomy with axillar lymphadenectomy was performed. Postoperative course was favorable. The patient was discharged from our unit 8 days after surgery, in good condition, with no complains.

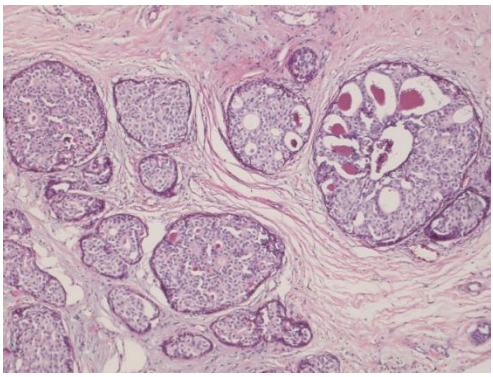

Fig. 3. Invasive cribriform carcinoma of the breast in male X 10.

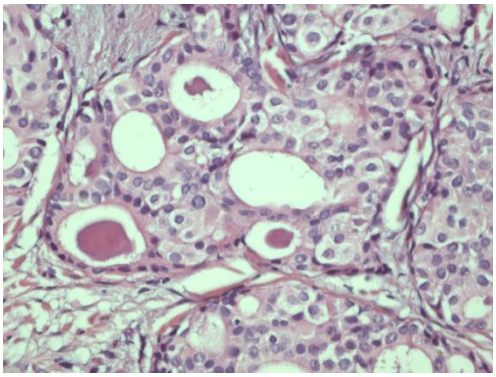

Fig. 4. Invasive cribriform carcinoma of the breast in male X 40.

Pathological examinations revealed: right breast – invasive cribriform carcinoma (fig. 3, 4) with lymph node metastasis pT1cN1aG1, 1 of 22 lymph nodes with metastatic carcinoma, ER (estrogen receptor) 90%, HER2 negative, PR (progesterone receptor) 80%; left breast – invasive ductal mixed with invasive cribriform carcinoma without lymph node metastases pT1cN0G1, ER 90%, PR 90%, HER2 negative. The patient has undergone both adjuvant chemotherapy (6 cycles of cyclophosphamide and doxorubicin/epirubicin) and hormonal therapy (tamoxifen). The 4-years regular follow up showed no signs of local recurrence or metastatic disease.

DISCUSSION

The management of MBC is mainly developed based on treatment guidelines elaborated for breast cancer in women due to the lack of large population studies and randomized clinical researches of MBC. An age- and stage-matched comparison between male and female breast cancer revealed that there is no significant sex-related difference in overall survival (3). There are studies that concluded that men with breast cancer have lower risk of death than comparable female patients (9). The main known prognostic factors for MBC are tumor size (85% survival rates when tumor sizes are less than 2 cm) and lymph node involvement (50% higher risk of death than those with negative axillary nodes) (10). Incidence of bilateral MBC is approximately 2%, and synchronous tumors are exceedingly rare (11). The importance of early diagnosis is overwhelming in MBC when surgical treatment may be radical, curative and sometimes sufficient. The significance of neoadjuvant chemotherapy in MBC remains uncertain and is used in few cases in order to obtain operability. Surgery is the mainstay of treatment for breast cancer in men. Usual surgery for MBC is modified radical mastectomy with axillary clearance or sentinel node biopsy. In rare locally advanced cases with muscle involvement a radical mastectomy should be performed with partial or total resection of pectoral muscles. Lumpectomy in initial MBC stages in selected patients followed or not by adjuvant radiation therapy has a little better cosmetic outcome and is performed in few surgical centers (2). Due to the presence of ER and PR in most patients with MBC hormone

therapy is indicated with a significant benefit in overall survival, local recurrence and metastatic disease control. Adjuvant radiation therapy is indicated in MBC with large tumors, cutaneous involvement, invasion of areola or subjacent muscles, axillary lymph-node metastases, involved margins on mastectomy specimen. Postoperative radiation therapy is also recommended in patients with multifocal, high grade tumors, high tumor proliferation rate, lymph, vascular and perineural invasion. Chemotherapy should be considered in men with intermediate or high-risk early breast cancer, especially those with hormone-receptor-negative disease as it reduces the risk of recurrence and death. HER-2 amplification in MBC is rare (2 to 15%). The effectiveness of targeted treatment with trastuzumab in MBC is uncertain due to the lack of controlled prospective studies, and may be used in patients with HER-2 positive breast cancers (3).

CONCLUSIONS

For our unit, the here presented clinical case of synchronous, bilateral male breast cancer of uncommon histological type – invasive cribriform carcinoma is an exceptional finding because, until now, there a no similar cases reported in literature. Due to its very low incidence in men, breast cancer is rarely suspected both by patients and medical personnel.

MANAGEMENT OF BILATERAL FEMORAL NECK FRACTURE IN A NONAGENARIAN PATIENT-CASE REPORT (Abstract): Simultaneous bilateral femoral neck fracture is rare injury. Cases with this type of fracture have been reported in the literature since the 1950s, following the introduction of electroconvulsive therapy which generates violent hip muscle contractions. In young patients' simultaneous bilateral femoral neck fracture results from high energy trauma (car accident or fall from height) in a normal bone. Pathological changes in bone structure occurring in chronic kidney disease, vitamin D deficiency, osteomalacia, osteoporosis, metabolic imbalances and administration of corticosteroids explain the occurrence of this particular type of fracture following low-energy trauma. We present the case of a 90-year-old female patient who suffered a simple fall from her own height resulting in a Garden IV bilateral femoral neck fracture. Our therapeutic option in this patient was bilateral uncemented bipolar hemiarthroplasty in a single session using a single tray of sterile surgical instruments and two sterile drapes. Postoperative outcome was very good, allowing the initiation of functional recovery on the first postoperative day. Uncemented hemiarthroplasty proved to be a good choice in such a patient in the associated diseases may trigger the risk of cardiovascular disturbances specific to bone cement implantation syndrome. **Keywords:** BILATERAL HIP FRACTURE, HEMI-ARTHROPLASTY, CEMENT IMPLANTATION SYNDROME, LOW ENERGY TRAUMA, SINGLE STAGE REPAIR.

Bilateral femoral neck fracture resulting from low energy trauma is uncommon and only few cases have been reported in the literature. It is more commonly associated with electroconvulsive therapy and tonic-clonic seizures and may occur in young adults following high energy trauma. The presented case reflects our experience in managing an elderly patient (nonagenarian) with significant cardiovascular comorbidities and who benefited from surgery in a single session.

CASE REPORT

A 90-year-old patient presented to the emergency department following a low energy trauma following same-level fall at home, resulting initially in partial and soon after total functional impairment. The patient was known with type 2 diabetes treated with oral antidiabetic drugs and diabetic sensori-motor polyneuropathy. Cardiovascular pathology was represented by grade III hypertension and chronic ischemic heart disease associated with significant carotid

atheromatous disease and a recent ischemic stroke. Initial clinical examination performed in the emergency department raised the suspicion of a bilateral hip fracture because the legs appeared shortened and significant externally rotated. Classical radiological examination of the pelvis confirmed the clinical suspicion of bilateral hip fracture with bilateral intracapsular femoral neck fracture Garden IV (fig 1).

Fig. 1. Anteroposterior radiograph of the pelvis showing bilateral femoral neck fractures

Immediately after admission the patient was examined by the anesthetist in order to assess if the patient can withstand general or spinal anesthesia. Cardiological assessment recommended to delay surgery and changes in therapeutic doses to normalize high blood pressure and heart rate. Surgery could be performed 48 hours following trauma and anesthetic consultation considered general anesthesia safer than spinal anesthesia regarding the expected duration of surgery and severity of cardiovascular disease. The first option of the surgical team was uncemented bipolar hemiarthroplasty in a single session in both hips. The patient was placed in supine position and the approach was the one usually used by the operating team, namely anterolateral. First we performed right hip replacement and then using the same tray of sterile instruments we performed a new draping and hemiarthroplasty in the contralateral hip using the same size prosthetic components in the right hip. Postoperative surveillance was done in the anesthesia and intensive care unit, and transferred to the orthopedic unit on the first postoperative day. After postoperative radiological assessment which confirmed a sufficient bone stock and the correct calibration and placement of prosthetic components, functional recovery first through passive and then active hip movements, with resumption of walking using a walker and full weight bearing since the second postoperative day (fig. 2).

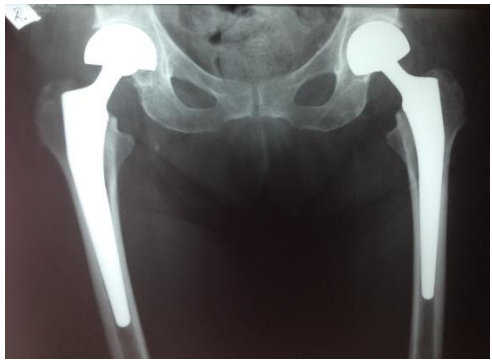

Fig. 2. Postoperatively radiograph of the pelvis showing bilateral uncemented hemiarthroplasty

The occurrence of these bilateral fractures following a low energy trauma accurately described by the patient excluding the possibility of an episode of seizure, raised the suspicious of significant changes in bone structure and density and a DXA scan of the forearm and spine was performed. Serological tests showed: mild hypothyroidism (TSH = 5.02 UUI/ml), PTH = 22.63 pg/ml, and vitamin D deficiency (7.91 ng/ml) for which therapy with

Vigantol was initiated. The severe changes captured by DXA scan of the lumbar spine, including multiple vertebral compressions and secondary scoliosis made the results uninterpretable. The occurrence of hip fracture automatically included the patient into the severe osteoporosis group although the obtained forearm values suggested osteopenia (*T score -1.5*).

Postoperative course was favorable both in terms of surgical wound healing and rehabilitation program and resumption of walking using a walker and full weight bearing. The patient was discharged on postoperative day 7 and referred to a specialized rehabilitation and physiotherapy unit. Clinical and radiological assessment at 3 months postoperatively showed a good function of both hip joints that allows independent walking over short distances using an walker. Radiological assessment of the pelvis revealed prosthetic components correctly calibrated and positioned and preservation of good quality bone in the proximal femur bilaterally.

DISCUSSION

Bilateral femoral neck fracture is extremely rare; a small number of cases being published in the literature. The introduction of electric shock therapy in the treatment of mental disorders occasionally resulted in bilateral femoral neck fractures due to the strong muscle contractions. The first reports of this fracture were published in the 1960s in this kind of patients (1).

High-energy trauma specific to polytrauma and electrocution are the main cause of these fractures when they occur in normal structure bone. Bone loss specific to primary bone disease, osteomalacia, osteoporosis or secondary changes in chronic kidney disease explain the occurrence of bilateral lesions following simple fall from the same level (2).

Transient osteoporosis of pregnancy was involved in the occurrence of bilateral femoral neck fracture during pregnancy in a 35-year-old patient who was not a victim of trauma (3).

Being a rare fracture it is often underdiagnosed as the clinical and radiological exams are focused on the hip whose symptoms are more dramatic. For this reason, X-ray of the pelvis and both hips can capture this rare lesion in confused patients suffering from neurological or psychiatric illnesses or following seizures.

Several variants of therapeutic approach have been presented in the literature starting with less invasive interventions such as orthopedic reduction followed by osteosynthesis up to simultaneous total hip arthroplasty. Sood A. et al. published in 2009 a similar case in which the bilateral fracture was the result of low energy trauma (fall from own height) in which their surgical option was bilateral cemented hemiarthroplasty through the anterolateral approach in supine position in a single session (4). In our patient, the intraoperative finding of sufficient bone stock and significant cardiovascular comorbidity that could favor the occurrence of rhythm disturbances, hypoxia and hypotension specific to bone cement implantation syndrome were strong arguments in favor of uncemented arthroplasty (5). Although the number of published cases of bilateral femoral neck fracture is limited, a high mortality rate of about 50% in elderly patients with associated comorbidities and of only 25% in young patients is reported (6). In most cases the cause is delayed surgery and rapid development of complications related to bedsores, of which deep vein thrombosis and pulmonary infection are most often fatal. In this respect, treatment guidelines for hip fractures rec-

ommend osteosynthesis or arthroplasty within 48 hours after trauma (7).

Surgery should be done as soon as the medical conditions are safe (8). In our patient the 48-hour preoperative interval was essential for adjusting the treatment for her heart disease and obtaining adequate blood pressure and heart rate so that her life not to be endangered in the perioperative period. McBryde et al. reported the safety and benefits of bilateral hip resurfacing arthroplasty (9). Arguments in favor of the supine position and anterolateral approach were the preference of the surgical team and avoidance of patient repositioning thus shortening the duration of the two successive surgeries.

CONCLUSIONS

The surgical management of our case, a nonagenarian patient with significant associated diseases, was a challenge and the treatment was adapted to its particular conditions. Uncemented hemiarthroplasty proved to be a good choice in such a patient where the associated diseases may trigger the risk of cardiovascular disturbances specific to bone cement implantation syndrome. Our therapeutic option in this patient was a bilateral uncemented bipolar hemiarthroplasty in a single session using a single tray of sterile surgical instruments and two sterile drapes. The possibility of treating both hips in the same session, thus minimizing the adverse effects of anesthesia, was a great advantage in a patient of extreme age and cardiovascular comorbidities. Early diagnosis and rapid identification and correction of imbalances that may delay surgery were the two steps essential for a successful treatment.

REDUCE CHILD MORTALITY AS A MILLENNIUM DEVELOPMENT GOAL IN ROMANIA (Abstract). **Aim:** To assess the efforts made in Romania towards achieving the Goal 4 from MDGs - Reduce Child Mortality. **Materials and methods:** A descriptive study about the deaths among Romanian children under five, between 2002 and 2015, from the perspective of the MDGs. To help track progress toward this commitment, following specific targets and indicators were developed: Target 1- Halve the mortality rate in children aged 1-4 years between 2002-2015; Target 2 - Reduce infant mortality by 40% between 2002 and 2015; Target 3- Eliminate measles by 2007. The comparison allows establish the status (achieved or not) for each target. **Results:** From 2002, the under-five mortality rate recorded a continuous descendent trend till now (20.8 to 10.3 under five deaths per 1000 inhabitants in 2013). The infant mortality rates declined from 17.3 to 8.5 deaths per 1,000 live births (2002-2013). Eliminating measles by 2007 - was achieved one year later, because of the measles epidemic in 2005 and 2006. High vaccination rates have been maintained, with the proportion of children 1 year old vaccinated against measles reaching and being maintained at between 94-98%. **Conclusions:** Substantial progress has been made in Romania, in achieving the Millennium Development Goal no. 4. All the three targets were achieved. However, infant mortality still remains above the average of European Union (4 infant deaths per 1,000 live-births). **Keywords:** MILLENNIUM DEVELOPMENT GOALS, UNDER-FIVE MORTALITY, INFANT MORTALITY, ROMANIA.

In September 2000, 189 countries from the total of 193 member states within the United Nations signed the Millennium Declaration, with the scope to eradicate the extreme poverty in all its forms by 2015. The commitment was based on a set of time-bound and quantified goals and targets, called the Millennium Development Goals, focused on combating poverty in its many dimensions - including reducing income poverty, hunger, disease, environmental degradation and gender discrimination (1,2).

These goals were created to improve the health status and wellbeing of people worldwide.

The Millennium Development Goals (MDGs) include 8 goals, 21 targets and 60 indicators for measuring progress between 1990 and 2015, when the goals are ex-

pected to be met (3):

- Goal No.1 – Reduce Severe Poverty
- Goal No.2 – Increase Compulsory Education Graduation Rate by 2012
- Goal No.3 – Promote Gender Equality and Empower Women
- Goal No.4 – Reduce Child Mortality
- Goal No.5 – Improve Maternal Health
- Goal No.6 – Combating HIV/AIDS, Tuberculosis and Other Diseases
- Goal No.7 – Ensure Environmental Sustainability
- Goal No.8 – Develop Global Partnerships for Development

The target in the Goal No.4 was "*Reduce by two-thirds, between 1990 and 2015, the under-five mortality rate*" and the included indicators were:

4.1 Under-five mortality rate;

4.2 Infant mortality rate;

4.3 Proportion of 1-year old children immunized against measles.

The use of infant mortality rates as a measure of overall health status for a given population is based on the assumption that it is particularly sensitive to socio-economic changes and to health-care interventions (4).

The infant mortality rate is commonly used as an indicator of the level of health in a community. The vast majority of these deaths are preventable with current technology, as evidenced by the extremely low child mortality risks prevailing in rich countries.

The purpose of this article is to assess the efforts made in Romania towards achieving the Goal 4 from MDGs - Reduce Child Mortality.

MATERIALS AND METHODS

This research represents a descriptive study about the deaths among Romanian children under five, between 2002 and 2015, from the perspective of the MDGs.

In the United Nations Millennium Campaign, Romania committed herself to reduce child mortality (5). To help track progress toward this commitment, following specific targets and indicators were developed:

Target 1: Halve the mortality rate in children aged 1-4 years between 2002-2015;

Indicator: Mortality rate in children aged 1-4 years;

Target 2: Reduce infant mortality by 40% between 2002 and 2015;

Indicator: Infant mortality rate;

Target 3: Eliminate measles by 2007;

Indicator: Proportion of 1-year-old children immunized against measles.

The comparison allows establish the status (achieved or not) for each target. The data sources were represented by the National Institute of Statistics, yearbooks of the Ministry of Health and Romanian Government.

RESULTS

Target 1

The risk of a Romanian child not reaching his or her fifth birthday was nearly six times greater in 1970 (66 deaths per 1000 inhabitants) than nowadays (6,7).

Under five years of age mortality rate recorded in 1990 a still high level of 38 children aged 1-4 per 1000 inhabitants. Between 1990-2000, under-five deaths overall declined to 22.2 per 1000 inhabitants. From 2002, as specified in target 1, the indicator recorded a continuous descendent trend till now (20.8 to 10.3 under five deaths per 1000 inhabitants in 2013), as presented in fig.1 (8).

Target 2

The infant mortality rate is the second

of three indicators used to monitor achievements towards the Fourth Goal of the eight Millennium Development Goals. In the last four decades (1970-2010), the infant mortality rates have significantly declined.

From a high of 49.4 deaths per 1,000 live-births in 1970, infant mortality has dropped to 29.3 in 1980, respectively 26.9 in 1990 (32 deaths per 1,000 live births in rural areas). In 2000 it was 18.6 and subsequently, declined at 9.8 (2010). Throughout the current decade is 8.5 deaths per 1,000 live-births (2013). The evolution of the infant deaths between 2002 and 2015, as specified in the target 2, is described in fig. 2.

Since year 2000, the infant mortality pattern has changed, the perinatal conditions replacing the respiratory diseases as a first cause of infant death. In 2013 the leading causes of death among children under one year were:

- perinatal conditions (38.8%);
- respiratory diseases (23.5%);
- congenital anomalies (23.5%).

Infant death may occur in neonatal or post-neonatal period. In Romania, the ratio between neonatal and post-neonatal deaths changed, in favor of the first. Thus, in 1990 the values for neonatal and post-neonatal rates were 8.9 and respectively, 18 deaths per 1,000 live births, whereas in 2012 they declined to 4.8 and respectively, 4.2 (8).

Target 3

The target referring to eliminating measles by 2007 was reached later, in 2008, because of the measles epidemic in 2005 and 2006. However, the number of vaccinations has been significantly increased, the epidemic has been controlled and in 2008 and 2009 no new cases of measles have been reported. High vaccination rates have been maintained, with the proportion of children 1 year old vaccinated against measles reaching and being maintained at between 94-98% (9).

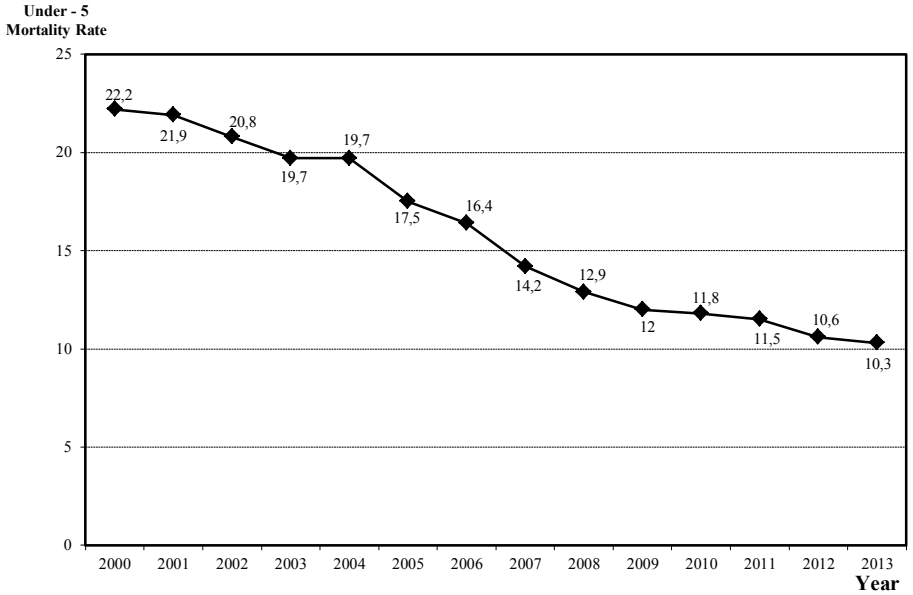

Fig. 1. Evolution of Under-five mortality rate in Romania, 2000-2013 (Romanian Statistics Annuary, 2014)

DISCUSSION

In Romania, mortality of children aged between 1 and 4 years dropped between 2002 and 2013 by 47.8%. The national target of halving the indicator (2002-2015) was achieved.

The United Nations worldwide target of a two-thirds reduction in under-five mortality (1990-2015) has already been achieved since 2009. Annual rate of reduction (1990-2013) was 5%.

Large reductions in infant mortality rates have occurred in Romania. The second target of the Millennium Development Goal no. 4 was achieved in 2012, but the indicator still remains well above the average of European Union (4 infant deaths per 1,000 live-births).

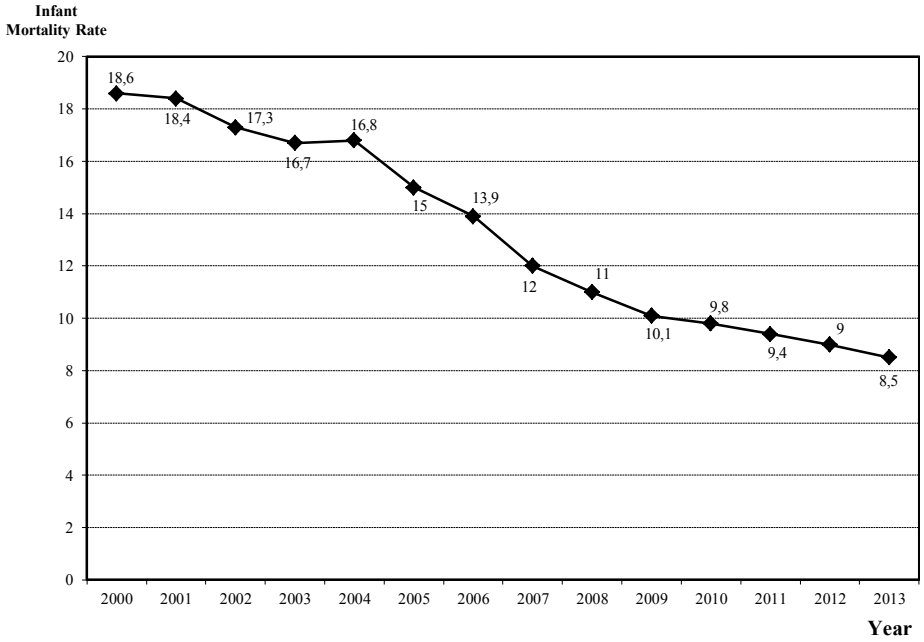

Fig. 2. Evolution of infant mortality rate in Romania, 2000-2013 (Romanian Statistics Annuary, 2014)

Neonatal mortality represents a significant proportion of child mortality (approximately 45%) and the child health Goal will not be reached unless neonatal mortality is addressed. The causes of neonatal death are different from the causes of death among older children. Health child programs and policies have to be focused on reducing neonatal mortality.

In order to maintain in the future the control of measles (target no. 3), the proportion of one-year-old children immunized against this disease must be kept within 96±2%

CONCLUSIONS

Substantial progress has been made in Romania, in achieving the Millennium Development Goal no. 4 - reducing child deaths - since 1990.

The global target no. 1 to reduce by two-thirds, between 1990 and 2015, the under-five mortality rate was achieved. The

national target no.1 - to halve mortality of children aged between 1 and 4 between 2002 and 2015 - was also, achieved.

The target no. 2 - Reduce infant mortality by 40% between 2002 and 2015 - was achieved. However, with regard to both indicators concerning child mortality, in spite of the remarkable progress made, Romania still lags far behind the other countries of European Union.

The target no. 3 - eliminate measles by 2007 - was achieved one year later (2008). These important gains will have to be maintained in the future.

INTERNAL HERNIAS AFTER BARIATRIC SURGERY

Hernias are among the most common long-term complications after bariatric surgery. Incisional hernias occur very often after conventional open bariatric surgery. The incidence of internal hernias after bariatric surgery (a special challenge) is more common than for other upper gastrointestinal tract operations. These hernias are not limited to laparoscopic procedures but are also observed after conventional open gastric bypass surgery. As the incidence is significantly increased after laparoscopic interventions, there seems to be a close association with minimally invasive procedures. The clinical symptoms of internal hernias without complete obstruction are non-specific and the correct diagnosis is often not straightforward. In addition to the aspects of prevention of internal hernias in laparoscopic surgery, this article discusses the diagnosis and treatment, taking into account the various forms of internal hernia after bariatric operations (Karcz W et al. Internal hernias after bariatric surgery. *Der Chirurg* 29.08.2015 86 : 9 : 855-860).

ETIOLOGY AND RESISTANCE PROFILE OF ISOLATED STRAINS FROM SEVERE SYSTEMIC INFECTIONS IN PATIENTS WITH IMMUNODEPRESSION- EXPERIENCE OF THE IASI INFECTIOUS DISEASES HOSPITAL 2011-2014

ETIOLOGY AND RESISTANCE PROFILE OF ISOLATED STRAINS FROM SEVERE SYSTEMIC INFECTIONS IN PATIENTS WITH IMMUNODEPRESSION- EXPERIENCE OF THE IASI INFECTIOUS DISEASES HOSPITAL 2011-2014 (Abstract): Microbial resistance is an increasingly serious threat to global public health and it is linked to patient's age, immune status, and also antibiotic overuse or misuse and repeated hospitalizations. The high incidence of infections caused by multidrug-resistant bacteria requires rethinking the first-line therapeutic schemes. **Aim**: Retrospective study of the etiologic and antibiotic resistance profile of the bacterial strains isolated from immunocompromised hosts diagnosed with severe systemic infections, aimed at gaining a better understanding of the potential infectious sources and optimizing the antibiotic therapy. **Material and methods**: 178 cases of severe sepsis associated with immunosuppression (caused by diabetes, malignancies, liver cirrhosis, chronic alcohol abuse, kidney failure) were admitted to the "St. Parascheva" Infectious Diseases Hospital Iaşi in the interval January 2011- December 2014. **Results**: The mean age of the study patients was 61 years, most patients being female (53%) and living in urban areas (51%). The causal agents were: *Escherichia coli* (20.2%), *Klebsiella pneumoniae* (16.8%), *Pseudomonas aeruginosa* (14.6%), *Methicillin-Sensitive Staphylococcus aureus* (MSSA) (11.2%), *Enterococcus spp.* (10.1%), *Methicillin-Resistant Staphylococcus aureus* (MRSA) (8.9%), *Proteus spp.(5%), Acinetobacter baumanii* (5%), *Streptococcus pyogenes* (1.6%), *Staphylococcus epidermidis* (1.1%) and *Citrobacter* (0.5%). As to the resistance profile the following were found: 100% susceptibility of MRSA and *Enterococcus species* to vancomycin, as well as for the *Enterococcus* species; 27% of *E. coli* strains were resistant to beta-lactams and 20% of *Klebsiella pneumoniae* to carbapenems. Antibiotic therapy associated two or three drugs with an immediate result and a favorable outcome in 84.2% of the cases. **Conclusions:** The etiological agents implicated in the occurrence of severe sepsis in patients with acquired immunosuppression were Gram-positive bacteria (GPB) as well as Gram-negative bacteria (GNB) with moderate resistance to usual antibiotics. The infections caused by GNB were predominant in immunocompromised patients, but also in those with associated urinary and respiratory tract infections and chronic indwelling urinary catheters. In our severe sepsis patients Gram positive bacteria caused mainly skin and joint infections.
Keywords: ANTIBIOTHERAPY, BACTERIAL RESISTANCE, SEVERE SEPSIS.

Infections caused by multidrug-resistant germs are a current public health problem worldwide which affects all medical specialties, especially intensive care, surgery, pediatrics, neonatology, gynecology and oncology. Under these circumstances, in selecting an appropriate antibiotic therapy, clinicians must consider the current resistance spectrum of the strains circulating in a certain geographic area. Equally important are the efficacy, side effects, and high cost of antibacterial medication, especially of the latest generation one. Infections are an aggravating factor in the case of immunosuppressed patients, in which making a diagnosis is difficult because of the predominance of subclinical forms and the therapeutic choices must include specific antibiotics with maximum effectiveness and minimum side effects. Recent studies have demonstrated an increasing frequency of infections with GPB and especially with *MRSA*, with and estimated incidence of 67%, and *Enterococcus spp.* with an estimated incidence of 12% (1,2,3). *Klebsiella pneumoniae* is one of the most highly resistant bacteria, which is, in over 50% of cases, refractory to treatment with third-generation cephalosporins, fluoroquinolones and aminoglycosides. The resistance to carbapenems is also on the rise in Europe (4). The resistance of *E.coli* to third-generation cephalosporins ranges from 25 to 50% (5). *E.coli* is also a common GNB cause of sepsis and represents the most common cause of nosocomial urinary tract infections (6,7,8).

METHODS

The cases of severe sepsis admitted to the "St. Parascheva" Infectious Diseases Hospital Iaşi in the interval January 2011-December 2014 were retrospectively studied. The 178 patients included in the study were diagnosed by physical examination, laboratory tests able to evaluate the immune system (complete blood count, inflammation tests, liver and kidney function tests, blood glucose level) and bacteriological tests (identification test by classical diagnosis algorithm and antibiograms by Kirby-Bauer method and CLSI- Clinical Laboratory Standards Institute- standards). The data were collected from the observation papers of the studied patients and were processed using Microsoft Office Excel 2013. During the course of disease we followed the resistance of the involved microorganism to classical antibiotics, antibiotic treatment schemes and disease course under treatment (monitored by physical exam, repeated laboratory tests, temperature curve, days of hospital stay, and the need of intensive care procedures in unstable patients).

RESULTS

The 178 patients included in the study accounted for 2.1% of all sepsis cases admitted during the study period. The mean age of the study patients was 61 years (range 20-91 years), most patients being female (53%) and living in urban areas (51%). The causative agents of the infectious episode were varied (tab. I).

Methicillin-sensitive S. aureus (*MSSA*) was the main Gram positive coccus implicated in the etiology of severe sepsis in immunodepressed patients (11.2%). In these cases the systemic infections with *MSSA* was associated with skin (60%) and joint infections (40%). *MRSA* (*methicillin resistant S.aureus*) was present in a lower percentage compared to *MSSA* (8.9% vs 11,2%). Susceptibility of *MRSA* to vancomycin, teicoplanin, linezolid, ciprofloxacin,

rifampicin and ceftaroline was preserved. Fifty-six percent of *MRSA* strains were sensitive to cotrimoxazole. None of the *MRSA* strains showed resistance to vancomycin or linezolid and these were the first therapeutic options. *MRSA* infections were treated with combinations of glycopeptides (vancomycin) with quinolones (ciprofloxacin), fifth-generation cephalosporins with quinolones (levofloxacin) or lincosamides (clindamycin) with quinolones (ciprofloxacin).

TABLE I
Causative agents implicated in severe sepsis

Causative agent	No. of patients	%
Escherichia coli	36	20.2
Klebsiella pneumoniae	30	16.8
Pseudomonas aeruginosa	26	14.6
Methicillin-sensitive S. aureus (MSSA)	20	11.2
Enterococcus spp.	18	10.1
Methicillin-resistant S. aureus (MRSA)	16	8.9
Proteus spp.	9	5.0
Acinetobacter baumannii	9	5.0
Enterobacter spp.	8	4.4
Streptococcus pyogenes	3	1.6
Staphylococcus epidermidis	2	1.1
Citrobacter	1	0.5

Another GPB with special implications in the etiology of severe sepsis in immunodepressed patients was *Enterococcus sp.*, with a prevalence of 10.1% and a resistance to ampicillin of 50%. No vancomycin-resistant strain was found. The presence of *Enterococcus* frequently worsened the immunodepressed status of patients suffering from diabetes, biliary disease, liver cirrhosis, malignancies.

The most commonly isolated Gram-negative pathogens were *Escherichia coli* (20.2%), followed by *Klebsiella pneumoniae* (16.8%) and *Pseudomonas aeruginosa* (14.6%). The incidence of severe sepsis with *E.coli* was higher in patients with preexisting urinary system disorders with associated urinary tract infections (30%). Twenty-seven percent of *E.coli* strains were resistant to ampicillin and 13.8% to third-generation cephalosporins. Gentamycin resistance among *E.coli* strains isolated was of 36.1%. *Klebsiella pneumoniae.* caused severe sepsis in 30 cases (16.8%) and was isolated from blood culture, but also from distilled beverages (23.3%), urine (20%) and tracheal aspirates (10%). Twenty percent of *Klebsiella* strains were extended spectrum beta-lactamase (ESBL+)-producing bacteria, and 12.2% were carbapenemase producing-bacteria.

Pseudomonas aeruginosa was isolated

from 14.6% of cases (26/178), especially from patients admitted to Intensive Care Unit (ICU). Sepsis induced by *Pseudomonas* began with respiratory tract and ear, nasal and throat (ENT) infections (53.8%), urinary (27%) and soft tissues infections (19.2%).

Acinetobacter baumannii and *Enterobacter spp.* affected a similar percentage of the study patients (5% vs 4,4%). *A.baumannii* was present in patients who developed ventilator-associated pneumonia during hospital stay; 75% of them had positive tracheal aspirate cultures. Antibiogram revealed a 100% sensitivity to colimycin; 62.5% of *Acinetobacter* strains maintained their sensitivity to carbapenems.

Proteus mirabilis caused severe sepsis in patients with immunodepression due to chronic liver diseases (liver cirrhosis) and kidney diseases (stage IV and V kidney failure). *Proteus mirabilis* and *Proteus vulgaris* were isolated from urine in 62.5% of cases; 72% of the strains were resistant to ampicillin and 45% showed resistance to aminoglycosides (gentamycin).There were also cases of sepsis caused by *Streptococcus pyogenes* (1.6%), *Staphylococcus epidermidis* (1.1%) and *Citrobacter* (0.5%). Of all study patients, 36 (20.2%) required admission to Intensive Care Unit (ICU), because they had at least two organ dysfunctions. The average hospital stay was 12 days and the outcome was favorable in 84.2% of the cases (150 patients).

DISSCUSIONS

The etiology of severe sepsis in immunodepressed patients is varied and complex. It usually includes germs with a lower pathogenic potential. These patients are more exposed to nosocomial multidrug-resistant infections in comparison to immunocompetent hosts and the risk is due to repeated contacts with hospital environment (9,10). In the last years the incidence of MRSA infections among patients admitted to ICU reached almost 35%, no significant differences compared with those who did not require these maneuvers (25%) being found (10). In our study the prevalence was of 8.9%, lower than the prevalence rates reported in the literature, most probably due to the fact that the infections were community-acquired. The resistance mechanism of MRSA strains is most frequently based on the expression of a modified penicillin binding-protein (PBP), known as PBP 2a, which is responsible for resistance to all beta-lactam antibiotics and other classes of chemotherapeutic agents (quinolones, macrolides, tetracyclines). Future biological molecular tests are necessary to confirm the mechanism of resistance (10). In order to fix this problem, the clinicians had to use reserve antibiotics: glicopeptids (vancomycin/teicoplanin), oxazolidinones (linezolid), streptogramins, with the mention that the last ones are not available in our country (11). The treatment of the study patients was based on the administration of vancomycin/linezolid. *Enterococcus* strains are also implicated in the initiation of severe sepsis and septic shock, with a significant rate of vancomycin resistance (30%) in some countries (11). In our study we found no vancomycin-resistant *Enterococcus* strains (VRE). *E.coli* strains resistant to third-generation cephalosporins have been reported in the European countries, mainly in Italy (23%) and Germany (15%) (12,13). In our study, *E.coli* resistance to third-generation cephalosporins was of about 13.8%, similar to that previously mentioned; on the other

hand a higher resistance to aminoglycosides (36.1%) was recorded. In 2012 a significant increase in carbapenem-resistant *Klebsiella pneumoniae* was recorded (15% respectively) (11,12,13), consistent with our findings (*Klebsiella* ESBL+ strains 20% and carbapenemase-producing strains 12.2%), in which the administered antibiotic was colimycin. The carbapenems are reserve antibiotics for more than a decade and are extremely important in the case of severe infections caused by such GNB as *Pseudomonas aeruginosa, Acinetobacter* or *Enterobacteriaceae* species (14,15). *Acinetobacter sp.* causes nosocomial infections so that patients at higher risk for unfavorable course will be difficult to treat due to the high rates of resistance to carbapenems. In our study *Acinetobacter* resistance to carbapenems was of 37.5%, higher than the resistance rates recorded in Europe. A rate of carbapenem-resistant *Acinetobacter species* of over 25% was found in 8 of the 18 EU countries reporting data on *Acinetobacter*, while five of them reported a *Klebsiella pneumoniae* resistance to carbapenems of over 5% (15). The rate of bacterial resistance significantly differs from one country to another. The rate of *Acinetobacter* resistance to carbapenems has already exceeded that of *Klebsiella pneumoniae.* The same is true in the present study, in which *Acinetobacter* resistance to carbapenemes is almost three times higher than that of *Klebsiella pneumoniae.* Fortunately, the nosocomial infections caused by *Acinetobacter* are seven times more rare than those due to the two *Enterobacteriaceae species* (15).

CONCLUSIONS

In our study, the etiology of severe sepsis in patients with immune deficiency included gram positive bacteria (*MRSA, MSSA, Staphylococcus epidermidis, Enterococcus sp, Streptococcus pyogenes*), as well as gram negative bacteria (*Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Acinetobacter baumanii, Pseudomonas aeruginosa, Citrobacter, Enterobacter sp.*). The resistance of these microorganisms to usual antibiotic treatment had often complicated the disease course, requiring the rethinking of therapeutic schemes, although the incidence of MRSA sepsis was below that reported in the other European countries (8.9%) and glycopeptide susceptibility has been preserved by 100% of the studied strains. Of the GNB *Escherichia coli* and *Klebsiella pneumoniae* were the most common causative agents, with a moderate resistance to beta-lactam antibiotics (20%) and aminoglycosides (36,1%), but with total susceptibility to colimycin. In this context, an appropriate antibiotic therapy can improve the chances of healing and, at the same time, may reduce costs and length of hospital stay.

ANGIOTENSIN CONVERTING ENZYME GENE POLYMORPHISMS IN CORONARY ARTERY DISEASE-A CONTROVERSIAL ROLE (Abstract): Coronary artery disease (CAD) is the most prevalent cause of morbidity and mortality worldwide. It is a multifactorial disease, which is influenced by genetic and environmental factors. The major risk factors of CAD are age, male gender, hypertension, diabetes, hyperlipidemia, smoking, family history of CAD and obesity. Genetic factors add further information in predicting CAD. The relationship between genetic risk factors and the development of CAD is not well understood, likely due to the complex interrelation of genetic and environmental risk factors. One of the currently explored genetic factors is angiotensin converting enzyme (ACE) polymorphisms, which may have an influence on the progression of coronary artery disease. We present the results of several recently published studies (2012,2013) on the association between traditional cardiovascular risk factors and novel genetic risk factors (polymorphisms of ACE gene: insertions/deletions). The results of these studies are controversial. Most of them show an association between DD polymorphisms and D allele and the severity of stenotic coronary lesions, evaluated using the Gensini score (Gensini>6). However, others found no association. These differences may be due to geographical discrepancies, ethnical characteristics, small number of subjects included and variability of used techniques. We can therefore draw the conclusion that an international study on a large number of patients, using the same technique for genetic determination and the same statistical software should be performed. **Keywords**: ANGIOTENSIN CONVERTING ENZYME, GENETIC POLYMORPHISMS, CORONARY ARTERY DISEASE, STENOSIS.

Cardiovascular disease (CVD) is the major cause of morbidity and mortality in Westernized societies (1). It is well known that the etiology of this devastating disorder involves both genetic and environmental factors. Sequence variants of the components of the renin-angiotensin-aldosterone system are suggested to have significant influences on cardiovascular homeostasis. Both gene targeting and transgenic studies in mice have clearly suggested a critical role of the angiotensin converting enzyme (ACE) gene in blood pressure regulation. Thus, the ACE gene has been

recognized as a top candidate gene for cardiovascular research. The relationship between genetic risk factors and the development of coronary artery disease (CAD) is not well understood, likely due to the complex interrelation of genetic and environmental risk factors (3).

CARDIOVASCULAR RISK FACTORS

Risk factors for CAD were officially described after the discoveries of the Framingham study:

1. Conventional risk factors: age (over 45 years for men, over 55 years for women), family history of heart disease, race (higher incidence in African-Americans);

2. Modifiable risk factors: smoking, high total cholesterol level (especially LDL-cholesterol), hypertension, lack of physical activity, obesity, diabetes, metabolic syndrome, stress or depression;

3. Nontraditional risk factors (novel risk factors): inflammatory markers such as C-reactive protein, coronary calcium, lipoprotein (a), interleukin-6, fibrinogen, homocysteine, small-dense low-density lipoprotein, insulin resistance;

4. Genetic factors, which represent the latest discoveries in the field of cardiology: ACE gene polymorphisms (4).

ANGIOTENSIN CONVERTING ENZYME POLYMORPHISMS

ACE is a zinc metallopeptidase widely distributed on the surface of endothelial and epithelial cells. Several different names refer to this enzyme in the scientific literature. ACE converts the inactive decapeptide angiotensin I (Ang I or Ang 1-10) to the active octapeptide and potent vasoconstrictor angiotensin II (Ang II or Ang 1-8), which is the main active product of the renin–angiotensin system (RAS). Long-term regulation of blood pressure and blood volume in the body is controlled by RAS.

Angiotensin II is a potent vasoconstrictor. It also acts on the adrenal cortex, causing the release of aldosterone, which stimulates tubules in the kidneys, allowing them to reabsorb more sodium and water from the urine. These effects directly act to increase the amount of fluid in the blood, making up for a loss in volume, and to increase blood pressure. Angiotensin II also mediates cell growth and proliferation by stimulating various cytokines and growth factors (5). Furthermore, angiotensin II may induce endothelial dysfunction by reducing nitric oxide bioavailability (6). These findings emphasize the importance of angiotensin II in cardiovascular pathophysiology and motivate exploration of the role of RAS in atherosclerosis and other cardiovascular outcomes. ACE also plays an important role in another hormonal system, the kallikrein kinin–cascade. ACE metabolizes bradykinin, which is a strong vasodilator, forming the inactive metabolite bradykinin 1-5. Therefore, ACE plays a prominent role in blood pressure regulation through this pathway as well (7, 23).

The ACE gene is located on chromosome 17q23. It spans 21 kb, and comprises 26 exons and 25 introns (8). It contains a polymorphism due to an insertion (I) or a deletion (D) of a 287 base pair (bp) *alu* sequence in intron 16, resulting in the 3 genotypes of insertion/insertion (II), insertion/deletion (ID), and deletion/deletion (DD). (8, 9, 10). The I/D polymorphism is associated with circulating and tissue ACE levels. Individuals homozygous for the D allele had higher tissue and plasma ACE concentrations than heterozygotes and II homozygotes (11). *ACE* polymorphism has

attracted a great deal of information as a potential cause of genetic variation in cardiovascular physiological function (12). Consequently, the *ACE* I/D polymorphism have been associated with various cardiovascular diseases, such as atherosclerosis (13), hypertension (14), and coronary artery disease (CAD) (15). *ACE*, as a candidate gene, can associate with traditional risk factors in predicting the severity of CAD (3, 24).

GENETIC STUDIES

The relationship between ACE polymorphisms and other cardiovascular risk factors (CRF) is not well understood in CAD, likely due to the complex interrelation of genetic and environmental risk factors. Several studies were aimed to investigate the associations of CAD risk factors and *ACE* polymorphisms in patients with CAD.

Patients included in the studies were referred for coronary angiography as a result of various clinical indications.

The experimental protocol was approved by the Ethics Committees, the study procedures being in accordance with the principles of the *Declaration of Helsinki II*, and all subjects provided written informed consent prior to enrollment.

Physical examination was performed on and a detailed family history was obtained for all subjects. The severity of CAD was evaluated according to the number of stenotic vessels on coronary angiography. The coronary angiography findings were reviewed by independent operators. The angiography results were reported as Gensini scores, which were computed by assigning a severity score to each coronary stenosis according to the degree of luminal narrowing and its importance based on location. Reduction in the lumen diameter and the angiographic appearance of concentric lesions and eccentric plaques were quantitatively evaluated. Gensini scores higher than 6 were considered a criterion for having CAD in the patients.

Informations about the conventional risk factors for CAD (1. hyperlipidemia, 2. hypertension, 3. diabetes mellitus, 4. family history of CAD, 5. smoking, 6. obesity) were obtained from all subjects. All studies used well defined inclusion criteria, according to strict definitions of the risk factors.

Hyperlipidemia was defined based on low-density lipoprotein cholesterol(>100 mg/dL for subjects with CAD) and/or high-density lipoprotein cholesterol (<40 mg/dL for men and <50 mg/dL for women) and triglyceride levels(>150 mg/dL), or prior requirement of lipid lowering medications. Hypertension was defined as blood pressure level above 140/90 on 3 different occasions or requirement of pharmacological intervention to lower blood pressure. Diabetes mellitus was defined as fasting venous blood glucose ≥126 mg/dL on 3 separate occasions or requirement of pharmacological intervention for diabetes mellitus. Family history of CAD was defined as having a first degree relative with established CAD before age 50, or before menopause. Cigarette smoking was assessed by asking participants about prior and current history of smoking habits. Body mass index (BMI) was calculated as weight (kg)/height (m^2). Overweight or obesity were defined based on the BMI levels (>25-29.9 and ≥30 kg/m^2 respectively).

CAD was defined as a documented coronary stenosis of at least 70% by quantitative coronary angiography in one or more major (more than 2 mm in diameter by

quantitative coronary angiography) coronary arteries. The patients included were divided into groups according to the number of diseased vessels (coronary obstruction of at least 70%) as determined by the number of diseased major coronary arteries (left anterior descending, left circumflex, and right coronary artery). Patients were grouped into 0, 1, 2, 3, or 4 vessel disease groups. Some studies selected patients without significant coronary obstruction by coronary angiography (less than 30%) as controls.

All studies extracted the DNA, used polymerase chain reaction (PCR) amplification and different SPSS programs for statistical analysis.

ANALYSIS OF THE STUDIES

Zhou Y.F. et al (16), enrolled 603 patients in three groups: 260 subjects were enrolled in the elderly control group (Male, n = 150, Female, n = 110), whose age were from 75 to 85 years (81.6 ± 4.55 years). They were admitted to the hospital for medical examination and routine treatment from the October 2006 to March 2013. They did not have hypertension, diabetes, coronary heart disease (CHD) or any other CVD. Two hundred and five patients aged 74 to 86 years (79.8 ± 6.28) years were enrolled in elderly hypertensive group (male, n = 103, female, n = 102). One hundred and thirty eight patients aged 75 to 83 years (79.12 ± 5.21 years) were enrolled in elderly diabetic hypertension group (male, n = 70, female, n = 68). The result was that in Chinese elderly population DD genotype and D allele in ACE gene were associated with hypertension and lipid levels. However, they were not risk factors for type 2 diabetes.

Guney A.I. et al. (2), enrolled 343 patients with CRF and angiographically proven CAD. Patients were grouped into 0, 1, 2, 3, or 4 vessel disease groups. Patients without significant coronary obstruction by coronary angiography (less than 30%) were selected as controls (140 patients). Their results showed that the frequency of the DD genotype was significantly higher in patients. D allele frequency was higher among CAD subjects when compared to the control group. The number of stenotic vessels were found to be statistically associated with a high frequency of DD polymorphism and D allele and a low frequency of I allele in patients, especially in male patients. The control group displayed II and ID genotypes more frequently than did the patients. The *ACE* I/D genotype was associated with hyperlipidemia and smoking history. They considered that the DD polymorphism and D allele may affect the severity of CAD, while I allele may have a protective effect. In conclusion, the *ACE* I/D genotype may interact with conventional risks criteria in determining the risk of CAD.

Dhar S. et al. (17), included 217 clinically diagnosed cases with CAD from the outdoor of Cardiology Department of Ramakrishna Mission Seva Pratishthan. 255 age and sex matched medically diagnosed healthy controls were taken for the study which were negative for Treadmill test (TMT_ve). All the samples were diagnosed by biochemical tests and other medical tests like electrocardiogram, echocardiography, or treadmill test.

The results of this study outlined that both DD [OR: 2.16; 95%CI: (60.60e67.40)] and ID [OR: 1.48; 95%CI: (93.28e97.72)] genotypes of the ACE gene showed significant associations in the development of CAD. Coexistence of diabetes and hyper-

tension was found to be a risk modifier of the disease. Tobacco intake in various forms elevates the risk of the disease among the cases with risk genotypes. Therefore, ID and DD genotypes of ACE gene came out to be predisposing factors for the CAD cases in our study population.

Poorgholi L. et al. (18) performed a cross-sectional study on a total of 1050 individuals referred to hospital for coronary angiography. 676 CAD-positive patients (documented by coronary angiography and Gensini scores higher than 6) and 374 CAD-negative patients were evaluated for ACE gene I/D polymorphism via the Polymerase Chain Reaction Amplification method. Patients' age, sex, smoking status and its duration as well as family history of CAD, hypertension, and diabetes mellitus were recorded.

The results showed that 504 (74.6%) of the CAD-positive patients were male, and the mean age of this group was 60 (60 ± 10). In the CAD-negative individuals, the mean age was 56 (56 ± 10) and 196 of them were male (52.4%). After the analysis of all groups and gender subgroups, neither genotype nor allele frequency was significantly different between the CAD-positive nor CAD-negative groups (p values for genotypes and allele frequencies were 0.494 and 0.397, respectively). Therefore, ACE gene I/D polymorphism were not associated with an increased risk of CAD in an Iranian population.

Sahin S.et al. (19), investigated whether the insertion/deletion (I/D) polymorphism in the ACE gene and serum ACE levels are associated with traditional risk factors of CAD. They enrolled 250 individuals without CAD and 750 individuals suffering from CAD who were angiographically diagnosed. Biochemical risk factors, the ACE (I/D) gene polymorphism, and ACE serum levels were compared. Compared to the control group, the CAD group showed significantly higher serum ACE levels ($P < 0.001$). The highest ACE levels were found in those with the DD genotype. Other genotypes also presented statistically significant differences. They observed a significant difference between the control and coronary patient groups regarding the levels of total cholesterol, triglyceride, high-density lipoprotein-cholesterol, and low-density lipoprotein-cholesterol ($P < 0.05$). ACE (I/D) genotypes and serum ACE levels may be associated with risk factors and the development of CAD.

DISCUSSION

We presented the results of several recently published studies (2012,2013) on the association between traditional CRF (hypertension, diabetes, hyperlipidemia, obesity, smoking habit, family history) and novel genetic risk factors (ACE deletion/insertion polymorphisms).

In all studies, DNA was extracted from peripheral leukocytes and amplified by polymerase chain reaction (PCR). Data were analyzed with different statistical softwares, such as *SPSS 11.5, SPSS 13.0, SPSS 14.0, SPSS 18.0, SAS 9.2* packages.

Inclusion criteria were similar between studies, but some studies chose healthy subjects for comparison (16) while others used patients without significant stenosis (less than 30%) for the second group (2, 18).

The results of those studies were controversial. Most of them showed an association between genetic risk factors (DD genotype, D allele) and the severity of stenotic coronary lesions, evaluated using the Gensini score (Gensini>6). Gensini

score is based on the number of stenotic coronary artery segments, degree of luminal narrowing and the regional importance of lesion location in the coronary tree. However, Poorgholi L. et al. (18), found no association between ACE I/D polymorphism and the progression of coronary artery disease in an Iranian population.

There are multiple implications of ACE gene in CAD. The presented studied focused on the development and severity of stenosis. Other directions scientists are working on are left ventricular dysfunction and in-stent restenosis, in the context of ACE gene polymorphisms. In-stent restenosis occurs after treatment of coronary artery stenosis in 12% to 32% of coronary interventions with stents. Experimental and clinical studies have suggested that the deletion/insertion (D/I) polymorphism of the ACE gene plays a role in this. Jorgensen E. et al.(20), performed a study on 369 patients after stent implant and concluded that the D/I polymorphism is not an independent predictor of coronary in-stent restenosis in general, but it may be of clinical importance in patients treated with ACE inhibitors or angiotensin receptor antagonists. Martinez R.A. et al. (21) also stated genetic variations of the ACE gene could be a genetic factor related to coronary artery disease in the Mexican mixed racial ancestry individuals, but do not support its role as a risk factor for developing restenosis after coronary stenting. However, the meta-analysis by Wang S et al. (22), showed that the DD genotype of ACE I/D polymorphism was significantly associated with increased risk of restenosis, particularly for PTCA stent.

CONCLUSIONS

We believe that these differences may be due to geographical discrepancies, ethnical characteristics, rather small number of study subjects and variability of the used techniques. We can therefore draw the conclusion that an international study on a large number of patients, using the same technique for genetic determination and the same statistical software should be performed.

THE EFFECTS OF RIBOFLAVIN AND METHYLENE BLUE ON NOCICEPTION AND VISCERAL PAIN (Abstract) **Background**: Methylene Blue (MB) can prevent electron leaking, increase mitochondrial oxidative phosphorylation, and reduce ROS overproduction under pathological conditions, currently being trace evidence that it can alter pain perception in humans by local administration during certain surgical procedures. Riboflavin or vitamin B2 (B2) constitutes a part of the vitamin B group, which in recent studies shows a growing implication in the treatment of some pathology that imply pain management. **Aim**: To investigate the effect of one dose of Riboflavin and Methylene Blue on nociception and visceral pain in mice. **Methods**: A total of 48 BALB/c male mice were divided into 3 groups: MB Group, B2 Group and C Group. MB (5 mg/kg b.w.), B2 (100 mg/kg b.w.) or an equivalent volume of saline was administered intraperitoneally. Mice were tested before (baseline) and after drugs administration over a 4h period. Nociception was evaluated by means of Hot Plate Test (HPT) and TFT (Tail Flick Test). Visceral pain was evaluated 2h after administration. **Results**: Four hours after MB administration we recorded an analgesic effect on the hot plate test ($p<0.05$ at 30, 60 and 240 min). No significant effect on the TFT was noticed. B2 vitamin had an antinociceptive effect as compared to control group only for HPT that persisted for 2h but had no effect on TFT. Both MB and B2 vitamin have shown an analgesic effect ($p<0.01$) on visceral pain when compared to the control group but the pain inhibition was more important after riboflavin administration. **Conclusions**: Even if the exact mechanisms are not clarified by our study, we demonstrated that both ATP modulators (MB & B2 vitamin) have analgesic effect on visceral pain and nociception. **Keywords:** METHYLENE BLUE, RIBOFLAVIN, PAIN

Methylene Blue (MB) is a synthetic redox compound containing a central thiazidic ring system (1) that had a wide usage from chemotherapy to dementia, antimalarial, and not least contributed to the discovery of the neuroleptic drug families due to its oxidation-reduction facilities (2).MB improves mitochondrial respiration and the metabolic rate stimulating the mitochondrial complex IV, enhancing it by 30% and increasing the oxygen consumption to 70% (3).

MB is inhibiting cGMP- mediated processes and neuronal NOS (4,5), and can

influence NO-synthases (ROS), mono-amino-oxidase A (MAO) and disulfide-reductases (6).

MB is able to interfere with peripheral and central nervous systems by modifying the glutamatergic, monoaminergic and cholinergic neuronal communication (7), and can also prevent leaking of electrons, increasing mitochondrial oxidative phosphorylation and reduce ROS overproduction (8).

In humans MB proved its analgesic effects after local administration either alone (intradermal anesthetic) in association with propofol injections (9) or in chronic low-back pain (10). In animals models it being reported that it could have antinociceptive effects.

Riboflavin (RF) also known as vitamin B2 constitutes a part of the vitamin B group that is essential for cellular functions and development. It plays an important role in oxidation-reduction reactions, reducing oxidative stress and is involved in mediating the immune responses (11).

RF has a modulating role on mitochondrial oxidative stress in the brain (12), and is documented that although most of the conditions were associated with B2 deficiency, it can be used to alleviate migraine as a prophylactic drug (13) or in diseases associated with metabolic disorders (14).

RF also demonstrated in recent studies that it can influence experimental nociception in mice by possibly influencing the inflammatory mediators (15) (TNF α, IL-1 or IL-6) and increase the effect of non-steroidal drugs in rats (16).

The purpose of our study was to assess the effects of both MB and RF on nociception and visceral pain in mice as long as both substances modulate serotonergic, noradrenergic, dopaminergic systems as well as NO and ROS all implicated in nociception modulation.

MATERIAL AND METHODS

Animals. The experiments were conducted on 48 BALB/c male mice (28-34 g), housed at 21 ± 2 °C under a 12-h light/ dark cycle, with access to food and water ad libitum. All animals were habituated to the testing laboratory for at least three days. The experimental protocols and procedures described in this article complied with the European Communities Council Directive 86/609/EEC and followed the International Association for the Study of Pain's (17) and the University of Medicine and Pharmacy "Gr. T. Popa" ethical guidelines for investigations of experimental pain in conscious animals.

Drugs. The drugs used in these experiments were: methylene blue 1% (Tis Farmaceutic, Romania), acetic acid (Sigma, Germany) and riboflavin (≥98%, Sigma, Germany).

Both MB and RF were freshly diluted in saline and administered intraperitoneal (i.p.).

The Hot-Plate Test (HPT). The hot-plate test was used to measure nociceptive response to heat according to the method described by Woolfe and MacDonald (18), with minor modifications. Briefly, the mice were placed into an open Plexiglas tube, on the hot-plate apparatus (Ugo Basile, model-DS 37, Italy) 55 ± 0.1°C and the time between placing the animal on the hot-plate and the occurrence of licking, shaking of hind paws or jumping off the surface was recorded as response latency. An automatic 15 s cut-off was used to prevent tissue damage. Animals displaying baseline latencies of more than 10 s were excluded from the study (20).

The Tail Flick Test (TFT). The tail flick test (19), was used to measure the latency for tail flick reflex following exposure to a heat stimulus. The heat source of the Tail-Flick unit (Ugo Basile, Italy) was focused on the distal portion of the tail at 4-5 cm from the tip and the reaction time necessary for the mouse to remove its tail was defined as the tail-flick latency. Animals displaying baseline latencies of more than 6 s were excluded from the study. The cut-off time was set at 12 s to avoid tissue damage (21).

Antinociception on the hot plate and tail flick tests was quantified as percentage of maximal possible effect (%MPE):

%MPE = [(post-treatment latency-baseline latency)×100 / (cut off latency-baseline latency)].

The Acetic Acid Induced Writhing Test (Visceral pain). Was performed as previously described by us, after acclimatization in an acrylic observation chamber for at least 20 minutes, the mice received 0.1 ml /10 mg b.w i.p. injections with 1.0% (v/v) acetic acid (20).

The antinociceptive activity in the writhing test was expressed as the percentage of inhibition of nociceptive behavior using the ratio:

% pain score = (control mean - treated mean) x 100/ (control mean)

Study design. A total of 48 mice were divided into three groups as follows: Group MB, mice receiving a single intraperitoneal dose of methylene blue (5 mg/kg b.w); Group RF that received a single dose of 100 mg/kg b.w. riboflavin and Group C that received an equivalent volume of saline in the same manner.

The TFT, HPT tests were performed at baseline and thereafter 30, 60, 120, and respectively after 240 minutes after administration. The writhing test was performed 2h after administration.

The doses used in this study are in range with literature data and have been proved a maximum antinociceptive effect from the doses tested in our lab (data not shown).

Statistical analysis. The data obtained were expressed as the mean value ± SEM. Statistical evaluations were performed using SPSS v 20.0 software with one-way ANOVA. Post hoc comparisons were performed using Tukey`s Test. The significance level was set at $p<0.05$.

RESULTS

The Tail Flick Test. Administered i.p. neither MB 5mg/kg b.w. or B2 100 mg/kg b.w. did not influence the reaction of the mice to thermal stimuli over the time period allocated for the experiment , with no statistical significance as compared to the control group.

The Hot Plate Test. A single dose of riboflavin produced a significant analgesic effect ($p<0.05$) that started 30 minutes after i.p. administration (fig. 1) and maintained for 2h (MPE of 30.8% reaching a maximum of 56% at 60 minutes) showing a decrease in effect after 240 min (MPE= -51.7). MB demonstrated the same analgesic effect ($p<0.05$) that occurred at the same time as for B2, with a MPE between 29% and 38%, the effect lasting over 4h%. Although the MPE was higher in B2 Group, the analgesic effect lasted longer in the MB Group.

The Writhing Test. Intraperitoneal administration of vitamin B2 showed a significant analgesic effect on acetic acid induced pain ($p<0.01$) same as MB ($p<0.05$) when compared to control group (fig. 2). The pain inhibition score was higher for

riboflavin (77%) as compared to the one MB demonstrated (23.2%) Tukey's multiple comparisons test showing strong significance between the two.

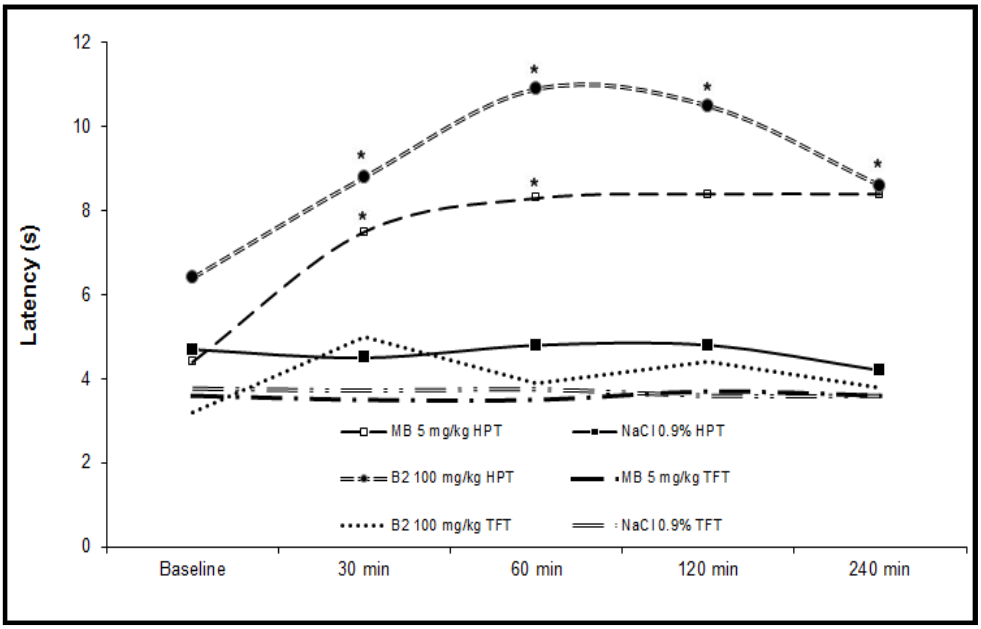

Fig. 1. The effects of B2 and MB on Hot Plate. The results are expressed as mean± S.E.M. * $p < 0.05$.

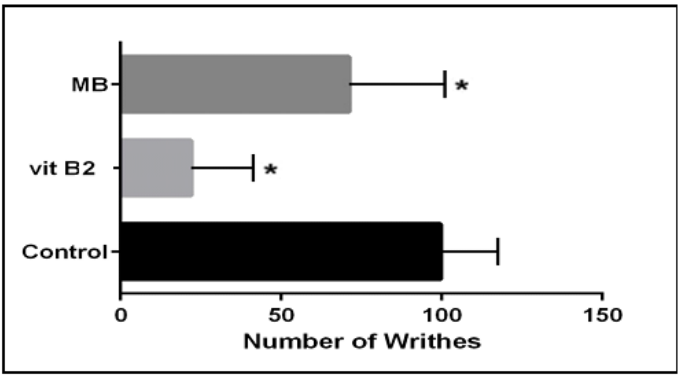

Fig. 2. The effects of B2 and MB on visceral pain in mice. The results are expressed as mean± S.E.M. * $p < 0.05$.

DISCUSSION

This study demonstrates, concordant with literature data, that methylene blue (22) and riboflavin (23) modify pain perception. Thus, our study is one more proof that ATP modulators had an analgesic effect on the hot plate test and visceral pain and a neglect effect of the thermonociception evaluated by the tail flick test.

The substances used by us are mitochon-

drial linked and have proved their ability to change the cellular ATP level and REDOX status of the cells. Thus, MB acts as an antioxidant and as an artificial electron donor to complex I-IV of the mitochondria, increasing ATP production and riboflavin has been shown to improve both complex I (NADH dehydrogenase) and complex IV (cytochrome c oxidase) activity. Riboflavin serves as a precursor of flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) coenzymes that participate in oxidative-phosphorylation reactions at the cellular level. A unique feature of FAD and FMN is their function as prosthetic groups in many enzyme systems and as catalysts of oxidation-reduction reactions.

There is a growing body of evidence that extracellular ATP has an important role in pain signaling (both the periphery and in the CNS). It is supposed that ATP is involved in acute pain; as long as ATP is released from damaged cells it excites directly primary sensory neurons by activating their receptors, by neither blocking nor suppressing the expression of P2X/Y receptors in sensory neurons or in the spinal cord, showing an effect on acute physiological pain. There is also evidence that endogenous ATP and its receptor system might be activated in pathological pain states, particularly in neuropathic pain. Thus, ATP is implicated in synaptic transmission of innocuous mechano-receptive and nociceptive input in the superficial dorsal horn; the purinergic ATP receptors being expressed in dorsal horn neurons and in DRG cells (24).

In our study we used two models of acute pain to evaluate the effects of methylene blue and riboflavin namely thermonociception models of pain (tail flick and hot plate tests) and visceral pain.

The hot plate and tail flick tests are commonly used for evaluating thermal pain sensitivity, heat selectively stimulating thermoreceptors and nociceptors. The tail-flick is considered mainly a spinal reflex, at least in its shorter latency form, persisting after section or cold block of upper parts of the spinal cord (25) but as with all reflexes, it is subject to supraspinal structures control (26).

By contrary, the hot plate test is supposed to have supraspinally integrated responses. The paw licking behavior is affected only by opioids but the jumping/shaking reaction time is increased equally by less powerful analgesics such as acetylsalicylic acid or paracetamol (27). Thus we must keep in mind that mainly tail-flick and less the hot plate tests are predictive only for substances that are morphinomimetic in the strictest sense, with very few effects for partial agonist compounds and none at all for mild antalgics.

Visceral pain results from activation of sensory afferent nerves innervating internal organs (28). Viscero-sensory axons are almost exclusively thinly myelinated A-delta and unmyelinated C fibers while the receptors exhibit chemosensitivity, thermosensitivity and/or mechanosensitivity. The afferent fibres convey sensory information from the upper gastrointestinal tract to the CNS via vagal and splanchnic nerve pathways (29). A nociceptive stimulus evoked by i.p. injection of acetic acid or citric acid in mice (a model of inflammatory visceral pain) stimulates sensory afferents and the transmission of nociceptive information, centrally leads to the activation of descending antinociceptive mechanism to a noxious stimulus (30). It has been proposed that distension of visceral organs leads to re-

lease of ATP from the epithelium lining the organ; the released ATP then acts upon P2X receptors in subepithelial nociceptors to elicit visceral pain (31). However, the ATP inhibitors (32) were ineffective in reducing nociception in animal models of visceral pain.

Our behavioral data demonstrate that both substances known to stimulate cellular ATP level, decrease pain perception explored by hot plate test and visceral pain. As long as exogenous ATP proved its pronociceptive effect when administrated locall or in DRG, we suppose that the ATP modulator used act rather on the ATP-sensitive potassium channel (K_{ATP}) family imply in analgesia and/or on purinergic receptor imply in pain inhibition.

CONCLUSIONS

Even this study does not clarify the intimate mechanisms of action for methylene blue and riboflavin it is proving that ATP stimulators after one dose has analgesic effects. Long term administration effects and the analgesic neuromediation activated need further studies.

PELVIC ENDOMETRIOSIS AND URETERO-HYDRONEPHROSIS: CLINICAL, IMAGISTIC AND SURGICAL IMPLICATIONS - CASE REPORT (Abstract): Endometriosis represent the presence and proliferation of functional endometrial-like tissue outside the uterine cavity, and is a chronic, recurrent, debilitating desease, in which kidney implications are rare, but complex. **Objective:** Evaluation of clinical, imagistic and surgical implications of uretero-hydronephrosis secondary to recurrent pelvic endometriosis. **Material and methods:** 30 year old patient diagnosed with primary infertility and left ovarian endometriosis (treated with classically conservative surgical procedure), presented acute onset of obstructive urinary symptoms, requiring internal drainage of the upper urinary straight path (Cook probe) for uretero-hydronephrosis grade III. CT and MRI examination reveals the presence of a imprecise pelvic mass incorporating right distal ureter and uretero-bladder ostium. **Results:** In this clinical and laboratory context, classic surgery is practicing with right anexectomy and direct right uretero-vesical reimplantation, also with psoas bladder-hitch. Histopathological examination confirmed the presence of recurrent ovarian endometriosis with right distal ureteral invasion. **Conclusion:** Recurent endometriosis , although considered a benign condition, often present invasive characters, determining considerable anatomical destructions and severe symptoms. **Keywords**: PELVIC ENDOMETRIOSIS, URETERO-HYDRONEPHROSIS, CT , MRI.

Endometriosis is a hormonal and immune system disease in which cells similar to that which line the uterus (endometrium) grow outside the uterine cavity, being commonly found on other organs of the pelvis. Endometriosis is typically diagnosed during the reproductive years, and is more common in women who are experiencing infertility than in fertile women (1,2). It is considered a disabling and expansive condition in the pelvic region and beyond, including internal scarring, adhesions, pelvic cysts, chocolate cyst of ovaries, ruptured cysts, and bowel and ureteral obstruction resulting from pelvic adhesions (3). Less frequently, 10% of women in the reproductive age have involvement of the genitourinary tract by endometriosis, leading to hydronephrosis as a result of adhesions and scar formation (4). In this cases, symptomatology is represented by dysuria, suprapubic pain, hematuria. Medical therapy is palliative and definitive therapy is surgical (5,6). Here we present clinical,

imagistic, and surgical implication in a case of pelvic endometriosis complicated with uretero-hydronephrosis.

CASE REPORT

In April 2011, thirty year old female patient (nulliparous/ no history of pregnancy) was admitted to our clinic with complaints of ongoing pelvic pain (accompanied by lower back pain/abdominal pain), dysmenorrhea, dyspareunia, constipation,chronic fatigue, nausea and vomiting, headaches, with exacerbation of the symptoms in the last 6 months, during her menstrual cycles. Her menarche occurred at the age of 14, with heavy and irregular menstrual periods. She did not receive a hormonal theraphy before, and reports that for the past 2 years she has been unsuccessfully trying to conceive. At this moment, patient denied any urinary symptoms. A pelvic examination revealed a normal sized uterus that was fixed and slightly tender, but with exacerbation of painful sensation in the left adnexal region. Vaginal examination reveals a painful induration in the posterior fornix. Transvaginal ultrasonography demonstrated a heteroecogenic multicystic formation (45/39/37 mm), located in the left of uterus.

A magnetic resonance imaging (MRI) was performed, revealed the presence of tumoral mass with polycyclic contour and multicystic appearance, located between the posterior wall of the uterus and left anterolateral wall of rectosigmoidian junction (fig. 1).

We performed a classical laparotomy with ablation of tumoral formation (anatomopathological report confirming the presence of an endometriotic ovarian cyst)-preserving the left ovary - and lysis of intra-abdominal adhesions, for an severe pelvic adhesive disease to the posterior surface of the uterus, posterior cul-de-sac endometriosis, contributing to a distorted pelvic anatomy.

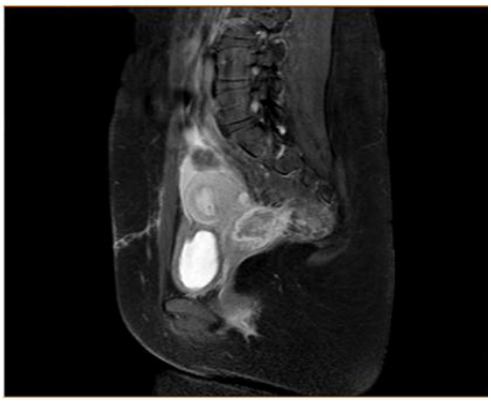

Fig. 1. Tumoral pelvic mass with polycyclic contour and multicystic appearance characterised by hyperintense signal on fat-saturated T1-weighted images – MRI.

The patient recovered well after her surgery and received Diphereline (Triptorelin Acetate) treatment - 3.75mg administered as one intramuscular injection repeated every 4 weeks (6 months). After surgery, the patient never presented for any clinical and laboratory reevaluation. In January 2013, the patient went to the emergency department for an acute episode of severe pelvic pain associated with abdominal cramps, vomiting, dysuria, and intermittent hematuria associated with the menstrual cycle. Renal functional tests (blood urea nitrogen/ creatinine/creatinine clearance rate) were abnormal, but whith normal urine culture. Pelvic ultrasonography revealed uretero-hydronephrosis grade II-III with no evidence of calculi, and the presence of a heteroecogenic multicystic formation (52/47/41mm), imprecisely delimited, located in the right of uterus. A contrasted abdominal computed tomography (CT) examination reveals the presence of severe obstruction of right distal ureter by an intraureteral enhanced soft

tumoral mass. In this context, urologists performed internal drainage of the upper urinary straight path (Cook probe) for uretero-hydronephrosis.

After intervension, a MRI examination reveals the presence of a imprecise pelvic mass incorporating right distal ureter and uretero-bladder ostium, characterised by hyperintense signal on fat-saturated T1-weighted images (fig. 2).

Fig. 2. Imprecise pelvic mass incorporating right distal ureter and uretero-bladder ostium, characterised by hyperintense signal on fat-saturated T1-weighted images – MRI.

The double-J stent was kept in 6 weeks postoperatively, and after this, classic surgery is practicing with right anexectomy and direct right uretero-vesical reimplantation, also with psoas bladder-hitch. Histopathological examination confirmed the presence of recurrent ovarian endometriosis with right distal ureteral invasion. She will be followed up with a cystoscopy and pelvic magnetic resonance imaging scan in 4 months to check for endometriosis recurrence.

DISCUSSION

Endometriosis is defined as the presence of endometrial glands and stroma outside the uterus. The prevalence of endometriosis is unknown but estimates range from 2 to 10% of women of reproductive age (7). It predominantly affects women of reproductive age and is associated with pelvic pain and fertility problems (8). The aspects of the pathophysiology can basically be classified as underlying predisposing factors, inflammation, metabolic changes, formation of ectopic endometrium, and generation of pain and other effects (9). The ectopic endometrium can be limited to the superficial peritoneum in an otherwise normal pelvis (peritoneal endometriosis) but can also develop into ovarian endometriotic cysts (endometriomas) (10). In some cases, it involves the uterosacral ligaments, the rectosigmoid colon, the vagina, and the bladder and can cause a complete distortion of the pelvic anatomy (11). Urinary tract endometriosis (UTE) is observed in 1-2% of women with endometriosis, about 80% have urinary bladder involvement (12). In the evolution of this disease, recurrency is an essential feature. In our case, urinary symptoms were present at 20 months after the first intervention, in the context of hormonal treatment. It is difficult to say that was just a primary uretero-bladder

endometriosis, which occurs when the endometrial tissue is congenitally located within the urinary uretero-bladder wall. Most likely, in our case, was the case of a secondary endometriosis, due to iatrogenic lesion occurring after primary pelvic conservative intervention.

In this cases, symptomatology is not specific, being represented by dysuria, suprapubic pain, cyclic urgency, and rarely hematuria, symptoms similar to those of recurrent cystitis, which may be responsible for its delayed diagnosis (13,14). Some authors suggest that negative urinary cultures in symptomatic individuals may suggest urinary bladder endometriosis (15). Transvaginal ultrasonography is the first-line imaging study when endometriosis is suspected: it is powerful, simple, widely available, and cost-effective, being recommended for diagnosing endometriotic ovarian cysts (16). On the other hand, MRI has high specificity for the diagnosis of endometriomas as a result of its ability to detect aged hemorrhagic content. MRI is also less operator dependent than transvaginal ultrasonography and is more sensitive for detecting foci of deeply infiltrating endometriosis, because of its ability to completely survey the anterior and posterior compartments of the pelvis (17).

In women in the reproductive years, endometriosis is merely managed: the goal is to provide pain relief, to restrict progression of the process, and to restore or preserve fertility where needed. In younger women, like our patient, with unfulfilled reproductive potential, surgical treatment attempts to remove endometrial tissue and preserving the ovaries without damaging normal tissue. Conservative treatment is very important, but may increase the risk of recurrence, like urinary tract endometriosis, the second most commonly involved site by extrapelvic endometriosis (18). Surgical management of uretero-bladder endometriosis may includes urethral resection for obstructive lesions, combined with reconstruction of the bladder, and association of medical therapy.

CONCLUSIONS

It is a rare case of endometriosis with involvement of the urinary tract leading to renal failure because of the silent obstruction of the ureter. In this case, the surgical treatment is the best choice, the symptomatology beeing nespecific and the usual investigations such as CT, RMN and ultrasonography only suggesting this chronic condition.

TRANSORAL ROBOTIC SURGERY (TORS) WITH THE MEDROBOTICS FLEX™ SYSTEM: FIRST SURGICAL APPLICATION ON HUMANS

Head and neck surgery can be fraught with difficulties in accessing the pharynx and larynx. Minimally invasive surgery has developed with the recent advances in technology. Currently, a variety of high-definition multichannel videoendoscopes and robots became available. The authors present their experience in a new robotic surgical system-'The Medrobotics Flex™ System' at our tertiary referral unit. The aim of this prospective study eas to assess the safety, functionality and ease of use of this new device. Thus far, this is the first study in live human subjects who have undergonesurgery for the following conditions: (1) obstructive sleep apnoea involving the base of tongue, the tonsil and the velum; (2) vocal fold polyp; (3) carcinoma of the lateral edge of the tongue. No complications were recorded and the system provided good visualisation and access to these subsites without compromising safety or success. In summary, the authors found the Medrobotics Flex™ System to have certain other advantages including ease of set up and use besides being reliable and safe. THE USE OF TITANIUM MESH IN FACIAL CONTOUR RECONSTRUCTION (Abstract): Bone defects following trauma, or the radical resection of facial tumors are often associated with the loss of soft tissue support. The objectives of facial reconstructive surgery should not only be the restoration of the defect, but also the aesthetic and functional craniofacial rehabilitation with the restoration of facial symmetry. **Aim:** The purpose of this study is to assess the practicality of titanium mesh panels for reconstructing the craniofacial skeleton. **Material and methods:** Between January 2015 and December 2017 the authors used titanium mesh for a number of 26 patients in 20 trauma-related cases and six cases of post-ablative defects when titanium mesh was covered using loco-regional flaps. **Results:** All the facial dimensions were restored. None of the titanium meshes was exposed postoperatively. **Conclusions:** Titanium mesh has proven to be a useful material for the reconstruction of the craniofacial skeleton, capable of providing a true individualized treatment. **Keywords:** TITANIUM MESH, CRANIOFACIAL SKELETON, FRACTURE, SYMMETRY.

Posttraumatic defects of the facial skeleton, or bone defects following tumor removal are usually associated with soft tissue support deficit, resulting in facial asymmetry, enophthalmos, lagophthalmos with secondary conjunctivitis, the loss of tooth-bearing segments, and speech impairment (1). All lead to a lower quality of life for the patient. Furthermore, the restoration of the complex architecture of the craniofacial bone frame is a challenging task for the surgeon.

The purpose of the reconstruction is to restore the aesthetic appearance and the lost functions by providing continuity of the bone contours, which ensures support for the soft tissues and allows the restoration of facial symmetry (2).

There are many possibilities for facial bone reconstruction such as titanium plates, bone grafts, composite flaps and titanium mesh. Titanium mesh has proven to be a useful material for the reconstruction of the craniofacial skeleton, capable of providing a true individualized treatment.

MATERIAL AND METHODS

Between January 2015 and December 2017, the authors used titanium mesh for a number of 26 patients including 20 (76.92%) trauma-associated defects and 6 (23.08%) post-ablative defects. In the

trauma-related group there were 6 (23.08%) cases of comminuted mandibular fractures, 3 (11.54%) fractures of the atrophic mandible, 6 (23.08%) cases of complex midface fractures, 3 (11.54%) fractures of the zygomatic complex with comminution of the zygomatic-alveolar crest, and 2 (7.69%) patients with sequelae following nose-orbital-ethmoid (NOE) fractures associated with anterior wall of the frontal sinus fractures. In the 6 (23.08%) patients with post-ablative bone and skin defects following the removal of cheek region basal cell carcinomas, titanium mesh was associated with loco-regional flaps consisting of 3 (11.54%) frontal flaps with a medial pedicle, 2 (7.69%) frontal flaps with a lateral pedicle and one (3.85%) rotated cheek flap.

All the titanium mesh panels were modelled intraoperatively, with the exception of two (7.69%) cases where stereolithographic 3D printed models were used for the pre-operative shaping of the titanium-mesh panels. The resulting modelled titanium meshes were sterilized and used intraoperatively. The mesh was fixed in place with titanium screws using a minimum three-point fixation method for ensuring spatial stability of the material. For the fixation of mandible fractures, the titanium mesh was bent according to the shape of the basilar border so that it would contain all fragments and the adjacent ends of the fracture. More fixation screws were therefore needed for the immobilization of all fragments.

RESULTS

All the dimensions of the comminuted and atrophic mandibular fractures were accurately restored. The affected segments were sensibly equal with the opposing side when compared with the help of imagistic methods. The functionality was resumed in the cases of mandibular fractures, with adequate healing, absence of persisting mobility in the line of fracture and resumption of proper mastication and deglutition.

Regarding the restoration of facial bone contours the results were excellent for NOE fracture sequelae cases and good for the other fracture cases, ensuring improved symmetry. The projection of the zygomatic bone and midfacial contours were reconstructed due to the possibility of multiple fragment preservation and fixation. Titanium mesh fixation at the level of the zygomato-alveolar crest allowed improved stability and possibility to bridge bone defects or comminution to achieve proper fixation in the anatomically reduced position of the zygomatic bone. The facial appearance of patients improved in all cases. There were no complaints of postoperative diplopia or restricted eye movements. An adequate support for the soft tissues was achieved in trauma-related cases.

For defects following the removal of malignant tumors the plasty had excellent results when the defect involved only the inferior orbital margin, anterior wall of the maxillary sinus and the orbital floor. The extension of the defect to the zygomatic bone body increased the complexity of the shaping process for ensuring good postoperative results. Titanium mesh allowed proper reconstruction of the orbital floor, without complaints of postoperative diplopia. Secondary plasties were needed for further fine adjustments regarding the position of the soft tissue coverage in two (7.69%) cases.

When stereolithographic models were used for the pre-bending of the titanium meshes, not only the results were more accurate, but the operative time was shorter.

None of the titanium meshes was exposed postoperatively.

The good outcomes of titanium mesh reconstruction are illustrated by the help of a case portraying the treatment of a double angle fracture of an atrophic mandible in an edentulous patient (fig. 1-7).

DISCUSSION

Titanium is considered the most biocompatible metal due to its resistance to corrosion from bodily fluids, bio-inertness, capacity for osseointegration, and high fatigue limit. Titanium's ability to withstand the harsh bodily environment is a result of the protective oxide film that forms naturally in the presence of oxygen (3, 4). The titanium mesh couples the advantages of the material with the ones offered by the geometry of the mesh itself that is purposely designed to allow simple three-dimensional modelling without compromising the stability and support of the structure (5, 6).

Versatility, adaptability, stability and malleability are only a few of the advantages of the titanium mesh. Modelling it according to the defect and giving the titanium mesh a complex form often needed for the reconstruction, eventually results in a structured shape capable of resisting mechanical stress and providing an individualized treatment (7).

In cases of comminuted fractures of the facial skeleton, titanium mesh allows improved containment and fixation of the multiple bone fragments, reconstructs contours, and even bridges regions of missing bony substance. These objectives could not be fulfilled to the same degree by the simple use of multiple titanium plates. For post-ablative defects, titanium mesh can provide an alternative to more complex, time consuming methods of treatment involving the association of bone grafting or composite flap raising with titanium reconstruction plates.

Although the price for the titanium mesh is higher than individual plates, it is offset by using fewer mesh panels than titanium plates otherwise needed by the same procedure.

One of the disadvantages of using the titanium mesh is that for the placement of the implant, an extraoral access is frequently needed, leaving a visible scar. Additionally, the removal of the mesh, when this is needed, is difficult due to the connective tissue growing around and through the structure of the panel (3). At the same time, this behavior is an advantage when the titanium panels are used for the reconstruction of the sinus walls, preventing the intrasinus exposure of the titanium mesh.

Although a considerable number of treatment methods exist for comminuted and atrophic mandibular fractures, choosing the best procedure remains a challenge due to the high infection rate, unsatisfactory mandibular shape and loss of bone fragments.

In cases of mandibular fractures with severe atrophy of the mandibular bone, the use of the “classic” titanium reconstruction plates are not indicated since it involves the decollement of the periosteum form a large surface of the bone, which can lead to osteitis/osteomyelitis. Angle fractures of the atrophic mandibles are another therapeutic challenge since the mouth guard fixation with circum-mandibular wires is not effective for this region. In comminuted mandibular fractures, periosteal stripping can lead to decreased vascularity and loss of the intermediate bone fragments. Additionally, it is extremely challenging to provide adequate stability and fixation for the multiple fragments by using simple titanium plates or a reconstruction plate, while also ensuring the correct mandibular body length (8).

In our opinion, the advantage of using the titanium-mesh in cases of comminuted mandibular fractures, is that by modelling

it around the lower border of the body of the mandible in a "U" shape, and going up just a few millimeters on the lingual side, the resistance of the panel is greatly increased while also leaving the lingual periosteum attached on the bone fragments, ensuring their vascularization and thus a favorable healing. On the vestibular aspect of the mandible, the titanium mesh is modeled to the shape and form necessary to envelop and preserve all the bone fragments. The characteristic design with multiple holes makes the reduction and fixation with screws possible for all the bone fragments. The good results that we obtained in our study are consistent with the results of other authors that have used titanium mesh for the reconstruction of the mandibular contour due to its semi-rigid fixation properties and the need for limited periosteal stripping (7, 8).

Comminuted fractures of the midface can result in important facial deformation if not properly reconstructed. The three-dimensional analysis of CT (Computed Tomography) or CBCT (Cone Beam Computed Tomography) scans offers important information regarding the number of fragments, degree of displacement, the presence of soft tissue entrapment or foreign bodies (9) and helps select the most appropriate treatment method (10).

Restoring the face symmetry after zygomatic complex or midface fractures can be difficult if there is comminution at the zygomatic-alveolar process. The three-dimensional modeling of the titanium-mesh panel and fixing it in such a way to reestablish a correct and stable vertical dimension allows an accurate rehabilitation of the zygomatic geometry, symmetric with the opposing side. Other authors also underline the importance of titanium mesh fixation for achieving improved fixation and individualized treatment in complex midface fractures (11). Although the bone frame support is restored by using the titanium mesh, it is important to also address the soft tissues by repositioning sutures fixed to the periosteum or to the titanium mesh, placed at the end of the surgery. Omitting to perform soft tissue rearrangement might lead to tissue ptosis and an aged facial appearance (12, 13). Corrective surgery can be performed later by inserting barbed threads for soft tissue lift (14), or by autologous fat transfer in order to restore the lost volume of the midface (15).

Due to the complex geometry of the region, comminuted NOE fractures need a material capable of covering a larger surface. The titanium mesh can stabilize the smaller bone fragments and by modeling it, due to its malleability, it ensures an excellent amendment of the region. This is consistent with the favorable results achieved in our study regarding NOE sequelae treatment using titanium mesh. Repositioning of the detached medial canthal ligament by anchorage to the modelled titanium mesh is also possible and ensures a good definition of the bony contour in the paranasal region and a normal intercanthal distance (11). In our opinion, an adequate exposure of the sunken region for the placement of the titanium mesh could be the most challenging aspect to minimize scars and damage to the overlying soft tissues when addressing sequelae of NOE fractures.

NOE fractures are frequently associated with fractures of the anterior wall of the frontal sinus. The purpose of the treatment is to protect the intracranial components, the deterring of cerebrospinal fluid leak, and the rehabilitation of the facial contour.

The management of the comminuted fractures of the frontal sinus is difficult because the bone fragments are too small for fixing them with wires or plates. The titanium mesh is one of the most used material for the anatomic rehabilitation of comminuted frontal sinus fractures generating minimal inflammatory response and imaging artefacts (16).

In many cases of malignant tumors of the midface, the resection often implies a maxillectomy which leads to deformities such as diplopia, depression of the cheek, as well as articulatory, masticatory and swallowing disorders. The timing and method of reconstruction is in relation with the histology and considering the need for postoperative radiotherapy. If a delayed reconstruction is decided, the defect can be initially addressed using an obturator prosthesis and/or an epithesis (17). Frequently, the main treatment for basal cell carcinoma is surgical resection. For this reason, in our case series, the reconstruction was performed at the same time with tumor removal.

Composite flaps or multiple flaps are needed for restoring the complex anatomy of the maxillary bone and for achieving a restoration of both bone and soft tissue. In our opinion, titanium mesh allows a good restoration of midfacial contours following the removal of malignant tumors. The reconstruction implies the shaping of the titanium-mesh panel to rebuild the missing bony architecture, but also ensuring an adequate coverage of the titanium mesh with a soft tissue flap. Considering the extent of the defect, several flaps can be used for the reconstruction. The frontal flap with a medial or lateral pedicle is a good option in the absence of sufficient local tissues for a genian flap coverage. For more extended defects, free flaps are needed to achieve adequate closure (1).

The composite temporo-parietal ostheofascial flap is an option for reconstructing bone defects at the level of the zygomatomaxillary complex and orbital floor. In this case, titanium mesh can be used for fixation of the composite flap, but also for the reconstruction of the skull defect at the donor site (18). When performing the reconstruction of the resected orbital floor, it is important to adequately restore the shape of the inferior wall, but also the correct level of the transition area located at the intersection of the medial orbital wall and the orbital floor. This medial bony strut is considered important in establishing the proper orbital volume and it is usually preserved for best functional results when performing bone decompression surgery for Graves orbitopathy (19, 20, 21).

Although the titanium mesh can be modeled to fit the bone defect perfectly, this objective is arduous to accomplish by the manual intraoperative shaping of the mesh due to the reduced operative access and the long time needed (22). This detriment can be overcome with the help of a stereolithographic model that can be used for the preoperative shaping of titanium-mesh panels when faced with complex three-dimensionally shaped defects that require increased accuracy and elaborated shaping of the mesh that would be difficult to perform intraoperatively. The titanium meshes pre-modelled to the exact anatomy of the individual's mirrored healthy side are then sterilized and used intraoperatively.

From our experience, the procedure decreases surgery time and increases the accuracy of the reconstruction. Still, it is stated by some authors that the repeated bending of the material in trying to achieve

the optimal shape could decrease the mechanical strength of the mesh (7). This aspect is of interest when the titanium mesh is used to reconstruct the mandible since the masticatory forces involved in the mandibular region are greater than forces acting in other facial regions. Prospects involve the use of individualized 3D printed titanium mesh trays by direct metal laser sintering that could improve the accuracy of reconstruction even more by eliminating the manual modelling of the titanium mesh (7).

CONCLUSIONS

From our study we conclude that the titanium mesh panel is a material capable of providing an individualized treatment for reconstructing the craniofacial skeleton in cases where large defects need to be rectified, for ensuring stability in cases of comminuted fractures and for providing soft tissue support and the rehabilitation of facial symmetry. Furthermore, the use of stereolithographic models warrants the perfect fit of the individualized panels and shortens the operative time.

NEWS

ETHYL GLUCURONIDE - A USEFUL BIOMARKER FOR ETHANOL INTAKE IN FORENSIC FIELD

Alcohol consumption has an important role in most of the forensic deaths, starting with acute alcohol intoxication as a cause of death and going on through many of the fatal accidents (road and occupational) where alcohol intake has its own influence. This is why ethyl alcohol determination in blood specimens is one of the most requested analyses in forensic field. A group of researchers from the Institute of Legal Medicine in Modena (Italy) investigated the role of ethyl glucuronide (EtG) in supporting medico-legal investigations, with the purpose to develop and validate a sensitive procedure for its quantitative determination in order to give a better interpretation of postmortem EtG concentrations in formulating medico-legal conclusions. They analyzed the distribution of this biomarker in different specimens, collected from 21 subjects, : central blood, peripheral blood and liver samples; in 13 of them urine was also available. The specimens were analyzed by liquid chromatography tandem mass spectrometry. EtG levels were higher in the liver samples compared to the blood sampled, and the urine samples (n=13) presented higher EtG levels than the corresponding liver samples, except for 4 cases. Due to the lack of controlled conditions such as the information on the time of alcohol intake and the ingested doses it was difficult to interpret the EtG levels, but the strength of the study was the simultaneous analysis of this metabolite in different matrices from the same subject. MULTIFACTORIAL ANALYSIS OF LOCAL AND LYMPH NODE RECURRENCES AFTER CONSERVATIVE OR RADICAL SURGERY FOR STAGE 0-II BREAST CANCER (Abstract): **Aim.** Multifactorial analysis of local and lymph node recurrences in stage 0-II breast cancer treated by conservative or radical surgery. **Material and methods**: In the interval January 1, 2005 - July 31, 2013, 477 breast cancer patients were assessed by imaging techniques at the Radiology Clinic of Iasi "Sf. Spiridon" Hospital and Radiology Service of the Iasi Regional Cancer Institute. Of these 229 (48%) patients underwent conservative surgery and 248 (52%) patients radical surgery. **Results:** Local recurrences were 2.8 times more frequent in conservatively *vs.* radically treated patients, and lymph node recurrences 2 times more frequent in patients treated conservatively. Breast tumors larger than 3 cm in diameter were at higher risk for local and distant recurrence in lymph nodes. **Conclusions:** Assessment in patients with local and lymph nodes recurrences of the relative risk for developing other types of recurrences (bone, pleuro pulmonary, liver, brain metastases) indicated that these are a risk factor for other types of recurrences, influencing the prognosis of patients. Local recurrences showed a higher relative risk for other types of recurrences than nodal recurrences. **Keywords:** LOCAL RECURRENCE, LYMPH NODE RECURRENCE, BREAST CANCER.

Conservative treatment is indicated breast cancer stages 0, I and II, with breast tumors less than 3 cm in diameter (1). The goal of conservative treatment is to decrease the risk of local recurrence to <1% per year and < 10% at 10 years.

The relative 5-year survival rate for breast cancer by tumor stages: stage 0 and stage I - 100%, stage IIA - 92%, stage IIB - 81% (the American Cancer Society). The main goal of clinical and imaging monitoring of patients operated for breast is the detection of recurrences with intent to improve survival (2-4).

This paper presents a complex, multifactorial analysis of local and nodal recurrences in patients operated for breast cancer stages 0-II and monitored in our institution.

MATERIAL AND METHODS

Between January 1, 2005- July 31, 2013 at the Radiology Clinic of "Sf. Spiridon" Emergency Hospital and Radiology Service of the Iasi Regional Cancer Institute 477 breast cancer patients were assessed by imaging methods. Patients enrolled in this

study had curable stage 0, I and II breast cancer; 229 (48%) patients underwent conservative surgery and 248 (52%) radical surgery. The ultrasound, mammographic, CT and MRI semiological patterns based on which a diagnosis of loco-regional and distant recurrences was made were evaluated.

For statistical processing we used *SPSS 16.00* for Windows to determine the frequency, multiple regression, enter method, regression coefficient, Pearson correlation (statistically significant at $-1 < r < 1$, no statistical significance when $r = 0$), relative risk (RR) assessment, and *odds ratio* (OR, statistically significant when OR> 1), Chi-Square Tests, ANOVA test, test of significance (significant at $p<0.05$) and confidence interval (CI).

RESULTS

At the time of surgery our patients were aged 21 to 86 years, mean age 57.02 ± 0.77 years; most patients belonged to age group 51- 60 years.

Postoperative treatment varied depending on pathological findings and immunohistochemical results. Thus, patients treated conservatively most commonly received chemotherapy associated with radiotherapy and hormone therapy (76.9%), while patients who underwent radical surgery most frequently received chemotherapy associated with hormone therapy (78.2%). Although radiotherapy is mandatory in the treatment of patients operated conservatively for breast cancer, 13 patients (5.67%) did not receive it (most often due to patient refusal).

Both local and lymph node recurrences were more frequent in patients treated conservatively. Of the 229 patients who underwent conservative surgery 31 patients (13.5%) had local recurrence and 11 patients (4.8%) lymph node recurrences. Of the 248 patients treated radically 12 patients (4.8%) had local recurrences and 6 patients (2.4%) lymph node recurrences (tab. I).

Most nodal recurrences occurred within the first 2 years after surgery in patients operated conservatively (81.9%), and after 3 to 7 years in the patients who underwent radical surgery (66.6%).

The location of nodal recurrences differed depending on the type of surgery. In the patients who underwent conservative surgery nodal recurrences were: axillary - 6 cases (54.5%), supraclavicular - 2 cases (18.1%), axillary and supraclavicular - 2 cases (18.1%), and mediastinal 1 case - (9%).

TABLE I
Distribution of cases by type of recurrence and minimum/maximum/average disease-free interval

Surgery type	Recurrence	No. cases (%)	Minimum disease-free interval (years)	Maximum disease-free interval (years)	Average disease-free interval (years)
Conservative	Local recurrence	31(13.5)	<1	13	2.8710
	Lymph node recurrence	11 (4.8)	<1	9	2.4545
Radical	Local recurrence	12 (4.8)	<1	8	2.921
	Lymph node recurrence	6 (2.4)	1	8	4.831

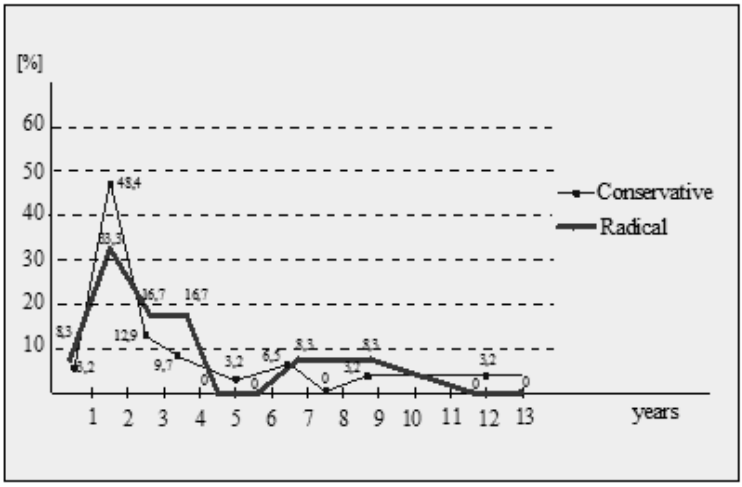

Fig. 1. Distribution of local recurrences according to disease-free interval

In patients receiving radical surgery lymph node recurrences were: supraclavicular - 3 cases (50%), axillaries - 2 cases (33.3%), and mediastinal - 1 case (16.6%).

For all recurrences the following data were extracted from the pathology reports after the first surgery for breast cancer: initial breast tumor size (in cm), number of removed lymph nodes, and the number of positive lymph nodes after the initial surgery (tab. II).

TABLE II

Correlation between recurrences and initial tumor size, number of excised lymph nodes and number of positive lymph nodes

Descriptive Statistics	Minimum	Maximum	Mean		Std. Deviation
	Statistics	Statistics	Statistics	Std. Error	Statistics
Tumor size (cm)	0.40	9.00	3.0482	0.21454	1.60544
Number of excised lymph nodes	0.00	27.00	11.9643	0.76233	5.70475
Number of positive lymph nodes	0.00	16.00	2.2453	0.43429	3.16170

In patients receiving conservative surgery, 17 local recurrences (54.8%) and 4 nodal recurrences (36.3%) were associated with the initial size of breast tumors larger than 3 cm; 12 local recurrences (38.7%) and only two nodal recurrences (18.1%) were associated with more than 5 positive axillary nodes.

In patients with radical surgery, 5 local recurrences (41.6%) and 5 nodal recurrences (83.3%) were associated with the initial size of breast tumors larger than 3 cm; 6 local recurrence (50%) and 3 nodal recurrences (50%) were associated with less than 5 positive axillary lymph nodes.

In patients who underwent conservative surgery there was a statistically significant association between local recurrences and

immunohistochemical data, hormone receptors (HR) and Her-2/neu protein, respectively (p =0.003, Pearson Correlation r = 0.195) for CI = 95%; thus most patients were HR-positive and Her-2/neu protein-negative (17 cases) as well as HR and Her-2/neu protein-negative (8 cases).

Nodal recurrences after breast cancer conservative surgery showed statistically significant associations with tumor stage (p = 0.004, Pearson correlation r = 0.188), 8 cases being stage II and 3 cases stage I, for CI = 95%. Statistical significant associations (p < 0.001, Pearson correlation r = 0.167) were found between lymph node recurrences and immunohistochemical data, for CI = 95%, most cases being HR- and Her-2/neu protein-negative (5 cases) and HR- and Her-2/neu protein- positive (four cases).

In the patients who underwent radical surgery the statistical correlations between local and nodal recurrences and immunohistochemical data were approximately similar.

TABLE III

The risk for other types of recurrences in patients with local recurrence

Risk Estimate	Conservative surgery, local recurrence			Radical surgery, local recurrence		
	Value	95% Confidence Interval		Value	95% Confidence Interval	
		Lower	Upper		Lower	Upper
Odds Ratio for bone MTS	**6.963**	2.454	19.756	**2.750**	0.555	13.631

Odds Ratio for skin MTS	0.952	0.924	0.980	0.976	0.957	0.995
Odds Ratio for peritoneal MTS	0.952	0.924	0.980	0.976	0.957	0.995

In patients presenting local recurrences, treated conservatively or radically, the relative risk for developing another type of recurrence was estimated by calculating the OR. Data were statistically significant at OR > 1 (tab. III).

In patients with lymph node recurrence, treated by conservative or radical surgery for breast cancer, the relative risk for developing another type of recurrence was estimated by calculation OR (tab. IV).

DISCUSSION

Numerous articles, retrospective and prospective studies have shown no differences in survival when conservative surgery for breast cancer (after proper staging) is compared with radical mastectomy. However, all studies conducted so far have reported a net difference in terms of local recurrences, which are more common after conservative surgery than after radical mastectomy (5-8).

In our study, local recurrences are 2.8 times more frequent after conservative than radical surgery (slightly elevated compared to literature data) (5). Most local recurrences were diagnosed 1 year after surgery, irrespective of the surgical approach (radical/conservative). The longest disease-free intervals were recorded in patients treated conservatively; supporting the fact that conservative surgery for breast cancer presents a long-term risk for the development of local recurrence (9).

Significant differences between patients treated by conservative or radical surgery for breast cancer were recorded in lymph node recurrences.

These were 2 times more frequent in patients treated conservatively, being most often axillary in the patients who underwent conservative surgery and supraclavicular in those who underwent radical surgery (10, 11). No differences were found in the longest disease-free interval (8 years in both cases), conservative and radical surgery being associated with a similar risk for nodal recurrences.

The most frequent local and lymph node recurrences occurred in patients with an initial breast tumor larger than 3 cm in diameter and more than 5 positive axillary nodes.

Immunohistochemical results showed that the risk of local or lymph node recurrence persists over time in hormone sensitive tumors (12, 13).

By calculating the risk of patients with local recurrence of developing in time other types of recurrences we found that patients treated by conservative surgery for breast cancer are at higher risk for other types of recurrence (bone metastases, pleuro pulmonary, liver or brain metastases) than those treated by radical surgery (bone or lung metastases) (14,15).

The same is true for patients with nodal recurrences. By calculating the relative risk of patients with nodal recurrence to develop in time other types of recurrence we found that patients treated by conservative surgery are at higher risk for other types of recurrences (bone, pleuro pulmonary or brain metastases) compared to patients who underwent radical surgery (pleural or liver metastases).

CONCLUSIONS

This study proves that local and lymph node recurrences are more frequent in patients treated by conservative surgery for breast cancer compared to those who underwent radical surgery. Diagnosis and treatment of neoplastic breast nodules smaller than 3 cm decreases the risk of local and lymph node recurrences.

Assessment of the relative risk for developing other types of recurrence in breast

cancer patients with local and lymph node recurrences (treated by conservative or radical surgery) showed that they are a risk factor for recurrence affecting the prognosis (local recurrences had a higher relative risk than nodal recurrences).

DISPARITIES IN THE ACCESS TO PRIMARY HEALTHCARE IN RURAL AREAS FROM THE COUNTY OF IASI - ROMANIA (Abstract). **Aim:** To identify the factors that may conduct to various forms of social exclusion of the population from the primary healthcare and to analyze health disparities as population-specific differences in the access to primary healthcare in rural compared to urban residence areas from Iasi, the second biggest county, situated in the North--East region of Romania. **Materials and methods:** This research is a type of inquiry-based opinion survey of the access to primary healthcare in rural compared to urban areas of the county of Iasi. Data were collected by face-to-face interviews. There were taken into account the socioeconomic status (education level in the adult population, employment status, family income, household size) and two temporal variables (the interval of time spent to arrive at the primary healthcare office as a marker for the geographical access and the waiting time for a consultation). The study group consisted of two samples, from rural and urban area, each of 150 patients, all ages, randomly selected, who were waiting at the family doctor's practice. **Results:** The study has identified disparities related to a poor economic status assessed through the employed status ("not working" 15% in urban and of 20% in rural).The income calculated per member of family and divided in terciles has recorded significant differences for "high" (36.7% urban and 14.7% rural) and "low", respectively (14.6% urban and 56.6% rural). High household size with more than five members represented 22.6% of the total subjects in rural and 15.3% in urban areas. The assessment of the education level in the adult population (>18 years) revealed that in the rural areas more than a half (56%) of the sample is placed in the category primary and secondary incomplete, whereas the value for secondary complete and postsecondary was 37.3%. The proportion of respondents in the urban areas who have post-secondary education is five times higher than those in rural areas (15.4% vs. 2.7%). The reduced geographical access assessed as the interval of time spent to arrive at the primary healthcare office revealed, on average, 25 minutes in urban versus 75 minutes in rural areas. **Conclusions:** The research outcomes highlight the fact that the population living in rural communities from the county of Iasi, are disadvantaged in accessing the primary health services, with negative consequences on the health status. **Keywords:** ACCESSIBILITY, PRIMARY HEALTHCARE, RURAL, URBAN

A complete and actual definition of the accessibility refers to "the possibility of the user to obtain the needed health care or the health service in the right place and the right time, according to the perceived needs, and assumes the lack of geographical, economic, financial, social, cultural, organizational or language obstacles" (1).

In the Member States of the European Union, the health services access is legislatively stipulated and guaranteed in the EU Charter of Fundamental Rights, Article 33: "Everyone has the right of access to preventive health care and the right to benefit from medical treatment"(2).

The fair and as complete as possible access to a basic package of services is an essential criterion for a well-organized and operating at optimal parameters health system, along with other objectives such as: general coverage, continuity of health care, patient's ability to choose the provider and costs of medical care (3).

Health disparities or healthcare inequalities refer to gaps in the quality of health and health care across various population groups (4).

The improvement of the access to health services represents the first priority objective of the policy adopted by the Ministry of Health from Romania (5). A special concern is focused on primary care because they act as a first point of consultation for all patients within the health care system.

The aim of this study is to analyze health disparities as population-specific differences in the access to primary healthcare and to identify the main perceived barriers to health care access in rural compared to urban areas from Iasi, the second biggest county, situated in the North – East region of Romania.

MATERIALS AND METHODS

This study research represents an inquiry-based descriptive analysis of the degree of access to primary healthcare in rural compared to urban areas of the county of Iasi. Data on socioeconomic variables were collected by face-to-face interviews.

There were taken into account the socioeconomic status (education level in the adult population, employment status, family income, household size) and two temporal variables (the interval of time spent to arrive at the primary healthcare office as a marker for the geographical access and the waiting time for a consultation).

The study group consisted of two samples, from rural and urban area, each of 150 patients, all ages, randomly selected, who were waiting at the family doctor's office. The location was the city of Iaşi and five rural communities inside the county of Iasi.

The database and statistics were performed in *Epi Info* ^{TM} *7*.

RESULTS

The median age was 39 years, with limits ranging between <1 year and 87 years. Distribution by age groups is shown in table I.

TABLE I

Distribution by age groups and residence

Age group (years)	Urban		Rural	
	No.	No.	%	No.
< 10	14	9.3	10	6.7
10-19	15	10	26	17.3
20-29	22	14.7	16	10.7
30-39	28	18.7	27	18
40-49	33	22	30	20
50-59	18	12	14	9.3
60-69	9	6	7	4.7
70-79	8	5.3	12	8
>80	3	2	8	5.3
Total	**150**	**100.0**	**150**	**100.0**

Of the total sample, 24% of the subjects living in rural and 19.3% of those from urban areas are children under 20 years of age.

Gender distribution was similar in urban (male 43.6%; female 56.4%) and rural areas (male 44.7%; female 55.3%). The report male/female was approximately 5/6 in both residence areas.

The assessment of the education level in the adult population (>18 years) revealed that a proportion of 5.3% of the rural patients and 3.3% of the urban patients reported only an elementary school education (tab. II).

The socioeconomic status of the respondents is an important variable associated with the degree of access to healthcare.

TABLE II

Percent distribution of adult subjects by education level and residence

Education level	**Urban**		**Rural**	
	No.	**%**	**No.**	**%**
Elementary	5	3.3	8	5.3
Secondary incomplete	51	34	76	50.7
Vocational, complementary or apprentice level	15	10	20	13.3
Secondary complete	56	37.3	42	28
Post Secondary	23	15.4	4	2.7
Total	**150**	**100.0**	**150**	**100.0**

The employment status was assessed as working or not working (unemployed or pensioner). Comparing the distribution in the two areas of residence, we found a proportion of 15% for "not working" in urban (1% unemployed; 14% pensioner) and of 20% in rural (3% unemployed; 17% pensioner).

The income calculated per member of family was divided into terciles in order to have three categories for the socioeconomic variable:

- high (36.7% urban and 14.7% rural);
- medium (48.7% and 28.7%, respectively);
- low (14.6% and 56.6%, respectively).

The household size expressed as the number of persons that share the same dwelling, as well as the expenses related to it, represented another variable taken into account in assessing the accessibility to primary healthcare, particularly from financial point of view. A household may be made up of one person or a group of persons.

The average number was of 4.2 persons per urban household and 4.4 in rural, respectively.

Families with more than five members represented 22.6% of the total subjects in rural and 15.3% in urban areas (tab. III).

The interval of time spent to arrive at the primary healthcare offices was, on average, of 25 minutes in urban and of 75 minutes in rural areas.

The access within a city is easier, thus a proportion of 38.6% of the investigated patients answered they need less than 30 minutes to arrive at their family doctor (fig. 1).

The average time patients spent waiting to see their health provider varied from less than 15 minutes to more than 60 minutes. Patients sit a long time in the waiting room

either in a rural or an urban practice (fig. 2). Short waiting times (< 15 minutes) have been recorded in less than 10% (7.2% urban, 7.8% rural).

TABLE III

Distribution by household size and residence

Persons (no.)	Urban		Rural	
	No.	%	No.	%
1	5	3.4	12	8
2	20	13.3	23	15.3
3	23	15.3	16	10.7
4	46	30.7	38	21.4
5	33	22	33	22
6	10	6.7	9	6
>6	13	8.6	19	16.6
Total	**150**	**100**	**150**	**100**

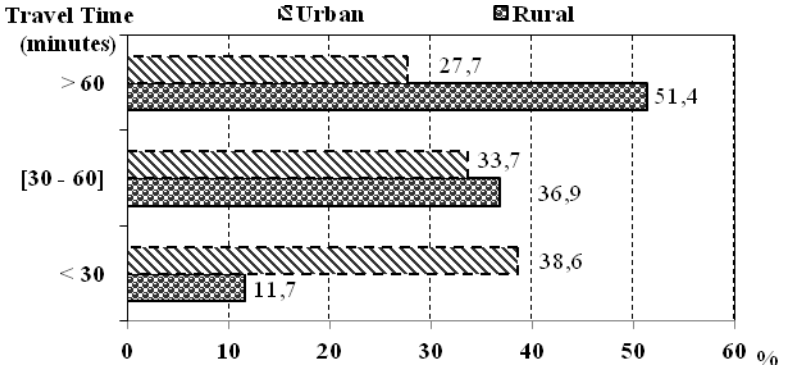

Fig. 1. Interval of time to arrive at the family doctor's office

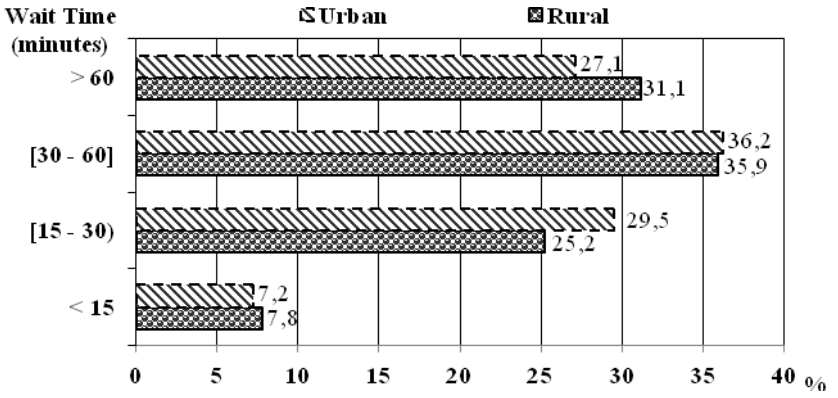

Fig. 2. Waiting time for a consultation at the family doctor's office

DISCUSSION

The comparison of the age group distribution between the two areas of residence highlights that the population who access the healthcare in rural areas is somewhat younger in rural, where one of four patients is under 20 years, compared with urban, where one of five is under 20 years, but neither difference is statistically significant. The proportion of the elderly (>60 years) who needed a consultation to a family doctor office was higher in rural (18%), compared to urban areas (13.3%).

Gender distribution shows a higher addressability among female compared to male patients, for both residence areas, but without significant differences ($p<0.05$).

The assessment of the education level in the adult population (>18 years) revealed that in the rural areas more than a half (56%) of the sample is placed in the category primary and secondary incomplete, whereas the proportion for secondary complete and postsecondary was 37.3%.

The differences in education between the urban and rural areas are more obvious when it comes to post-secondary education; the proportion of respondents in the urban areas who have post-secondary education is five times higher than those in rural areas (15.4% vs. 2.7%). The respondents in urban areas, not surprisingly, have a higher level of education than respondents in rural areas.

Low-income families were four times numerous among rural patients, compared to those living in urban areas (56.6% vs. 14.6%), whereas high-income rural families represented one third of the corresponding value from urban (14.7% vs. 36.7%). These differences are statistical significant ($p<0.01$)

In the same time, the proportion of the unemployed and pensioners was higher (20%) among people living in rural communities, than the value recorded in the city of Iasi (15%).

These aspects should be taken into consideration in the evaluation of the accessibility, being well-known the fact that the degree of poverty of a population correlates directly with a poor economic status and inversely with the educational level, and that both influences the optimal access to the healthcare (6).

Households made up of a single person are twice frequent in rural compared to urban environment (8% and 3.4%, respectively), the difference being significant ($p<0.01$). One of five households in rural (22.6%) had six or more persons; the corresponding percentage found in urban areas was of 15.3%.

The access to medical care in rural areas can be limited due to the dispersion of the primary care practitioners. The spread of the human communities correlates with the distance between health care facilities and dwellings and, in consequence, 51.4% of the patients of villages travel more than one hour to meet their family physician. The average interval of time to arrive at the primary healthcare practice was three times higher in rural compared to urban residence areas ($p<0.01$).

Another variable analyzed in this research was the waiting time to see a physician. A long time is unpleasant because the patient is often anxious about the appointment, in pain, or worried (7). One of three patients in both residence areas was waiting on average an interval of 30-60 minutes.

More than a quarter of the subjects of the two studied samples complained about long waits of more than 60 minutes.

In case of patients who often have been

kept waiting a long time by their healthcare providers, there is the risk to postpone the consultation if it is not a life-threatening illness or a severe injury. For waiting time, no significant differences have been recorded between the studied residence areas. Long waiting time reduces the accessibility to healthcare and leads to dissatisfaction among patients.

CONCLUSIONS

The identified factors that may conduct to various forms of social exclusion of the population from the primary healthcare in rural compared to urban residence areas from the county of Iasi are:

- *poor economic status* assessed through direct variables (unemployed status, low family income, high household size with more than five members) and an indirect variable – the low level of education;
- *reduced geographical access* assessed as the interval of time spent to arrive at the primary healthcare office.

These disparities represent in the same time inequities in the population's access to primary healthcare in rural environment.

The research outcomes highlight the fact that the population living in rural communities from the county of Iasi, are disadvantaged in accessing the primary health services, with negative consequences on the health status.

EPIDEMIOLOGICAL EVALUATION REGARDING THE ROLE OF CYSTIC FIBROSIS AS A RISK FACTOR FOR CHILD MALNUTRITION (Abstract): Cystic fibrosis (CF) is the most common monogenic autosomal recessive disorder with progressive chronic evolution which is potentially lethal. Poor growth is a characteristic of children suffering from cystic fibrosis. A poor nutritional status is an independent risk factor for inadequate survival in cystic fibrosis and is associated with disease complications. The appropriate nutritional management is an important part of the treatment so that the patient with cystic fibrosis can achieve normal growth and development and maintain the best possible health status. A balanced diet supplemented with snacks high in fat and calories is necessary to increase the caloric intake in children with cystic fibrosis. Children with cystic fibrosis have higher caloric needs than healthy children of the same age and sex. Malnutrition in CF is multifactorial. Cystic fibrosis is a complex multisystem disorder affecting mainly the gastrointestinal tract and respiratory system. In the past, malnutrition was an inevitable consequence of disease progression, leading to poor growth, impaired respiratory muscle function, decreased exercise tolerance and immunological impairment. A positive association between body weight and height and survival has been widely reported. The energy requirements of patients with CF vary widely and generally increase with age and disease severity. Cystic fibrosis remains a paediatric disorder which is often underdiagnosed but which, if therapeutically managed properly (by means of drug therapy as well as by appropriate physiotherapy techniques), can lead to improved quality of life and, thus, to a bigger life expectancy. **Keywords:** CYSTIC FIBROSIS, MALNUTRITION, CHILDREN, NUTRITIONAL STATUS

Cystic fibrosis (CF) is the most common lethal inherited genetic condition affecting the Caucasian population. One in twenty-five individuals in the UK are carriers of the gene and the condition is inherited in an autosomal recessive manner, which results in an incidence of one in approximately 2,500 (1, 2). CF is less

common in Oriental and black populations. It is estimated that 8500 individuals in the UK have CF (2, 3). Cystic fibrosis is one of the genetic disorders commonly seen in the paediatric pathology. It is an autosomal recessive disease whose incidence in Caucasians is 1 : 2000 – 1 : 2500 in new-borns with a heterozygote frequency from 1 to 25 individuals. The frequency of the disease in the black race is 1/17,000 live new-borns, in mongoloids is 1/100,000 live new-borns and in the Republic of Moldova is 1:1,000-1:1,200 (4).

The study by Farrel combines a variety of methods to determine the prevalence of cystic fibrosis in the European Union. The results of literature reviews, surveys, and registry analyses revealed a mean prevalence of 0.737/10,000 in the 27 European Union countries, which is similar to the value of 0.797 in the United States, and only one outlier, namely the Republic of Ireland at 2.98 (5).

Cystic fibrosis is a complex multisystem disorder affecting mainly the gastrointestinal tract and respiratory system. Intestinal malabsorption occurs in approximately 90% of patients. In the past, malnutrition was an inevitable consequence of disease progression, leading to poor growth, impaired respiratory muscle function, decreased exercise tolerance and immunological impairment (3, 4). A positive association between body weight and height and survival has been widely reported. The energy requirements of patients with CF vary widely and generally increase with age and disease severity. For many young adults requirements will be 120–150% of the age-related estimated average requirement. To meet these energy needs patients are encouraged to eat a high-fat high-energy diet with appropriate pancreatic enzyme supplements. Many patients are unable to achieve an adequate intake as a result of a variety of factors including chronic poor appetite, infection-related anorexia, gastro-oesophageal reflux and abdominal pain. Oral energy supplements and enteral tube feeding are widely used

Improvements in respiratory and nutritional management have led to an impressive increase in life expectancy for individuals with CF. CF, which was once considered a life-threatening disease of childhood is now considered a life-limiting disease of adulthood rather than a terminal childhood illness (1, 2). The median predicted survival is now 35 years and there are now more individuals with CF aged>16 years in the UK than <16 years (2, 3).

Malnutrition in CF is multifactorial. There has been evidence of strong links between improved nutritional status and survival for >30 years. A study that compared patients of two North American CF clinics, one of which treated patients with the then traditional low-fat diet and the second treated patients with a high-fat diet, has found the patients treated with a high-fat diet to be taller and heavier (2, 6). Importantly, this improvement in nutritional status was deemed to be the main reason for a 9-year survival advantage. Since this early study a poor nutritional status has been shown to independently contribute to prognosis (2, 7, 8, 9). Growth failure and wasting are both highly significant independent prognostic indicators of survival. In patients with height < 5th percentile at age 5 years risk of death is significantly increased; this increased risk persists at age 7 years (2, 7, 8). Patients with >85% ideal body weight have a better prognosis at 5 years of age than those with < 85% ideal body weight (2,

8). There is also a positive association between nutritional status and lung function. Conversely, malnutrition results in poor growth, impaired respiratory muscle function decreased exercise tolerance and immunological impairment that results in increased susceptibility to infections (2, 10).

The aims of the nutritional management of CF are that children and adults should be adequately nourished, have normal weight, height, body composition and pubertal development and have optimal vitamin, antioxidant and essential fatty acid status. With increased life expectancy there are constantly new nutritional challenges emerging (2, 11). Pancreatic insufficiency usually develops in infancy and approximately 92% of individuals with CF are pancreatic insufficient by 1 year of age. Approximately 95% of patients in northern Europe will eventually be pancreatic insufficient as a result of an inadequacy of their own pancreatic enzyme secretions (2, 12). With the introduction of newborn screening within the UK and the early identification of milder mutations the percentage of patients with pancreatic sufficiency may increase. In individuals with CF malabsorption is secondary to pancreatic insufficiency. In patients with CF a host of other factors contribute to malabsorption, including a deficiency of pancreatic bicarbonate that reduces duodenal pH an increased loss of bile salts in the stool, an imbalance in the type of bile salts produced, abnormal ion transfer in the gut as a result of the basic defect in the CFTR (Cystic fibrosis transmembrane conductance regulator) impaired mucosal uptake and transport of long-chain fatty acid across the gut wall and altered gut motility (2, 13, 14, 15).

Growth failure is a common presentation of patients with pancreatic insufficient cystic fibrosis. However, full blown kwashiorkor is extremely rare. Cystic fibrosis is also considered to be rare in the South Asian population.

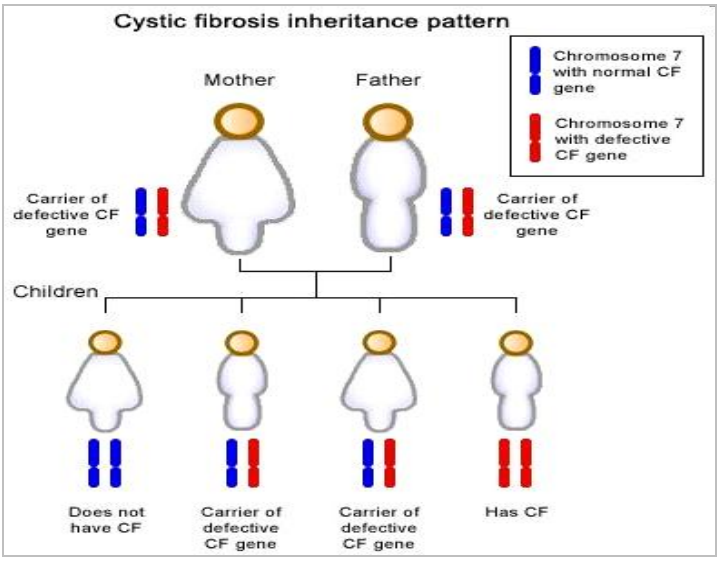

Fig. 1 Cystic fibrosis inheritance pattern

Protein energy malnutrition results in a group of disorders, including marasmus and kwashiorkor. Kwashiorkor, caused by decreased protein availability, results in oedema, muscle wasting, skin and hair changes, irritability, and anorexia (16, 17). In developing countries it occurs mainly as a result of primary protein calorie malnutrition. However, in developed countries, it usually arises as a result of chronic disease rather than primary nutritional deprivation (16, 18). Cystic fibrosis is frequently presents in infancy with failure to thrive. CF is the most common inherited autosomal recessive disease in the Caucasian population, but is considered rare in the Indian subcontinent population (16, 19) and in North Africa.

Epidemiological aspects. According to the National Centre for Cystic fibrosis in Timisoara (where a pilot study was conducted in the 2nd Paediatric Clinic of Timisoara in the '80s, on a number of 10,000 live births), the incidence of the disease in Romania is 1 : 2054 newborns. In terms of survival rate, it can be noted that, in Western Europe, life expectancy was situated around the age of 17-18 in the 70s, in 2005 it increased to about 32, and, at present, due to scientific progress, the patients who were the newborns with CF at the beginning of the 90s can survive well over 40 years of age (4).

The gene for cystic fibrosis is located on the long arm of the 7th chromosome, which encodes the regulatory protein of the cystic fibrosis trans membrane conductance regulator (fig. 1). The gene can undergo multiple gene mutations (about 1300) and it may have more than 300 polymorphic variants, among which the most commonly found in Europe is the Δ F 508 CFTR mutation. (20) F508del accounts for 70% of the cases worldwide3 and for 52–54% of CF cases in Greece. Frequencies vary from a maximum of 100% in the isolated Faroe Islands of Denmark, to a minimum of about 20% in Turkey.

In the last two decades, CF has been increasingly diagnosed in Latin America, the Middle East, and populations derived from the Indian subcontinent that have emigrated to Western Europe, thus implying the presence of CF in significant numbers among the citizens of India and Pakistan who have remained in their homelands (21).

In South Africa alone, it is expected that over 110 African CF babies are born annually. With an overall infant mortality rate of 52 per 1000, CF would only make up between 0.12 and 2.5% of the total.

In India, the CF incidence is estimated to be 1 in 40,000 to 100,000 live births. In Japan, the estimated incidence is 1 in 100,000 to 350,000 live births, but is likely to be higher than anticipated.

The incidence of CF in the Middle East varies according to the ethnic background and the degree of consanguinity. Consanguinity is claimed to be about 65% in the Arab world. Estimates range from 1 in 2,560 to 1 in 15,876 (20, 22). A few mutations in the Middle East are shared with many other regions in the world, i.e. F508del, N1303K, W1282X and 3120+1G >A.

In Uruguay, Ecuador, Colombia, Venezuela and Brazil, the presence of descendants of African origin is important, although its percentage does not exceed 10%. The incidence of CF ranges respectively from 1/3,900 to 1/8,500 neonates in Cuba and Mexico (23).

The incidence of CF, based on derivative populations, is about 1 in 3,500 in North America.

There are no accurate CF prevalence figures for northern African countries bordering the Mediterranean, although small CFTR mutation detection studies have been done in Algeria and Tunisia, showing largely European mutations such as F508del, G542X and N1303K, albeit at different frequencies. Some unique mutations were identified in these populations (20).

Reports from South Africa show the presence of CF in persons of pure African descent, thus demonstrating that the earlier observation of the presence of CFTR mutations in African Americans was not simply due to a mixture of European genes A small proportion of CF patients (<3 %) remains undiagnosed until adulthood (24, 25).

CF affects both females and males in all racial and ethnic groups, but it is common among Native American and Latino population, particularly in areas of Pueblo and Zuni (Colorado). In France, for example, there is a very high incidence of CF in Northwest Brittany and a lower incidence in the South Ethnic. Specific mutations are observed in some populations such as the Nordic mutation 394delTT, the 3905insT mutation in Switzerland, the R1162X mutation in Northeast Italy, and the Eastern Slavic CFTRdele2, 3 (21kb) mutation (20, 26).

Therapeutic aspects. Malnutrition may be aggravated by the presence of anorexia, resulting from gastro-oesophageal reflux and/or cough, respiratory infections and chronic psychosocial stress. The role of dietary treatment is to improve or maintain adequate nutritional status of the patient and break the vicious malnutrition-infection cycle (27). Despite CF being the most common lethal inherited genetic condition affecting the Caucasian population, it remains relatively rare, with approximately 8,500 individuals with CF in the UK (2, 3). Nevertheless, increasing numbers reach adulthood and go through the transitional process. Ensuring a seamless transfer is one of the greatest challenges facing both children's and adult services. Poor growth is a characteristic of children suffering from cystic fibrosis. A poor nutritional status is an independent risk factor for inadequate survival in cystic fibrosis and is associated with disease complications (28).

The appropriate nutritional management is an important part of the treatment so that the patient with cystic fibrosis can achieve normal growth and development and maintain the best possible health status.

A balanced diet supplemented with snacks high in fat and calories is necessary to increase the caloric intake in children with cystic fibrosis. Children with cystic fibrosis have higher caloric needs than healthy children of the same age and sex for the following reasons: higher energy consumption during respiration; energy use in fighting fevers and infections; few energy-producing foods are properly digested and absorbed into the body even if the treatment is optimal. In patients with cystic fibrosis what is recommended is the high calorie and high protein diets, which are rich in fats, and have a normal amount of carbohydrates as well as supplements of fat-soluble vitamins. The hyper-caloric diet can be achieved by: spontaneous intake, nutritional supplements (orally, by nasogastric gastrostomy tube) and parenteral nutrition (4, 16).

The recommended calorie needs is: 1,700–1,950 calories/day for preschool children; 2,300–3,000 calories/day for school children; 2,900–4,500 calories/day for adolescents. Dietary supplements are recom-

mended to malnourished patients with cystic fibrosis and to patients with suboptimal dietary intake despite all the measures taken. Consumption is recommended after meals or at bedtime. Dietary supplements available for patients with cystic fibrosis are: **Frebini** (special, energy enriched food for children between 1-12 years old), **Nutren junior** (especially designed for a nutritionally balanced diet and suitable for children between 1-10 years old), **Nutridrink** (a ready-made nutritional, liquid supplement with milk flavour and other 8 different flavours for increased compliance), **Infatrini** (a high-energy formula in a small volume, with an optimal ratio between macronutrients and micronutrients, and with prebiotics), **Cystilac** (nutritionally complete special formula with prebiotic blend).

CONCLUSIONS

Cystic fibrosis remains a paediatric disorder which is often under diagnosed but which, if is therapeutically managed properly (by means of drug therapy as well as by appropriate physiotherapy techniques), can lead to improved quality of life and, thus, to a bigger life expectancy.

Hp1404 - A NEW ANTIMICROBIAL PEPTIDE

Antimicrobial peptides are active against a variety of microbes including antibiotics resistant strains. In a study by Li Z *et al*, a novel cationic antimicrobial peptide Hp1404 was identified from the scorpion *Heterometrus petersii*. It is an amphipathic α-helical peptide with inhibitory activity against gram-positive bacteria including methicillin-resistant *Staphylococcus aureus*. At low concentration, it is able to penetrate the membrane of *S. aureus*, and at high concentration it disrupts the membrane directly. The bacterium does not develop drug resistance after multiple treatments at sub MIC concentration. Hp1404 has low toxicity to mammalian cells and balb-c mice and it can improve the survival rate of the MRSA infected balb-c mice in the peritonitis model. In conclusion, Hp1404 can be considered to have potential applications as an antibacterial agent (Li Z, Xu X, Meng Let al. Hp1404, a New Antimicrobial Peptide from the Scorpion Heterometrus petersii. *PLoS One*. 2014;9(5):e97539. doi: 10.1371/journal.pone.0097539).

Regional Institute of Oncology Iasi
3. Palliative Care Compartment

PALLIATIVE CARE - INTEGRATION MODEL INTO ONCOLOGICAL ASSISTANCE FOR THE PATIENTS OF REGIONAL INSTITUTE OF ONCOLOGY IASI (Abstract). **Aim**: This paper aims to present a retrospective analysis of activity from Palliative Care Compartment of Regional Institute of Oncology Iasi during 12 months of activity and to propose a model of integration of the palliative care in oncology. **Materials and methods:** Data were collected from 415 patients hospitalized to the Palliative Care Compartment using the computerized database, records and books of existing appointments. **Results:** Data analysis reveals that 170 cases (40%) were aged higher or equal to 70 years and a number of 142 patients (34%) were aged between 60-69 years. Results regarding the provenience of the patients shows that most of them are from urban areas. Gastrointestinal neoplasms were present at about one-third of the patients – 133 cases (32%) and 95 (71%) of these cases had metastases. Most patients - 114 cases (27%) required hospitalization for a period between 8 and 14 days. Palliative care has interdisciplinary relations with other specialties. In 2013 from other specialties were transferred to palliative care a number of 156 patients, most of them (87 cases) from Oncology Department. **Conclusions:** Integrating palliative care in oncology would increase the quality of life of patients, would relieve the other sections or hospitals by patients who need palliative care, would decrease hospitalization costs and would avoid performing aggressive maneuvers at the end of life. **Keywords:** PALLIATIVE CARE, CANCER, INTEGRATION, ONCOLOGY

Palliative care is a holistic approach to relieving the suffering of people with chronic and life ending illnesses. The science of palliative care has undergone rapid developments, most notably with advances in pharmacological interventions to help control chronic pain and distressing symptoms. This vital and essential aspect of optimizing patients'quality of life has undoubtedly contributed to the widening acceptance of palliative care (3, 7).

The World Health Organization (WHO) states that "palliative care is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through

the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual". WHO sustain that PC interventions should start early in the course of illness, in conjunction with other therapies that are intended to prolong life. Therefore, in the care of advanced incurable cancer patients, there should not be a transition from oncology to palliative care but a continuous adaptation or change of goals (6).

Palliative care treats people suffering from serious and chronic illnesses such as cancer, cardiac disease such as congestive heart failure, chronic obstructive pulmonary disease, kidney failure, Alzheimer's, Parkinson's, amyotrophic lateral sclerosis and many more (3).

Palliative care is interdisciplinary in its approach and encompasses the patient, the family and the community in its scope. In a sense, palliative care is to offer the most basic concept of care – that of providing for the needs of the patient wherever he or she is cared for, either at home or in the hospital. Palliative care affirms life and regards dying as a normal process; it neither hastens nor postpones death. It sets out to preserve the best possible quality of life until death (1, 5).

In most of the world, the majority of cancer patients are in advanced stages of cancer when first seen by a medical professional. For them, the only realistic treatment option is pain relief and palliative care. Effective approaches to palliative care are available to improve the quality of life for cancer patients. The WHO ladder for cancer pain is a relatively inexpensive yet effective method for relieving cancer pain in about 90% of patients (7).

In Romania it is estimated that less than 7,000 of the 4 million people who need palliative care actually receive care. Romanians receiving palliative care report improved pain and symptom control, less anxiety, greater choice in place of death, an overall improvement in quality of life and great satisfaction with services provided. Many aspects of oncological care are under rapid development, but there is a high variability on access to high level quality palliative care and substantial regional (rural/urban) disparities. Recent successes focus on access to pain medication and the perceived need of HCP (Health Care Professionals) for improvements in education and access is growing (2).

In Romania there is no unique way of collaborating relationships with other health care providers for the specialized Palliative Care services providers. Each Palliative Care provider establishes relationships according to their own developing strategy definitely based on the financial backgrounds they have available at one point in their development (4).

The primary mission of Palliative Care services in Romania over the foreseeable future is to improve the quality of life of those people with illnesses not responsive to curative treatment and their families care.

MATERIALS AND METHODS

This paper aims to present a retrospective analysis of activity from Palliative Care Compartment of Regional Institute of Oncology Iasi during 12 months of activity (January 1 to December 31, 2013). Data were collected from 415 patients using the computerized database, records and books of existing appointments.

The inclusion criteria were represented by patient consent, the presence of oncological

diseases (which is also one of the hospitalization criteria) and age over 18 years.

The exclusion criteria were patient refusal, the absence of an oncological disease and age less than 18 years.

RESULTS AND DISCUSSION

Data analysis reveals that 170 cases (40%) were aged higher or equal to 70 years and a number of 142 patients (34%) were aged between 60-69 years. Was registered a number of 109 patients (26%) under the age of 60 years. Must be mentioned that the minimum age was 20 years, the maximum 92 years and the average age of patients was 66.2 years (fig. 1).

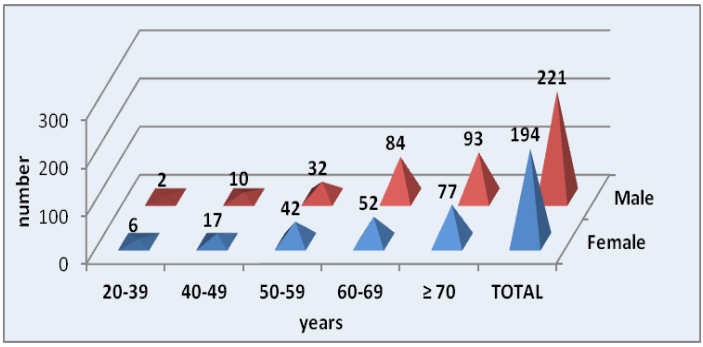

Fig. 1. Patient distribution by age and gender

The distribution based on gender shows a slightly higher preponderance of male patients, which represents a 53% (221 cases) compared with females who have a percentage of 47% (194 cases). This uneven distribution by gender shows a slight increase addressability of males to palliative care service.

Because the Regional Institute of Oncology is located in Iasi, most of the patients - 337 cases (81%) come from this county. The other counties of Moldova present a percentage of addressability between 1% and 5%. These percentages could demonstrates a poor dissemination of information outside of Iasi county regarding palliative care and a low addressability caused probably by the large distance between counties.

Results regarding the provenience of the patients show that most of them are from urban areas. We found a number of 295 patients (71%) coming from urban areas and 120 patients (29%) in rural areas, their ratio being 2.5:1 (fig. 2).

Depending on the oncological condition it was noted that the gastrointestinal neoplasm were present at about one-third of the patients – 133 cases (32%) and 95 (71%) of these cases had metastases. Was found that urogenital cancer was present in a number of 126 patients (30%), and 103 (82%) of these patients had metastases. Other localizations of cancer were respiratory, brain, bone, and skin, in a percentage that varied from 1% to 22% (fig. 3). In the other category was included a number of 35 patients (8%) who had a different type of cancer such as parotidian, thyroidian, glottic, amidgalian, tongue, non-Hodgkin lymphoma, but also the patients who had metastases with unknown starting point (tab. I).

Since most patients were in an advanced stage of illness, data analysis revealed that

more than a third – 302 cases (73%) had metastases. There is a possibility that this percentage to be higher, caused by their lack of diagnosis because they had no symptoms. Most patients who had metastases were among those with gastrointestinal, respiratory and genitourinary cancer. From the total of 302 patients who had metastases we found that 129 cases (43%) were female and 173 cases (57%) male (fig. 4)

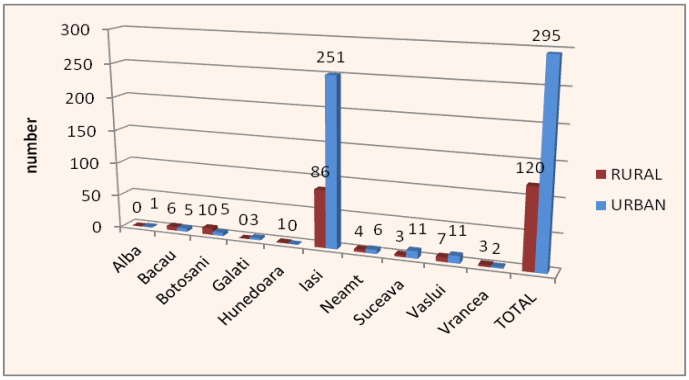

Fig. 2. Patient distribution by county and provenience

TABLE I

Patients' percentage by cancer localisation

Cancer Localization	MTS PRESENT	MTS ABSENT	%
Respiratory	63	27	22%
Gastrointestinal	95	38	32%

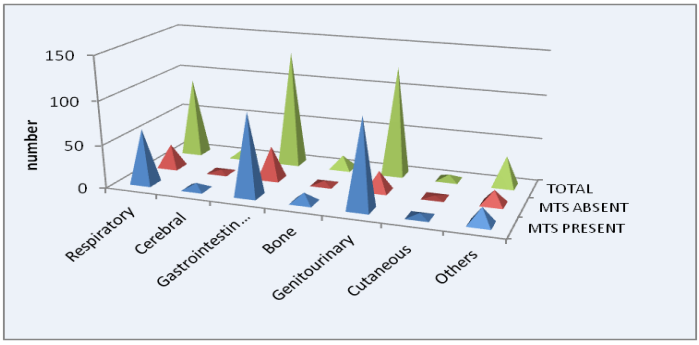

Fig. 3. Patient distribution by cancer localization and metastases

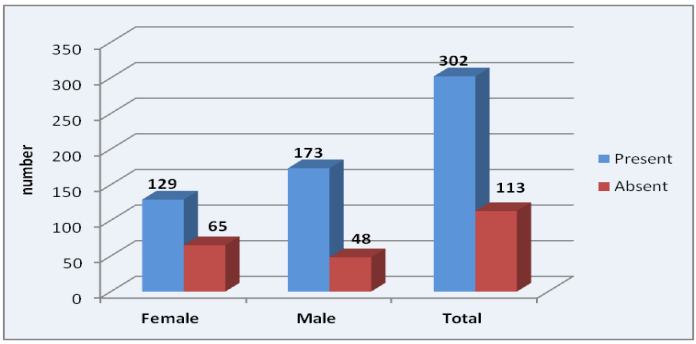

Fig. 4. Patient distribution by gender and metastases

Regarding the duration of hospitalization was noted a wide range of it, between 1 day and 166 days. This fact is explained by the death of the person immediately after admission, after the occurrence of an acute event on the background of severe chronic diseases and on the other hand by the need for a prolonged hospitalization for some complex oncological cases. It was found that a number of 151 patients (36%) had duration of hospitalization up to 8 days. Most patients - 114 cases (27%) required hospitalization for a period between 8 and 14 days (fig. 5). Was registered a total of 96 cases (23%) who required palliative care for a period between 15 and 28 days and a relatively high percentage (13%) for more than 28 days (tab. II). Must be mentioned that the average hospitalization of the patients hospitalized to palliative care was 15 days.

TABLE II

Patients percentage by days of hospitalization

Hospital days	Number of cases	%
≤ 3 days	64	16%
4-7 days	87	21%
8-14 days	114	27%
15-21 days	58	14%
22-28 days	38	9%
≥ 29 days	54	13%

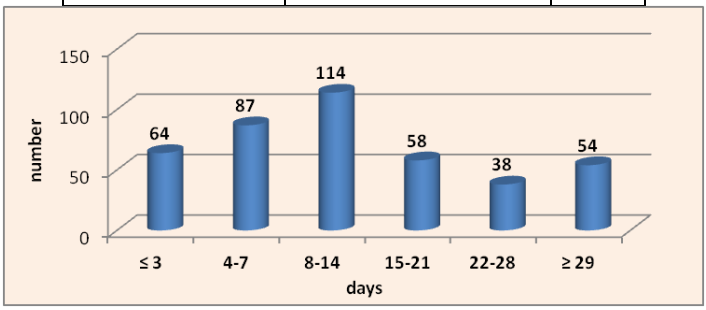

Fig. 5. Patient distribution by duration of hospitalization

Palliative care has interdisciplinary relations with other specialties. As Palliative Care Compartment is a part of Regional Institute of Oncology Iasi, most patients are from this hospital, but also from other hospitals or addressed by GPs.

In 2013 from other specialties within Regional Institute of Oncology were transferred to palliative care a number of 156 patients, most of them (87 cases) from Oncology Department. From Surgery, including plastic surgery, thoracic surgery, gynecologic surgery, oncologic surgery come to palliative care 41 patients, for different purposes such as thoracic drainage, intestinal occlusion and biopsy. The Radiotherapy and the Hematology send a number of 15, respective 13 cases, who needed palliative and supportive treatment.

Except these patients was registered a considerable number of oncologic cases that were hospitalized to palliative care from other hospitals (Neurosurgery Hospital, Pneumology Hospital, Saint Spiridon Hospital, Cuza-Vodă Hospital, Parhon Hospital and others). The family doctors also sent to the Regional Institute of Oncology those patients diagnosed with cancer that needed specialized palliative care.

Being in a interdisciplinary relation the palliative care sent to other specialties a total number of 30 cases, distributed as follows: 14 to Oncology, 9 to Surgery, 5 to Radiotherapy and 2 to Hematology (fig. 6).

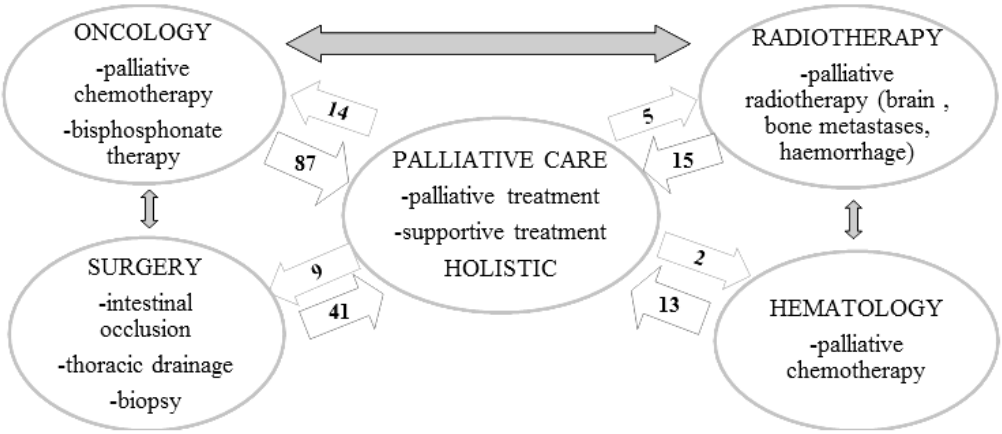

Fig. 6. Interdisciplinary relation between Palliative care and other specialties

CONCLUSIONS

Many aspects of oncological care are under development, but the high variability on access to high quality palliative care and substantial regional disparities demand a structured approach to improve patient care.

Deciding who to serve and restricting services only to these people is perhaps the biggest challenge for palliative care services in Romania in the coming years.

Integrating palliative care in oncology would increase the quality of life of patients, would relieve the other sections or hospitals by patients who need palliative care, would decrease hospitalization costs and would avoid performing aggressive maneuvers at the end of life.

TUMOR NECROSIS FACTOR-α AND INTRA-ABDOMINAL CANDIDA INFECTION IN HIGH-RISK SURGICAL ICU PATIENTS

A recent study conducted by Wójtowicz and collaborators evaluated the influence of genetic polymorphisms on the susceptibility to Candida colonization and intra-abdominal candidiasis, a blood culture-negative life-threatening infection in high-risk surgical ICU patients. They conducted a prospective observational cohort study including 89 patients at high risk for intra-abdominal candidiasis (68 with recurrent gastrointestinal perforation and 21 with acute necrotizing pancreatitis). were analysed eighteen single-nucleotide polymorphisms in 16 genes previously associated with development of fungal infections from patient's DNA by using an Illumina Veracode genotyping platform. Single-nucleotide polymorphisms in three innate immune genes were associated with development of a Candida corrected colonization index greater than or equal to 0.4 (Toll-like receptor rs4986790, hazard ratio = 3.39; 95% CI, 1.45-7.93; p = 0.005) or occurrence of intra-abdominal candidiasis (tumor necrosis factor-α rs1800629, hazard ratio = 4.31; 95% CI, 1.85-10.1; p = 0.0007; β-defensin 1 rs1800972, hazard ratio = 3.21; 95% CI, 1.36-7.59; p = 0.008). The authors established a strong association between the promoter rs1800629 single-nucleotide polymorphism in tumor necrosis factor-α and an increased susceptibility to intra-abdominal candidiasis in a homogenous prospective cohort of high-risk surgical ICU patients and concluded that their finding highlights the relevance of the tumor necrosis factor-α functional polymorphism in immune response to fungal pathogens. Immunogenetic profiling in patients at clinical high risk followed by targeted antifungal interventions may improve the prevention or preemptive management of this life-threatening infection. HYPONATREMIA AT AUTOPSY: CAUSE OF DEATH OR SIMPLY A MARKER OF SEVERITY OF THE UNDERLYING DISEASE (Abstract) **Aim**: To analyze the possible interpretations of hyponatremia detected at autopsy in vitreous humor in relation to the cause of death and/or associated pathology (cause of death or a simple marker of the severity of associated diseases). **Material and methods:** Hyponatremia is the most common electrolytic disorder in hospital practice, considered as a risk factor for hospital mortality. We conducted a 3-year forensic casework analysis in view ofestablishing the relationship of hyponatremia with mortality: hyponatremia as a direct cause of death or hyponatremia caused by the severity of the underlying disease which is the cause of death. **Results**: The forensic cases are not fully reliable. Although the target question has not been answered, our findings plead for the association of hyponatremia with severe diseases (sick cell syndrome) and not for hyponatremia as a cause of death, but this does not seems to be proven either, the percentage of cases with significant hyponatremia increasing from zero in cases of trauma and sudden violent death to 50% in cases of severe chronic diseases. **Conclusions**: The values obtained by us are in agreement with the data in the literature. Our findings plead for the scenario hyponatremia as a marker of the severity of the underlying disease. **Keywords**: HYPONATREMIA, POSTMORTEM BIOCHEMISTRY, CAUSE OF DEATH, SICK CELL SYNDROME

Hyponatremia is the most common electrolyte disorder in hospital practice, a risk factor for hospital mortality (1, 2). It is defined as serum sodium concentration of less than 135 mEq/L, and considered severe when below 125 mEq/L; a decrease in Na^+ level below 120 mmol/L causes mental confusion and a drop below 110 mmol/L causes coma (1, 2, 3). There are some differences in the reported limits, depending on the used laboratory methods. Jetter reported a postmortem stability of Na^+ in the blood within the first 12 hours but Coe showed that there is a decrease by an average rate of 0.9 to 1.0 mEq/L/hour; Na^+ appears stable postmortem in the vitreous humor and in relation with antemortem serum levels (6).

Clinically, hyponatremia is associated with increased mortality and it is stated that this could be an indicator of disease severity, improper management or inadequately performed investigations; some studies present it as associated with severe diseases and not as a cause (3), or associated with diseases with increased mortality (4).

Hyponatremia is often due to hyperglycemia and/or hyperlipidemia in some pathological conditions (ketoacidosis in diabetes) or to increases in plasma proteins (multiple myeloma). It is necessary, therefore, to differentiate between a true hyponatremia and pseudohyponatremia (8). Plasma sodium is different from plasma water sodium; the physicochemical and physiological effects of Na^+ depend on the concentration present in water. The serum contains 93% water and 7% minerals, proteins and lipids. Increases in plasma lipids that occur in primary dyslipidemia type I, IV or V, or in secondary dyslipidemia (nephrotic syndrome, biliary cirrhosis, decompensated diabetes, acute pancreatitis), and increases in plasma proteins (multiple myeloma) can reduce significantly the amount of water per liter of plasma, to 800 -850 ml, which will increase the difference between measured and actual Na^+.

The artifactual increase of Na^+ can be calculated knowing the value of plasma triglycerides: increase of Na^+ (%) = (2.1 x g / dL triglycerides) - 0.6. Measuring the plasma lipids after death is quite difficult with relatively unsatisfactory results, with difficulties in interpreting the values obtained. The influence of stomach contents on postmortem determinations is not clear either. The situation is similar for the postmortem determination of plasma proteins.

The diagnosis of pseudohyponatremia can be confirmed when plasma Na^+ is low (correlation between antemortem and postmortem values, between vitreous humor and blood), natriuria is normal, and triglycerides are higher than 500 mg/dL (serum lactescent). If plasma osmolarity is normal the causes of pseudohyponatremia (hyperlipidemia or hyperproteinemia) are excluded. Measuring osmolarity after death is also difficult, the sample pretreatment methods influencing the results; in clinic serum ultraspinning is used. The concentrations in pre-analytic factors are determined in the postmortem investigations of vitreous humor (8, 9); they increase especially the reproducibility of determinations.

MATERIAL AND METHODS

The electrolyte concentrations in samples of vitreous humors from 567 cadavers were biochemically determined. The sampling of vitreous humor was performed using a sterile syringe by puncturing the sclera in the external angle using a 21G x 1.5" needle. The analyses were performed on samples completely transparent, crystalline, without fragments of tissue vacuumed. The samples of vitreous humor were kept in glass tubes with a rubber stopper, without additives. Some of the samples were analyzed immediately, while others were frozen and analyzed at most on the third day (the cases of autopsies performed at the end of the week). The determination of the concentration of ions Na^+, K^+ and Cl^- in the vitreous humor was performed with the semi-automatic Easylyte analyzer, using the ion-selective electrode technique. Quality control was performed daily using the Tri-level EasyQC control kit.

Tanatochemical picture of 6 cases of hyponatremia (Forensic Service - Vaslui)

Case 1: 75-year-old female found dead

at home. Signs of vomiting. Postmortem examination shows intestinal occlusion complicated by inguinal hernia, as well as a lung cancer complicated by acute bronchopneumonia. Tanatochemical picture showed: urea = 535.33 mg / dL, creatinine 2.68 mg / dL, Na^+ = 108.6 mmol / L, K^+ = 15.56 mmol / L, Cl^- = 79.5 mmol / L. There was no question about the cause of death, but the mechanism of death was unclear.

Case 2: 53-year-old male 53 found dead; the cause of death was acute ethylic poisoning in a person with chronic alcoholism. Tanatochemical picture showed: urea = 19.7 mg / dL, creatinine = 0.35 mg / dL, Na^+ = 106.4 mmol / L, K^+ = 5.93 mmol / L, Cl^- = 88 mmol / L, HbA1c = 6.84% (picture of alcohol abuse). Was ethylic coma or hyponatremia the cause the death? Postmortem exam also revealed dilated cardiomyopathy, hepatic steatosis, and pancreatic sclerolipomatosis.

Case 3: A case similar to the previous one. Biochemical values: urea = 42.8 mg / dL, creatinine = 0.41 mg / dL, Na^+ = 95.2 mmol / L, K^+ = 11.06 mmol / L, Cl^- = 81, 8 mmol / L, HbA1c = 6.28%.

Case 4: 40-year-old male found dead at home. The autopsy established the cause of death as being a hemorrhagic enterocolitis. Postmortem biochemistry: urea = 23.19 mg / dL, creatinine = 0.8 mg / dL, Na^+ = 111 mmol / L, K^+ = 12.14 mmol / L, Cl^- = 97.2 mmol / L. The data do not support the diagnosis of hypovolemic shock.

Case 5: 3-month-old child with chronic pulmonary heart, congestive heart failure due to a congenital cardiac malformation. Postmortem chemical tests revealed: urea = 43.33 mg / dL creatinine = 0.36 mg / dL, Na^+ = 107.8 mmol / L, K^+ = 7.71 mmol / L, Cl^- = 68.9 mmol / L.

Case 6: 67-year-old male with cardiovascular disease who followed treatment with diuretics. Tanatochemistry revealed: urea = 21.49 mg / dL, creatinine = 0.41 mg/ dL, Na^+ = 86mmol / L, K^+ = 6.5 mmol / L, Cl^- = 66.4 mmol / L.

Our study aimed at analyzing the possible interpretations of hyponatremia detected postmortem in vitreous humor as a cause of death or a simple marker of the severity of associated diseases).

RESULTS AND DISCUSSION

Out of 567 selected cases, 207 (36.5%) had a Na^+ level below 135 mEq/L. We grouped the cases according to the immediate cause of death, for example a head trauma patient who died from septic complications, was introduced in the sepsis group and not in the head trauma group (tab. I).

In the cases of deaths from cirrhosis and severe liver diseases (neoplasm), hyponatremia always occurred, two cases presenting hyponatremic dehydration; plasma proteins or triglycerides were not determined postmortem. We identified 22 cases presenting hypertonic dehydration (Na^+ > 155 mEq / L). We also identified in this group 2 cases who died from alcohol withdrawal psychosis, but with constants that did not allow the enlisting in any of the patterns, low Na^+, normal urea, increased K^+, Cl^-> 105 mEq / L.

In the cases of death by drowning hyponatremia was common. All drowning took place in freshwater (possible criterion to be used to differentiate from drowning in salty water). The possibility of exchanging fluids in the alveoli is mentioned in the literature, as well as the possibility of postmortem early diffusion. Hyponatremia was reported in case of water birth. Some authors share the idea of using hypo-

natremia as a marker of submersion in fresh water in both the diagnosis and mechanism of death, asphyxia or hydroelectrolyte disorders (7, 10). In some groups, careful assessment is required to differentiate it from a pseudohyponatremia (see the group with pancreatitis, diabetes, cirrhosis). Our group seemed to be problematic or challenging due to the consistence in forensic cases. The problem with the groups for the study of hyponatremia related to mortality is obvious in case of critical analysis, as shown by some authors (2): retrospective studies on small groups without controls; the control studies show a higher mortality in hyponatremia cases (18).

TABLE I

The relationship between hyponatremia and various causes of deaths

	Average	DS	Max	Min	Hyponatraemia(%)	Significance (%)	Hyponatraemia /total	Significtion /total
Strokes	137.44	4.29	143.8	130.2	36	0	4/11	0/11

Cardiopathy	136.29	9.46	152.1	86	30.3	7.4	41/135	10/135

The cases with "low salt pattern" showed postmortem evidence of associated pathology (patients with multiple and severe chronic organic disorders). The osmolarity of external fluids was mostly determined by electrolytes that can spread into the cell but the osmolarity of cellular fluids was determined mostly by „solutes that are constrained within the cell by virtue of their size and physical characteristics, and by the permeability limits of cell membrans" (adenosine triphosphate, creatine

phosphate, amino-acids, metabolic intermediates including the hexose and trinose phosphates -Conway, 1957 quoted by 11). The compensation of negative charges of the intracellular solutions was performed by cations (especially K^+, but also Na^+).

The amount of non-spreading solutions is normally constant; the balance is achieved between the metabolic activity, usage and the slow migration within the cell. An important factor seems to be the pH that alters the dissociation of some solutions. Conway, 1945 -1960, Brown and Stein, quoted by Flear and Singh showed that "the osmolarity of ECF and its Na^+ concentration (Na^+ and its accompanying anions are the major solutes) is determined by the intracellular osmolality" "Disturbance at this level can cause hyponatremia, and because it has arisen as a result of illness or trauma, affected cells can be regarded as << sick cells>>". We made a new analysis and there were still 128 cases with Na^+ below 130 mEq/L, and excluding the cases of drowning and those with an elevated K^+ level, 75 cases remained; these were cases of severe congestive heart failure, pulmonary tuberculosis, cirrhosis and hepatic steatosis, peritonitis, sepsis and severe respiratory failure.

We found a correlation between the severity and the possible chronicity of diseases and the level of hyponatremia. No correlation between age and hyponatremia was found. Hyponatremia in old people seems rather related to the associated pathology and severity of disorders, with a reduced functional reserve. The cases with heart failure revealed by chronic pulmonary stasis presented reduced hyponatremia; those with anasarca with severe, congestive heart failure showed significant hyponatremia; the cases with pulmonary tuberculosis, even with rapid death through massive hemoptysis showed important hyponatremia according to the data in the literature (Westwater, Stiven and Garry 1939, quoted by 11, found hyponatremia in patients with pulmonary tuberculosis, in degrees according to the severity of the disease; they also found correlations between hyponatremia and prognosis). Cases with significant hyponatremia were included in the groups with cellular distress related to the cause of death (bronchopneumonia, severe sepsis, cirrhosis, congestive heart failure), but there were also hyponatremias in the groups with cellular distress without any unrelated to the cause of death (obvious cause of sudden death and violent death in sick patients).

There is very low percentage of hyponatremia-related mortality. In the literature (1, 2) it is stated that the risk of mortality increases with the severity of hyponatremia, but this has not demonstrated. However, "accepted wisdom is that hyponatremia is a marker of poor prognosis" (2). A critical analysis of the studies regarding hyponatremia shows multiple issues (studies on small groups and without controls). In our group, significant hyponatremia occurred only in cases with of cardiac, respiratory, liver, and kidney decompensation. It was noticed that the estimation of hyponatremia depends on the studied population, (higher prevalence in ICU). Although Flear and Singh's hypothesis of "sick cell syndrome" recently gained scientific support, there are still multiple questions related to this issue, being even called a "Cinderella of metabolic abnormalities"; similar studies on the connection between hyperglycemia and the risk of mortality have been performed lately (2, 11, 13).

We noted that in cases with macroscop-

ic evidence of decomposition where we expected Cl^- levels to be below 105 mEq/L, the levels were higher, around 110 mEq/L (we associated these situations with possible hypoproteinemia with hyponatremia consequences of some anionic deficits – the anionic deficit could induce a decrease in plasma Na^+ and an increase in chlorine); studies are needed on this subject.

An important theme related to hyponatremia with possible forensic implications is that of the neurologic complications and of hyponatremia correction (13) to establish an optimal rebalancing rate with the risk to develop a central or an extrapontine myelinolysis, and of the incidence of brain injury in postoperative hyponatremia with a higher risk in menstruating women (12, 13, 15, 17).

CONCLUSIONS

Given the complexity of every case, our studies show that the determination of hyponatremia is not specific in postmortem examinations; we have cases with the same immediate cause of death presenting hypernatremia or hyponatremia, hypertonic and hypotonic dehydration; there are many factors related to the body, associated pathology, postmortem interval (K^+ increased in decomposition, with accelerated growth in the renal failure), postmortem changes. The values obtained by us are in agreement with the data in the specific literature.

Our findings plead for the scenario hyponatremia as a marker of the severity of the underlying disease, an index of the functional reserve, but the deductive connection to the cause of death cannot be made. We recommend a full postmortem examination and routine biochemical tests, and based on all findings the results must be interpreted critically. The affected cells causing a hyponatremia with hemodynamic and cerebral effects may generate a vicious circle making the interpretation of the rate of the influence of hyponatremia in causing death very difficult.

NEWS

GLUTEN INTRODUCTION AND CELIAC DISEASE

Celiac disease (CD) is a gluten-sensitive enteropathy with genetic predisposition. The dose and timing of gluten introduction's in the child's diet influence the risk of CD. A prospective study conducted by Ketil Størdal show that the risk of CD in childhood depends on age of gluten introduction and duration of breastfeeding. The proportion of cases of CD was increased in children who received gluten before 4 months age (4.24/1000) and after 6 months of age (4.15/1000) than in those with gluten introduction between 4 and 6 months of age (3.68/1000). Also, the same study showed that the risk of CD is great for kids at that breastfeeding was prolonged after the age of 1 year. These results are useful for developing guidelines for infant feeding (Størdal K, White RA, Eggesbø M. Early feeding and risk of celiac disease in a prospective birth cohort. *Pediatrics*. 2013; 132(5):1-8).

VARIABLES OF JOB SATISFACTION IN MEDICAL ASSISTANT PROFESSION (Abstract). **Aim:** To identify the key favorable issues, showing a high degree of job satisfaction, and also the adverse issues that may affect the work performance among medical assistants. **Material and methods:** This research is a type of inquiry-based opinion survey carried out by administering a self-managed, anonymous questionnaire, consisting of five sections with 25 items. The study group included 175 medical assistants from all specialties, working in public hospitals in the city of Iaşi, who answered the questionnaires. A number of 167 subjects have responded, the return rate being of 95.4%. The respondents were asked to indicate the amount of agreement or disagreement on a typical five-level Likert scale. **Results:** The study has identified some positive aspects: positive perception of the medical assistant profession (76.6%); concern about personal growth and career development (86.3%); good relationships established with other colleagues (71.2%), and some negative aspects: inappropriate work conditions and equipments (70%); the income compared to the volume of work was perceived by majority as an important source of dissatisfaction (80.8%); willingness to work abroad (53.9%). **Conclusions:** The findings of the present research focused on the variables of job satisfaction in the medical assistant profession and should be a real concern for managers, because the job dissatisfaction may affect the employee's productivity. **Keywords:** JOB SATISFACTION, MEDICAL ASSISTANT, QUESTIONNAIRE.

Job satisfaction is a major concern for managers because it is generally accepted that a satisfied employee would have more professional achievements (1, 2). It has been demonstrated a direct link between lack of performance and job dissatisfaction (3). The state of satisfaction/ dissatisfaction is a consequence of the degree of motivation to undertake a certain activity; one feels satisfied when one has reached the proposed target and dissatisfied when that did not happen.

Zamfir(4) estimates that job satisfaction encompasses the following dimensions: economic satisfaction, based on salary and obtained material benefits; satisfaction related to the work itself (working conditions, equipments and the actual work content); psycho-social satisfaction, provided by: the relationship with colleagues and the

head of the department, the opportunities for career development, the recognition of work's results and the adopted organizational policy.

A medical assistant is an important member of the health care delivery team by performing clinical and administrative tasks, and supporting the work of physicians and other health professionals. He also represents the link between the medical doctor and the patient, being of a vital importance to the success of the medical practice.

This research is a type of inquiry-based opinion survey carried out by administering a self-managed, anonymous questionnaire, consisting of five sections with 25 items. The aim was to identify the key favorable issues, showing a high degree of job satisfaction, and also the opposite issues that may affect the work performance among medical assistants. The employees have been explained the importance of the study and that the purpose is to improve their activity and not to introduce punitive measures.

MATERIAL AND METHODS

In the design of the questionnaire there were taken into account the following criteria for the assessing the employee satisfaction: the career decision, the work itself, seen as a set of activities; the concern of the employee for the career development; the working conditions and environment; the relationship with the colleagues, the head of the department and other high levels of authority in the hierarchy of the health organization; the recognition of the work's results and performance; the remuneration system and the income.

The questionnaire pre-testing was performed on a total of 50 subjects. The study group included 175 medical assistants working in public hospitals in the city of Iași, who answered the questionnaires. A number of 167 subjects responded, the return rate being of 95.4%.

The respondents were asked to indicate the amount of agreement or disagreement (from strongly agree to strongly disagree) on a typical five-level Likert scale (1= strongly disagree; 5= strongly agree; 6= don't know). After the questionnaire was completed, each item has been analyzed separately. Responses were processed by counting the grades of the same type. The database and statistics were performed in *Epi Info*™ *7*.

RESULTS

The sample included medical assistants from all specialties, with the following structure: medical specialties 81 (48.5%), surgery 70 (41.9%), radiology and clinical laboratory 16 (9.6%). The average age was 38.2 ± 7.3 years, with limits ranging between 24 and 59 years (tab. I).

Gender distribution shows a high percentage of female, 157 female nurses (94%), compared to 10 male (6%). The report male/female was approximately 1/16. The choice of a medical profession was perceived by about three quarters of respondents (76.6%) as a source of high or very high satisfaction. Around two thirds of medical assistants taken in the study declared that they were satisfied (31.7%) and very satisfied (33.5%) of their current job. The proportion of the totally dissatisfied and very little contented was 14.4%. In this respect, the activity effectively performed by the studied subjects is considered to be: dynamic and stimulating in 130 cases (77.8%); routine in 28 cases (16.7%). Nine medical assistants did not give a conclusive answer ("do not know", 5.4%).

TABLE I
Distribution by age groups

Age group (years)	No.	%
< 30	16	9.6
30-39	79	47.3
40-49	60	35.9
50-59	12	7.2
Total	**167**	**100.0**

The degree of concern for self-improvement and career development was declared as being very high by 55.7% of respondents, respectively high (30.6%). The working conditions and environment represented another variable for the employee satisfaction. The general atmosphere in the department/ hospital was assessed positively by half (49.1%) of subjects and the concrete working conditions, equipments were considered to be satisfactory by only 28.1% (tab. II).

TABLE II
Assessment of satisfaction in relation with the working environment

In what measure are you satisfied of the:		Score					
		1	**2**	**3**	**4**	**5**	**6**
General atmosphere from the care unit/ hospital?	No.	15	20	48	50	32	32
	%	8.9	11.9	28.7	29.9	19.2	19.2
Work conditions and existing equipments?	No.	31	32	54	27	20	3
	%	18.5	19.2	32.3	16.2	11.9	1.9

Two types of relationships at the workplace may influence the degree of job satisfaction: those with other colleagues and with various levels of authority from the health organization. In the studied sample, a proportion of 71.2% declared themselves satisfied about the relationship with other colleagues, indicating scores of 4 (agree - 33.5%) and 5 (strongly agree - 37.7%) for this item.

The recorded answers for the item "Did your colleagues, when appropriate, recognize and appreciate your effort/ merits?", were positive in half of cases (56.3%). A proportion of 7.2% answered "don't know". Other scores were awarded as follows: 1 - strongly disagree, 9 subjects (4.8%); 2 - disagree, 18 subjects (10.8%); 3 - neither agree, nor disagree, 35 subjects (20.9%).

The interpersonal relationships at the workplace have been also analyzed in terms of their involvement and support provided in difficult situations. Approximately two thirds (64.7%) of the medical assistants consider that their colleagues would strongly help them in critical moments. In the same time, the relationship with the boss/ supervisor was considered to be satisfactory in 64.1% of cases, this contributing to an increased efficiency of the performed activity (tab. III).

The activity of the hospital management

team was favorably assessed by half of the surveyed medical assistants (54.5%), the share of strong or quite dissatisfied representing about one quarter of total (23.9%).

TABLE III
Perception of the relationship of subordination

In what measure:		Score					
		1	2	3	4	5	6
Your boss recognized and appreciated your effort/ merits?	Nr.	13	17	24	47	55	11
	%	7.8	10.2	14.4	28.1	55	6.7
Your boss supported you in professional and personal problems?	Nr.	8	21	23	36	71	8
	%	3.6	12.6	13.7	21.5	42.5	6.1
In your care unit is it encouraged the freely expression of your own points of view?	Nr.	26	25	37	35	39	5
	%	15.6	14.9	22.2	21	23.3	3

Another variable for the job satisfaction was the income. A proportion of 11.4% of subjects were satisfied with the income in connection to the performed work, and only 5.4% declared themselves very satisfied. The totally dissatisfaction due to an inappropriate income was found in a percentage of 29.9%, meaning that the medical assistants gave the minimum score. The perception "quite dissatisfied" was recorded in almost half of cases (50.9%).

The willingness to work abroad was manifested in a proportion of 53.9%. Approximately one third (37.7%) do not want it, the rest of answers being included in the category "do not know".

DISCUSSION

Nurses are working in all structures and levels of the health system, being by far the largest group of healthcare workers. Due to its specificity (providing health care), the health sector absorbs predominantly female workforce, especially in case of the medical assistants (5). This fact is outlined by the report male/female, of approximately 1/16, found in this research. The distribution by age showed a higher weight in the age group 30-39 years, when the professional performance is high.

A challenging work that gives positive satisfaction, arising from intrinsic conditions of the job itself, represented a key motivator for performance and a reason of job satisfaction in more than three quarters of the sample. In the same time, the findings emphasized the psychological need to achieve and grow, fulfilled by training activities (courses, workshops, peer experience exchange). Thus, a permanent concern for self-improvement and career development was recorded in 86.3% of subjects.

People who get along with coworkers will develop positive interpersonal relationships at workplace, which will fuel the work achievement and the success in the career (1). The findings of the study revealed that the relationships with the colleagues were assessed as a source of: satisfaction (71.2%); recognition of the person-

al efforts/merits (56.3%); support provided in critical moments (64.7%).

Abraham Maslow developed a general theory of human motivation, on the premise that human motivations are based on different needs (6). These were grouped into five categories, ordered under the form of a pyramid, those of the basic level being most pressing (fig. 1). From the perspective of Maslow pyramid, the basic needs could be met by a minimum wage and working conditions that do not endanger health (7).

Positive issues are: the choice of the medical assistant profession and of the subsequent job represent a source of satisfaction; work itself was assessed as being dynamic and stimulating; subjects were highly concerned about self-improvement, personal growth, achievement and career development; good relationships established with other colleagues. *Negative issues* could be: inappropriate work conditions, equipment; willingness to work abroad recorded in more than half of cases; the income compared to the volume of work was perceived by majority as an important source of dissatisfaction.

The existence of good working conditions may not always increase the degree of motivation, but certainly, bad conditions will lead to its reduction (8). In the studied sample the perception of the work itself was significant more favorable compared to the working environment and working conditions.

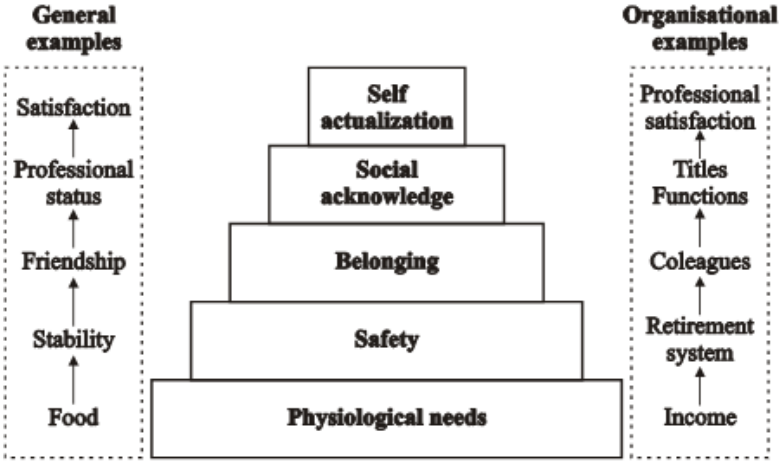

Fig. 1. Maslow pyramid of needs

The research focused, also, on the relation between salary and the work satisfaction, as a premise for the quality of health care provided by the medical staff. In any country, the income was and continues to be considered a strong predictor for job satisfaction (9).

A warning signal is represented by the medical assistants who answered the questionnaire and declared that they were totally or quite dissatisfied in terms of income (80.8%). In the same time, the lack of satisfaction in various degrees was also, founded in relation with the work conditions (71.9%).

The manager of a health organization

must ensure that each employee is enough motivated to be productive, in other words, to provide quality health services. The employees have various needs and different motivations to be met, and the concern for the income is no less honorable than any other motivation from Maslow's pyramid (based on need of safety, need of belonging, companionship or friendship, and need for esteem and social recognition), thus we may conclude that actually all motivations matter in the employee's productivity.

As a consequence, half of the surveyed staff (53.9%) would work in other countries. Thus, the already recorded human capital injection from Central and Eastern Europe to other regions, may lead to a worsening shortage of health human resources (10).

CONCLUSIONS

The study identified some positive aspects, which showed a high degree of job satisfaction, and some negative aspects (both recorded in at least half of cases).

Positive issues are related to good experiences, and these are due to `motivators' - the work itself, achievement, recognition, challenging work, responsibility. Motivators that give positive satisfaction, arise from the intrinsic conditions of the job itself.

Dissatisfaction is rather due to bad experiences and results from the lack of specific factors (good working conditions, appropriate salary and benefits). These are extrinsic to the work itself, and include aspects such as company policies, supervisory practices, or wages/salary.

In order to perform an effective management it is necessary to find a balance between the work satisfaction of the employee and the fulfillment of the organizational proposed goals (providing health care and services).

The findings of the present research focused on the variables of job satisfaction in the medical assistant profession and should be a real concern for managers, because the job dissatisfaction may affect the employee's productivity.

VIRAL MENINGITES ADMITTED TO AN INFECTIOUS DISEASES HOSPITAL: A RETROSPECTIVE CASE SERIES (Abstract):Given its epidemic potential and development of severe forms of disease, viral meningitis (VM) is a serious public health problem. **Aim**: to characterize the main clinical, epidemiologic features, the etiology and treatment of VM cases admitted to the Iasi Infectious Diseases Hospital, in 2012. **Material and methods**: We retrospectively analyzed the medical records of the patients admitted for viral meningitis at the Iasi "St. Parascheva" Infectious Diseases Hospital in the interval January 1- December 31, 2012 (98 cases). The etiologic diagnosis was made by determining the IgM/IgG antibodies against Coxsackie virus and/or West Nile virus in blood/CSF. **Results:** There was a four-fold increase in the number of cases as compared to the average for the years 2009-2011. Most cases (73.5%) were children aged 1 to 14 years. 61.8% of patients were males, 51.7% from urban areas. The most common symptom was headache (85.7%), followed by fever (77.6%), and vomiting (66.3%). Neck stiffness was absent in 28.6% cases. In43.5% of the 39 patients serologically investigated a Coxsackie virus infection was confirmed and 1/20 was positive for West Nile virus; three varicella-zoster virus infections and one mumps infection were diagnosed clinically. 68.3% of the patients received first-line antibiotic treatment. **Conclusions:** The illness mainly affected children, fever and neck stiffness being sometimes absent. The etiology was known in 22.4% of cases; enter viruses being the most frequent causative agent. Most patients received antibiotic therapy. The course was favorable in all cases. **Keywords:** FEVER, HEADACHE, EPIDEMIC.

Viruses are an important cause of acute meningeal infections and sometimes may cause a dramatic clinical picture for which an etiologically focused therapy is not available (1).

Involvement of viruses easily transmitted between humans (digestive or respiratory route) gives them an epidemic potential, especially during the warmer months of the year.

The impact of immunization campaigns (mumps virus), spreading of some arboviroses (West Nile virus) to new areas, climatic and social factors have determined a change in the viral meningitis (VM) profile.

The aim of this study was to characterize the main clinical, epidemiologic fea-

tures, the etiology and treatment of VM cases admitted to the Iasi Infectious Diseases Hospital, in Northeastern Romania, in 2012.

MATERIAL AND METHODS

We conducted a retrospective study based on the medical records of patients diagnosed with VM at "St. Parascheva" Infectious Diseases Hospital of Iaşi in the interval January 1 - December 31, 2012.

Patients of all ages, immunocompetent, with confirmed VM following lumbar puncture and cerebrospinal fluid (CSF) cytological and biochemical analysis were included in the study. Bacterial (culture and latex-agglutination), tuberculous (culture), and non-infectious causes were excluded.

The epidemiological, clinical, hematological and therapeutic variables were also studied. The etiologic diagnosis was made by determining serum IgM and IgG antibodies against Coxsackie virus (VirionSerion kit) and West Nile virus in blood and CSF in collaboration with the Iasi Regional Public Health Institute and Bucharest Cantacuzino Institute.

The collected data were analyzed using dedicated software (Microsoft Excel + Analyze-it) and various statistical tests (mean, Chi^2, 95% confidence intervals). A $p < 0.05$ was considered significant.

RESULTS

A total of 98 cases met the inclusion criteria.

Compared with the interval 2009-2011, when the annual average of diagnosed cases was 24.3, in 2012 a four-fold increase was recorded (fig. 1).

Patients were aged 1 to 36 years, mean age 12.5 years (95% CI: 10.8 - 14.2 years). 73.5% of the cases were children under 14 years of age, with 52.8% of them belonging to the 7-14 years age group (fig. 2).

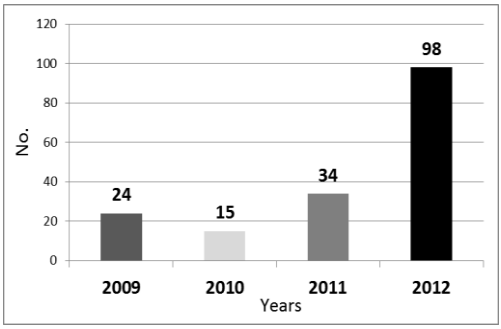

Fig. 1. Yearly distribution of VM cases admitted to the Iasi Infectious Diseases Hospital (2009-2012)

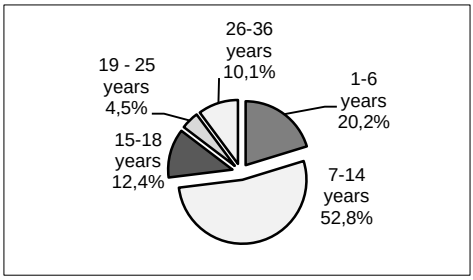

Fig. 2. Age-group distribution of the study patients

The male sex was prevalently affected - 61.8% of the cases, the percentage being slightly higher among patients over 14 years of age (66.7%), but lacking statistical significance ($x^2=0.04$, $p=0.84$). Patients were from both urban (51.7%) and rural areas (48.3%).

The vast majority of VM cases - 74.1%, occurred during the warmer months of the year, between June 15 and September 15 (fig. 3). The highest number of cases was recorded in August - 36 (40.4%).

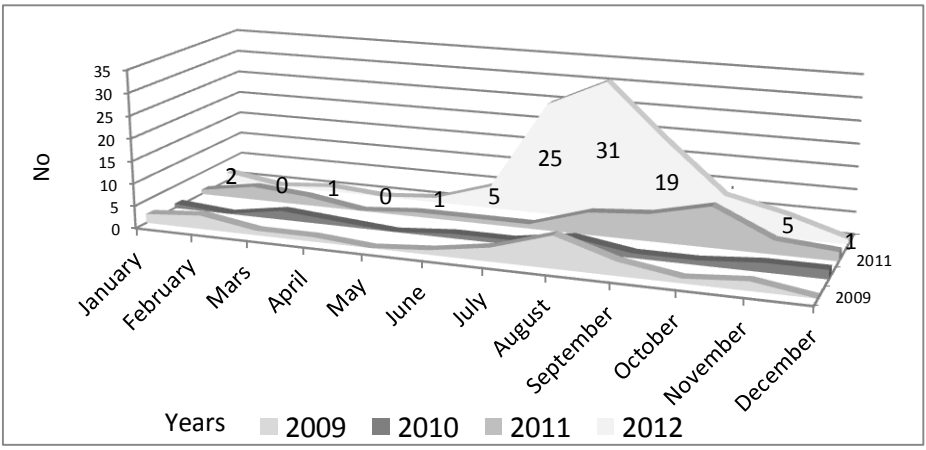

Fig. 3. Monthly distribution of VM cases diagnosed in the interval 2009-2012

The most common symptom of VM was headache present in 85.7% of the patients since the onset. Increases in body temperature (above 37.5^0C) were found in only 77.6% of the patients. Of these, in most cases (79.7%) it did not exceed 38.5^0C. Fever lasted 1- 4 days, average 2.45 days (95% CI: 1.93 - 2.96 days). Two thirds of the patients (66.3%) experienced central-type vomiting (most often before admission - 70.1%). The number of vomiting episodes ranged from 1 to 9 (mean 2.31 - 95% CI: 1.7 - 3.1). Other digestive manifestations were reported in 20.2% of cases: odynophagia - 6.7%, abdominal pain - 11.2% and diarrhea - 2.24%. Other common symptoms were photophobia - seen in approximately one third of cases (35.7%), nonspecific maculopapular exanthema - 19.4%, generalized myalgia - 15.3%, and impaired consciousness (dizziness or drowsiness) - 15.3% of the cases. Few cases presented generalized seizures - 4.1% or lower limb paresis - 1% (fig. 4).

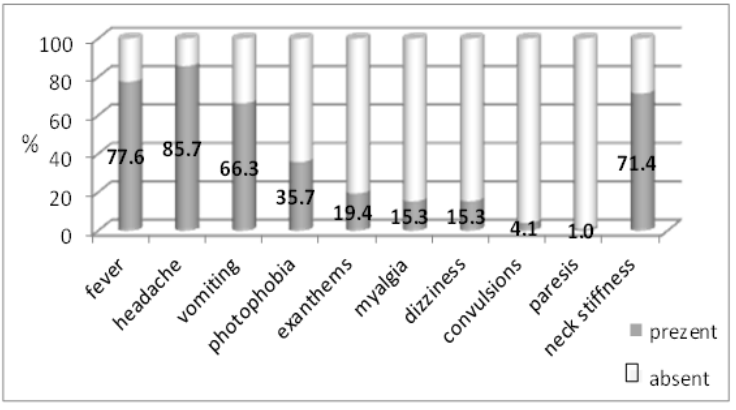

Fig. 4. Signs and symptoms of VM

In nearly one third of the patients (28.6%) neck stiffness and other meningeal signs were mild or absent, possibly due to patients' age.

Blood constants have contributed to the initial etiological orientation (tab. I). Baseline fibrinogen was determined in only 43.8% of the patients, being above 4 g/l in 41% of them.

Thirty-nine patients (39.8%) were investigated serologically for the detection of Coxsackie virus infection. The infection was confirmed in 43.5% of them: 33.3% had IgM and IgG antibodies, and the remaining 10.2% only IgM antibodies. Twenty patients (20.4%) were investigated for West Nile virus infection. The infection was confirmed in one case. Three patients were diagnosed clinically with varicella-zoster virus meningo-encephalitis (2 immune compromised patients with a recent history of herpes zoster and one with chickenpox). One case of mumps meningitis was diagnosed clinically.

TABLE I

Baseline laboratory findings

		Mean	**95% CI**	**Lowest**	**Highest**
Peripheral blood	WBC (/mm^3)	10,911.9	9,454.4 – 12,369.3	4,500	20,400
	PMN (%)	73.2	68.61 - 77.7	46	91
	ESR (mm/h)	27.6	19.9 - 35.2	5	50
CSF	No. leukocytes (/mm^3)	212.5	135.1 - 289.9	32	640
	Lymphocytes (%)	75.2	65.7 - 84.7	39	100
	CSF albumin(g/l)	0.69	0.56 - 0.81	0.24	1.4
	Glycorrhachia (g/l)	0.65	0.57 - 0.70	0.2	1.1
	Glycorrhachia/glycemia	0.63	0.54 - 0.72	0.26	1.07
	Chlorurorrhachia	7.35	7.25 - 7.43	6.7	7.7

Most patients (68.3%) received first-line antibiotic treatment for a period of 48 hours to 10 days, average 4.5 days (95% CI: 3.49 - 5.46). Dexamethasone was administered in 57.3% of the patients for 2 to 10 days (average 6.9 days, 95% CI: 5.43 - 8.43).

The disease had a favorable course in all cases. No death was recorded. The average length of hospital stay was 7.9 days (95% CI: 6.1 - 10.6).

DISCUSSION

Viruses are considered to be the most frequent cause of meningeal infections. The incidence of VM in the US or UK varies between5 and 20 cases per 100,000 inhabitants per year (2, 3). However, given the difficulties in making an etiological diagnosis and the different reporting methods it is likely that the true incidence is underestimated.

In 2012, at the Iasi Infectious Diseases Hospital, the number of VM cases (98) exceeded that of bacterial (42c), tuberculous (12c) or fungal meningitis (3) and was four times higher than the average for the interval 2009-2011. Other counties (Botoşani, Suceava) from Northeastern Moldova reported outbreaks of viral meningitis that started in June 2012 and affected mainly kindergarten children. The highest number of cases was reported in Suceava County, where the incidence of

VM was more than two standard deviations above the regional average (41.78 cases/100,000 inhabitants for the interval May 28-August 12, 2012). Although in the Iasi County the number of cases reported in 2012 has seriously increased as compared to the previous period, the incidence of VM was below the regional average ($8.54\%_{ooo}$).

Both enteroviral and mumps meningitis are more common in children (1), most likely due to the absence of previously acquired immunity (primary infection). A similar situation was found in our study patients, 73.5% of the cases being under 14 years of age.

Sex ratio in VM varies with the involved virus and is in favor of women for herpes viruses (4) and of men for enteroviruses (5) and mumps virus (3); the slight predominance of male patients in our study group may suggest the more frequent involvement of the latter.

Both enteroviruses and West Nile virus commonly cause disease during the warm season. Our group of patients is no exception, 74.1% of the cases being recorded in the interval June 15 – September 15. Compared with 2009-2011, the number of cases began to rise in June, with a peak in August (40.4%) and a significant number of cases reported in September and October (fig. 3).

The association of fever, headache, vomiting, photophobia, and neck stiffness is common in the infectious inflammation of the meninges. However, some authors have shown that sometimes one or more of these symptoms may be absent, making the diagnosis more difficult. In our study, fever was present during the disease course in only 77.6% of the patients, percentage similar to that reported by Gulnar (5) for enteroviral meningitis and Nowak (6) in a series of 43 cases of clear-fluid meningitis (85%). Headache was the most common clinical manifestation in our group of patients, being present in 85.7% of the cases compared with 60-100% in the literature (5, 7). Jet vomiting was described in only 66.3% of our patients, compared to 80% in Turkey (5). Occurrence of transient rash or other digestive phenomena (odynophagia, diarrhea) is common in enteroviral infection, these symptoms often preceding the onset of meningitis (3). These were present in 19.4% of our patients, more often than in other studies (5), and could suggest the involvement of echovirus 9 (3). Neck stiffness was present in 70.8% of the study patients, more frequently than in other similar studies (3, 5, 6).

Baseline WBC count was not very useful in the diagnosis of VM, the average being at the upper normal limit, as reported by other authors (3, 5, 8). Our study showed an increased proportion of polymorphonuclear leukocytes in 72.4% of the patients upon admission. An average ESR of 27.6 mm/h is comparable with the data in the literature (5). The mean levels of CSF parameters were characteristic of viral meningitis and significantly contributed to the diagnosis in most cases.

VM etiological diagnosis rate is relatively low due to its cost and required technical equipment. Recent prospective studies reported the identification of the causative virus in 14.3 - 57.1% of the cases (9, 10). Simion and colleagues found the etiology in only 16.5% of a series of 103 VM cases (11) admitted to the "Dr. Victor Babes" Hospital of Infectious and Tropical Diseases at Bucharest. Under these circumstances, we believe that the identification of the causative agent in 22.4% of VMs in our study (17 cases with Coxsackie virus, 3

cases with varicella-zoster virus, 1 case with mumps virus and 1 case with West Nile virus) is satisfactory, especially if we take into account that not all patients underwent the necessary viro-immunological investigations.

Non-polio enteroviruses, and especially echoviruses and Coxsackie B viruses, are the most common cause of VM (70-85% of the cases) (3, 4, 10). The confirmation of Coxsackie virus B2 as the causative agent in 31 VM cases in Suceava County made us focus the serological investigation in our patients on this viral subtype. Besides the presence of acute phase antibodies against Coxsackie virus in 17 of our cases, the affected age group, the relatively frequent occurrence of skin rash and involvement of the digestive system (odynophagia, diarrhea) as well as seasonality, all plead for a greater involvement of this type of virus in the etiology of VM cases at the Iasi Infectious Diseases Hospital in 2012.

The incidence of mumps meningitis has decreased significantly (4) in areas where routine vaccination of children is practiced, Romania included. In 2012, in our clinic only one case (1.02% of all cases) of mumps meningitis was diagnosed clinically; since some authors estimate that only 50-60% of mumps meningitis is preceded by parotid swelling (1), and immunological tests have not been performed in all our cases, the actual number could be higher.

Arboviruses are an important cause of viral meningo-encephalitis especially in certain geographical areas. An extensive outbreak of neuromeningeal West Nile virus infection occurred in 1996 (12) prevalently affecting adults living in South Romania (morbidity 12.4/100,000 inhabitants in Bucharest). In 2012, only one such case was confirmed in the Iasi County.

Herpes simplex viruses 1 and 2 and varicella-zoster virus can sometimes cause meningitis, especially in women after primary infection or if immunosuppressed (5, 9). In our series one case of varicella meningo-encephalitis in an immunocompetent child and 2 cases of zoster meningitis in immune compromised adults (chemotherapy and therapy with antibody to TNF-alpha) were found.

Differentiation between viral and bacterial infection upon admission based solely on clinical and CSF characteristics is sometimes very difficult. Persistence of uncertainty about the true cause of the disease is leading to the administration (sometimes unnecessary) of antibiotic treatment, which contributes to higher costs, risk for undesirable side effects, development of bacterial resistance, and disruption of endogenous ecosystem (13). This was also highlighted by our research, in which more than half of the patients were treated with antibiotics for at least a few days. Antibiotics were discontinued as soon as a bacterial etiology was excluded by additional laboratory investigations (hematology, microbiology, immunology and virology).

Based on clinical findings and controlled studies, the administration of dexamethasone as adjunctive therapy is recommended in bacterial meningitis, especially in severe forms with altered consciousness (14). In our series, more than half of patients (57.3%) received dexamethasone for an average of 6.9 days.

It is estimated that 98% of VM patients fully recover within 3 months from the disease onset. Rarely, mild cognitive impairment or unusual fatigue may persist over longer periods of time (1). Although no psycho-cognitive tests were performed, our patients were clinically assessed at the

end of the acute phase and one month after discharge, no persistent abnormalities being recorded.

CONCLUSIONS

During the year 2012 there was a significant increase in the number of viral meningitis cases as compared to the average for the previous years, but still below the regional average.

Children were mainly affected. The peak incidence was recorded in August. Fever and neck stiffness were sometimes absent.

Etiological confirmation was possible in 22.4% of cases. The most frequent causative agents were Coxsackie viruses; West Nile, mumps and varicella-zoster viruses were also involved.

Differentiation from other types of meningitis was often difficult at onset prompting the administration of first-line antibiotics in a significant proportion of the cases.

2. Discipline of Primary Health Care and Epidemiology

GASTROESOPHAGEAL REFLUX DISEASE: EPIDEMIOLOGICAL DATA, SYMPTOMATOLOGY AND RISK FACTORS (Abstract): **Background:** Patients with gastroesophageal reflux disease (GERD), present a typical symptomatology with heartburn and regurgitations in about 80%. **Objective:** This study will assess the prevalence of gastroesophageal reflux disease and some demographic features of the study group. It will also be assessed the sensitivity and specificity of GERD Questionnaire and the risk factors of the disease. **Material and methods:** For the current study 426 patients were selected who were admitted to a tertiary gastroenterology-hepatology hospital in Athens, Greece, complaining about having the common symptoms of GERD (heartburn and regurgitations). The study period was January 2008–March 2011. Positive diagnosis has been based on personal history, clinical examination and by upper gastrointestinal endoscopy. **Results:** Of 426 patients, 20 were excluded from the study. 150 (36.9%) were women and 256 (63.1%) men. The mean patient age was 48.77 years with SD 14.32 years. The age group with the highest frequency of GERD was the 40-59 years including 196 (48.3%) patients and also the group between 20-39 years including 111 (27.3%) patients. 60 (14.8%) patients were not diagnosed with GERD after following an upper gastrointestinal endoscopy. **Conclusions:** The M:F ratio for patients with Barrett esophagus is 5:1. The sensitivity for the diagnosis of GERD using questions about the typical symptoms (regurgitation, heartburn) is about 72.6%. Although, the prevalence of GERD is higher in males than females, the prevalence of esophagitis and GEFV grade between sexes in not statistically significant. On the other hand, there is a strong statistical significance between sex and grade of HH presence ($p < 0.05$). **Keywords:** GASTROESOPHAGEAL REFLUX DISEASE (GERD), UPPER GASTROINTESTINAL ENDOSCOPY, HIATAL HERNIA (HH), ESOPHAGITIS, GASTRITIS.

Heartburn and acid regurgitation, typical symptoms of gastroesophageal reflux disease (GERD), are considered to be reasonably specific for diagnosis (1,2). The dominant mechanism of GERD is contact of the esophageal mucosa with acid, and GERD can also produce symptoms or signs of tissue injury within the oropharynx, larynx and respiratory tract. Recent studies have suggested GERD causes a wide spectrum of non-esophageal conditions including asthma, non-obstructive dysphagia, and non-cardiac chest pain (3, 4). Moreover, it has been reported that acid-suppressive therapy resolves heartburn and epigastric pain in GERD patients (5, 6). Therefore,

epigastric pain may be a clinical symptom of GERD.

GERD is a common condition and its prevalence varies in different parts of the world. Several population-based studies have reported its prevalence is more frequent in Western (7-10) than in Eastern countries (11,12).

MATERIAL AND METHODS

Subjects

From January 2008, to March 2011, 426 consecutive potentially GERD positive patients visiting a Gastroenterology department received an upper gastro-intestinal endoscopy and completed the GERDQ questionnaire (13, 14) regarding GERD symptoms.

Symptom evaluation

Prior to the upper gastrointestinal endoscopy, patients filled out the GERDQ questionnaire regarding the presence and frequency of typical symptoms of GERD (heartburn and acid regurgitation). They also filled out a form about atypical symptoms and extraesophageal symptoms (15).

GERDQ has been created from three different validated questionnaires evaluated in the DIAMOND study (16) and is made up of six questions (four on symptoms, two on disease impact) completed by the patient and overseen by the physician. Answers are compiled according to a scale of options («never», «1 day», «2-3 days», and «4-7 days») and are scored accordingly. Each option equates to a 0-3 score.

Upper gastrointestinal endoscopy and classification of esophageal mucosal injury

Flexible video endoscopy was performed in each patient under premedication with midazolame and topical anesthesia of the pharynx with xylocaine gel. The lower esophagus, squamocolumnar junction, gastroesophageal junction and diaphragmatic hiatus were thoroughly inspected under adequate endoscopic inflation to maintain optimal visualization without over inflation or masking due to tight tonic contraction of the lower esophageal sphincter (LES) (17,18). The presence and degree of esophageal mucosal injury were graded according to the Los Angeles classification (19). 20 patients were excluded from the study. Patients were classified into 6 groups on the basis of upper endoscopic findings: esophagitis, gastritis, esophagitis and gastritis, other than esophagitis and gastritis finding, negative, Barrett esophagus. Hiatal hernia (HH) was defined as a circular extension of the gastric mucosa above the diaphragmatic hiatus and was categorized in three groups as small (< 3 cm), medium (3-5 cm) and big (> 5 cm).

Classification of the gastroesophageal flap valve

The gastroesophageal flap valve (GEFV) was inspected with a retroflexed endoscope and graded I to IV according to the Hill classification as follows (20): grade I, prominent fold of tissue along the lesser curvature closely opposed to the endoscope. Grade II, fold present, but slightly less well defined than in grade I and it opens rarely with respiration and closes promptly. Grade III, fold not prominent. The endoscope was not gripped tightly by the tissues and often failed to close around the endoscope. Grade IV, fold absent with the lumen of the esophagus gaping open, allowing squamous epithelium to be viewed from below. Grades I and II were classified as normal valves and grades III and IV as abnormal valves.

Statistical analysis

The prevalence rates of esophagitis, gastritis, Barrett esophagus, hiatal hernia

and the frequency of abnormal GEFV were calculated. Age, male to female ratio, presence of hiatal hernia, grade of mucosal injury using the Los Angeles classification and symptom category were compared between groups with normal and abnormal grades of GEFV, using unpaired *t*-tests. The χ^2*test* was performed to evaluate normal and abnormal grades of GEFV. Multiple comparative tests were performed among the groups with esophageal mucosal injury or symptoms. A p value <0.05 was considered to be statistically significant. The statistical software used for this purpose is *SPSS version 20.0* for MAC.

RESULTS

In this study the total number of patients were 406 of both sexes. 256 male patients (63.1%) and 150 female patients (36.9%). The mean age for both sexes was 48.7±14.3. Maximum and minimum age was 88 and 15 years respectively. We categorized the patients in 5 age groups as follows: '<20', '20-39', '40-59', '60-79' and '>80' (tab. I).

TABLE I

Age groups of patients with typical symptoms of GERD

Age groups (years)	Frequency	Percent
<20	1	0.2%
20-39	111	27.3%
40-59	196	48.3%
60-79	89	21.9%
>80	9	2.2%

The age group with the highest frequency is the 40-59 with 196 patients (48.3%). There is also a statistical significance between sex and the age groups ($p < 0.001$).

The upper gastrointestinal endoscopy showed the following data about the findings: esophagitis was present in 101 patients (24.9%), gastritis in 92 patients (22.7%), patients that presented both esophagitis and gastritis were 82 (20.2%), Barrett esophagus was present in 20 patients (4.9%), the endoscopy was negative for any pathological findings in 54 patients (13.3%) and 57 patients (14.0%) had some other findings not related to GERD (tab. II).

In tables III, IV and V are presented the GEFV, mucosal injury and HH presence per gender.

TABLE II

Endoscopic findings

	Frequency	Percent (%)
Esophagitis	101	24.9
Gastritis	92	22.7
Esophagitis and gastritis	82	20.2
Barrett esophagus	20	4.9
Negative endoscopy	54	13.3
Not GERD – related	57	14.0

TABLE III

GEFV categories between female and male patients

Hill's scale	Sex	
	Female	**Male**
I	57 (14.0%)	104 (25.6%)
II	67 (16.5%)	97 (23.9%)
III	13 (3.2%)	30 (7.4%)
IV	13 (3.2%)	25 (6.2%)
I + II	124 (30,5%)	201 (49.5%)
III + IV	26 (6.4%)	55 (13.6%)

Data are expressed as *n* (%).
There is not any statistical significance between sex and GEFV.

TABLE IV

Grade of esophagitis between female and male patients

Grade of esophagitis*	Sex	
	Female	**Male**
No esophagitis	91 (40,1%)	136 (59.9%)
A	23 (37.1%)	39 (62.9%)
B	13 (29.5%)	31 (70.5%)
C	15 (34.1%)	29 (65.9%)
D	8 (27.6%)	21 (72.4%)

*According to the Los Angeles classification criteria. Data are expressed an *n* (%).
There is not statistical significance between sex and grade of esophagitis.

TABLE V

Hiatal hernia presence between female and male patients

Hiatal Hernia	Sex	
	Female	**Male**
Without	99 (44.6%)	123 (55.4%)
Small (<3cm)	32 (26.0%)	91 (74.0%)*
Medium (3-5cm)	17 (30.9%)	38 (69.1%)*
Big (>5cm)	2 (33.3%)	4 (66.7%)

*p <0.05. Data are expressed as *n* (%).

TABLE VI

Prevalence of mucosal injury in patients with different grades of gastroesophageal flap valve (Hill's scale)

Hill's scale		Grade of esophagitis*			
	No esophagitis	**A**	**B**	**C**	**D**
I	108	27	22	4	0
II	117	31	11	3	2
III	2	3	6	19	13
IV	0	1	5	18	14

*According to the Los Angeles classification criteria. Data are expressed as *n.* Strong statistical significance (p< 0.01), Correlation r = 0.65.

In Figure 1, there is a better view of the relationship between the grade of esophagitis and the gastroesophageal flap valve grade. When the GEFV is normal (grade I and II), there is no, grade A or grade B esophagitis. When the GEFV is abnormal (grade III and IV), grade C and D esophagitis is more prevalent.

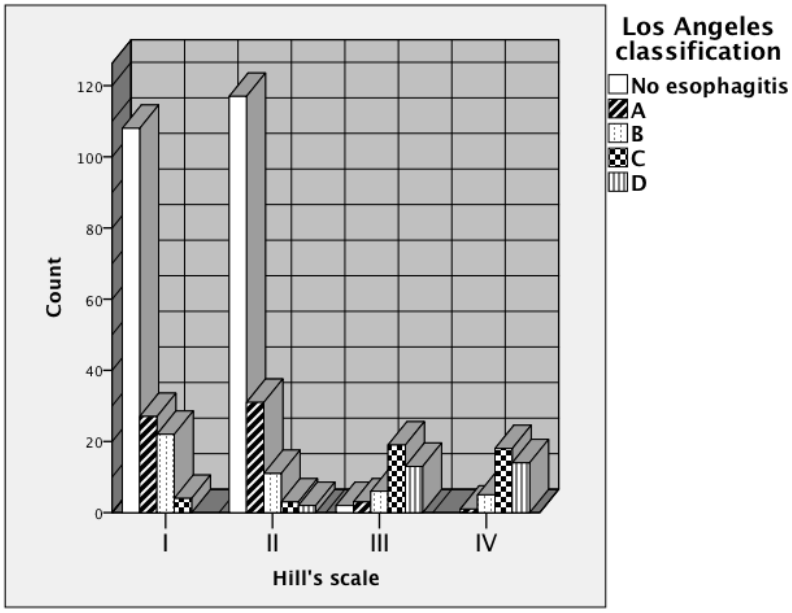

Fig. 1. Bar diagram showing the correlation between the grade of the esophagitis (using the Los Angeles classification) and the gastro-esophageal flap valve grade (using Hill's scale).

CONCLUSIONS

The present study demonstrates a close association between increasing deformation of the GEFV and endoscopically demonstrated GERD. Although, the prevalence of GERD is higher in males than females, the prevalence of esophagitis and GEFV grade between sexes in not statistically significant. On the other hand, there is a strong statistical significance between sex and grade of HH presence. The Male to female ratio for Barrett esophagus is 5:1. Analyzing the GERDQ and the upper gastrointestinal endoscopies of the patients examined, GERDQ in this study had a specificity of 85.9% and a sensitivity of 72.6%.

LYME DISEASE–UNUSUAL MEDICAL ENCOUNTER FOR AN UROLOGIST (Abstract): Lyme disease also called „the illness with a thousand faces" ("The Great Imitator") because it may mimic very well the symptoms and signs of other diseases, is an unusual medical encounter for the urologist. Every patient with Lyme disease has his own clinical feature, while the superposition over an unknown but easy to discover urological disease may lead to a misdiagnosis. **Case presentation**: Male patient A. P. was an emergency transfer in our clinic with multiple system organ failure. The mirage of first imaging finding, bilateral obstructive ureteral calculi was obviated after the serological confirmation of Lyme disease suspected after the thorough history obtained from his family. The intensive care treatment, broad-spectrum antibiotics and hemodialysis sessions, together with external urinary drainage, lead to the improvement of the patient status, and subsequent proper urological treatment to urolithiasis cure. **Conclusions**: This case identifies several challenges faced by practitioners, challenges which involve the diagnosis and the treatment of Lyme disease associated with urolithiasis. Although Lyme disease remains a controversial clinical entity, its diagnosis is based on a history of possible exposure to ticks, the appearance of specific clinical symptoms, whether or not combined with serological tests. **Keywords**: LYME DISEASE, *BORRELIA BURGDORFERI*, UROLITHIASIS.

Lyme disease, also called „the illness with a thousand faces" ("The Great Imitator") because it may mimic very well the symptoms and signs of other diseases, is an unusual medical encounter for the urologist. Every patient with Lyme disease has his own clinical feature, while the superposition over an unknown urological disease but easy detectable through imaging may lead to a misdiagnosis.

CASE PRESENTATION

The patient AP, age 46 (Hx 9546) was hospitalized in the Urology and Renal Transplantation Clinic Iasi being an emergency transfer from a county urological medical unit. The patient with urogical history (left ureterolithotomy for pelvic ureteral calculi during childhood) and known for therapeutically neglected nephrolithiasis was hospitalized in severe condition, 3rd degree coma, GCS=3, fixed mydriasis, respiratory acidosis, hemodynamic instability (also present during transport), TA=40/20 mmHg, heart rate 36/minute, idioventricular rhythm. The biological examination reveals severe

nitrogen retention, severe electrolyte imbalances, inflammatory syndrome and other metabolic changes (tab. I).

The emergency imaging assessment (ultrasonic and radiologic) reveals bilateral obstructing voluminous urolithiasis with 2nd -3rd degree bilateral uretero-hydronefrosis with correct transonicity (fig. 1).

Immediately after admission to the intensive care the patient receives device to aid breathing and is inserted central venous catheter, an inotropic support being set up. Despite the hemodynamic instability a hemodialysis session is performed in order to regulate the severe hydro-electrolytic and acido-basic imbalances.

TABLE I
Initial biological assessment

Test	Result	Normal values		Test	Result	Normal values
Urea	**666**	10 – 50 mg%		Na	**117**	135 – 148 mmol/l
Creatinine	**29,31**	0,7 – 1,3 mg%		K	**9,5**	3,5 – 5,1 mmol/l
Blood sugar	**224**	70 – 115 mg%		Cl	**82**	98 – 107 mmol/l
GOT	18	1 – 38 u/l		pH	**6,8**	7, 31- 7, 41

Fig. 1. Abdominal simple x-ray – bilateral obstructing voluminous urolithiasis

The appearance just hours after admission of the patient's next of kin allow the obtainment of the first historical data and this leads to the idea of a possible infection with *Borrelia burgdorferi*. Thus the onset of the symptoms is related to an insect (tick) bite in the scrotum two weeks ago, followed by the appearance of a polymorphous symptomatology that included erythema at the site of the bite, fever, sweating, headache, myalgia, reason why the patient referred to the territorial ER Department, being recommended a urologic assessment for the scrotal erythema. The examination performed by the territorial urologist 5 days before confirmed the scro-

tal lesion, but was limited to the indication of thorough local washing and subsequent reassessment for the lithiasis associated pathology. Progressively in the next few days the patient's general condition became affected, culminating in the abolition of the consciousness the day he came back to the emergency territorial urological unit.

All these anamnesis completions indicate the possibility to associate the bilateral obstructing voluminous urolithiasis with the Lyme disease. To confirm the suspicion of infection with *Borrelia burgdorferi* we dosed the antibodies to Borrelia by the immunochemical method with chemiluminescence detection (CLIA), whose values were high (IgG 55 AU / ml, IgM 9.2 AU/ml). Western blot confirmatory test was not possible.

But until serological results came out the cardiovascular recovery was a priority being obtained with inotropic support, acid-basic and electrolytic regulation, empirical broad-spectrum antibiotic therapy. 16 hours after admission due to the persistent anuria and due to the presence of the bilateral ureterohydronefrosis, the patient was subject to a urologic intervention being performed a bilateral percutaneous nephrostomy with the aspiration of clear urine from both pyelocaliceal systems.

The subsequent development was sow, no diuresis on nephrostomies, with repeated hemodialysis sessions but the patient experienced gradual improvement of the general condition, he regained consciousness, became cooperative and resumed his spontaneous respiration being extubated 48 hours after admission. Blood pressure values stabilized and gradually the hemodynamic support doses were reduced until their complete interruption. 5 days after admission he gradually resumed diuresis, while maintaining nitrogen retention (serum creatinine between 10.6 and 15.3 mg%, CrCl = 5 ml / min) requiring chronic hemodialysis, which was subsequently performed within the dialysis territorial unit.

The reassessment performed 3 weeks after discharge revealed stationary moderate nitrogen retention (urea = 66 mg%, creatinine = 2.2 mg%, CrCl = 46 ml / min). Given the global diuresis (2000 ml / day) the attending physician decided to suspend hemodialysis and assess the patient subsequently in order to decide the urological behavior.

The patient came back after 3 weeks more in the Urology Clinic being reassessed in order to solve the bilateral ureterolithiasis problem. The biological investigations reveals minimum nitrogen retention (urea = 55 mg %, creatinine = 1.57 mg %). The imaging assessment, ultrasound and pyelography assessment confirm the 1 cm right lumbar ureteral calculus and the 4-5 cm left pelvis one, the elimination of the contrast substance and residual distension of the bilateral pyelocaliceal system (fig. 2).

First a push-back of the lumbar ureteral calculus and its percutaneous extraction were performed and subsequently left pelvic ureterolithotomy which was difficult considering the antecedent intervention and the changes of the subjacent ureter. The postoperative evolution was simple with primary wound healing and suppression of bilateral nephrostomy cathether.

More than 6 months after the intervention the patient who had been monitored all along (creatinine=1.5-1.6 mg %), is clinically and imagistically reassessed, the success of the interventions performed being thus revealed (fig. 3).

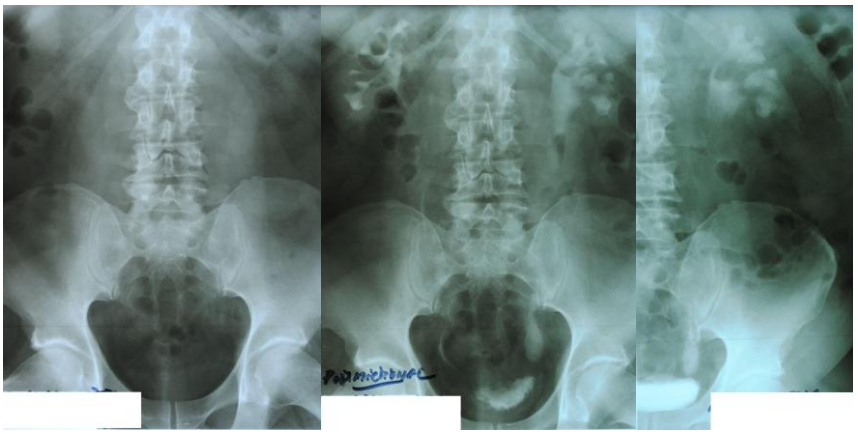

Fig. 3. Intravenous pyelography – control

DISCUSSION

Urologist's coping with Lyme disease is really unusual, a rarity of the ambulatory or emergency medical work; nonetheless, in the case presented herein, it reminds the necessity of a deep and thorough analysis of each clinical case. The challenge for physicians and patients consists of the rapid recognition and appropriate treatment of infection, especially in patients with non-specific clinical manifestations (1, 2).

Analyzing retrospectively the succession of events, we could say that the examination of the scrotum at a first evaluation correlated with a thorough anamnesis should raise the suspicion of a Lyme disease. The rapid evolution of symptoms and the impairment of the general condition made the patient to present for evaluation at the territorial emergency department; this department, based on the evaluation protocol, emphasized organ and system multiple failure, considered a consequence of the evolution of the sepsis with urinary starting point (infected lithiasic bilateral ureterohydronefrosis). The invalidation of these assumptions about the cause of the organ and system multiple failure (MSOF) is based on several arguments: first

of all, the sequence of events reported by the patient's next of kin and subsequently by the patient (the event that triggered the suffering being the tick bite in apparent health status), then the absence of any urinary-type symptomatology (absence of changes in the appearance of urine, absence of back pain symptoms) and. Finally, aspiration of clear urine from the bilateral pyelocaliceal system in the moment of the external urinary derivation in postponed emergency and microbiological confirmation of its sterility at that time.

The morpho-pathological substrate of the renal impairment in Lyme disease is represented by the membrano-proliferative glomerulonephritis with or without interstitial nephritis (3). This post-infectious event seems to be based on a mechanism using circulating immune complexes, fact evidenced in dogs and in some cases in humans (3, 4, 5).

The clinical testing for Lyme disease remains a matter of controversy (6). The Centre for Disease Control and Prevention in the United States recommends using a dual algorithm: screening by indirect immunofluorescence or enzyme immunoassay test, followed by confirmation through Western blot. Although this approach has a high specificity, the sensitivity of the dual algorithm of diagnosis for patients with Lyme disease at 4-6 weeks at least after infection is of only 44-56%, making it unsuitable for a clinical diagnosis test. Therefore, according to the Centre for Disease Control and Prevention in the United States, the diagnosis of Lyme disease is based primarily on the clinical data, on the exposure to the bite in an endemic area, as well as on the high level of anti-Borrelia antibodies (7). In the presented case, lacks from organizational reasons the serological confirmation by Western blot, this test being unavailable in our center.

CONCLUSIONS

The case presented herein identifies several challenges encountered by the urologist in terms of diagnosis and treatment of Lyme disease associated with urolithiasis. Although Lyme disease remains a controversial entity, its diagnosis is based on the history of the exposure to tick bites, as well as on the clinical examination, combined or not with serological tests.

PATHOLOGICAL COMPARATIVE ASSESSMENT OF TWO CASES OF THYMIC CYST AND CYSTIC THYMOMA AND REVIEW OF THE LITERATURE (Abstract): Cystic changes of the thymus are rare lesions. In addition to their appearance in non-neoplastic congenital and acquired conditions, they have been seen in association with certain malignancies of the thymus. Our aim is to highlight the possibility of confusing between benign and malignant thymus cysts having different cure approach. We report two thymic cyst cases, one congenital ectopic condition, and the other one, a cystic thymoma. Investigations included blood counts, echograms, and computed tomography. The cysts were excised by mediastinal route and examined pathologically. The final diagnosis was made only after histopathological examination of the surgery biopsy revealing two types of cystic thymic lesions: congenital and tumoral. Because thymic cysts may present malignant transformation, they represent a diagnostic challenge that is resolved only by surgical excision and histological examination. Due to cystic changes masking tumoral features in these cases, thorough sampling is required to ensure that a malignancy is not overlooked. **Key words:** THYMIC CYST, CYSTIC THYMOMA, MESOTHELIAL CYST

Thymic cysts are regarded as rare anomalies (1); they may occur at any anatomic level, from the base of the neck to the diaphragm. There is some controversy receiving the causes of thymic cysts. According with Speers (2) thymic cysts represents different entities: congenital, inflammatory and neoplastic. Congenital cysts can be found along the anatomical course of the third pharyngeal pouch, inflammatory cysts may be due to an acquired inflammatory process (3, 4, 5), and neoplastic cysts (6, 7) are more frequently in larger tumors than in smaller ones, resulting by cystic degeneration of the tumors. Suster and Rosai (8) reported 18 cases of multilocular thymic cysts, in addition to unilocular cysts, most of the cases represented by congenital or acquired inflammatory cysts, and some of them were related to neoplasms. In any case, local disruption of thymic tissue can induce the formation or growth of cysts. In the current paper, we make a comparative pathological discussion between the two thymic cysts: the first, a thymic cyst of congenital origin,

and the second, a cystic mass of neoplastic origin, represented by a cystic thymoma.

CASE PRESENTATIONS

Case 1.

An asymptomatic 23-year-old man was referred to our hospital with a suspicion of "pericardial cyst" based on chest echocardiography made few months ago. The family history was non-contributory and the past personal history contained no episodes of pneumonia, pleurisy or chest pain. Laboratory data and ECG were normal. Chest X ray demonstrated a mass located in the anterosuperior mediastinum. Echocardiography exam showed a cyst structure located adjacent to the right atrium, measuring about 7 x 4 x 6 cm. There was no pericardial fluid, intracavitary thrombus and pulmonary hypertension. The results of computed tomography (CT) of the chest consisted in a cystic mediastinal mass with a definite, thick, fibrous capsule and fluid content. Cyst resection was recommended because of the cyst's large size and the high possibility of compression to the right atrium.

Following surgical operation, macroscopical examination revealed a well-encapsulated bilocular (fig. 1) thick-walled cystic mass with serous fluid content. Histopathological examination of the cyst revealed that its inner surface was lined with columnar epithelium, with thymic elements in the fibrous wall (fig. 2) and small foci of normal thymus (fig. 3) outside the cyst. From these histological findings, the patient was morphologically diagnosed with congenital thymic cyst. The patient left the hospital in good conditions and the postoperative evolution was favorable.

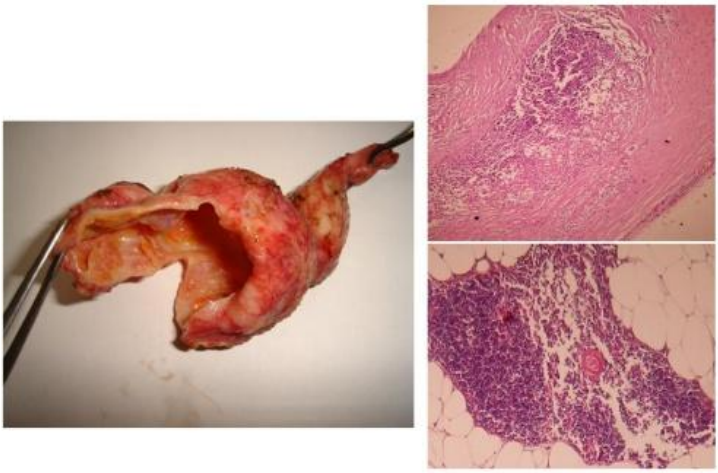

Fig.1- Encapsulated cystic mass; Fig. 2 -Thymic elements in the fibrous wall (HE, x20); Fig. 3 - Small external foci of normal thymus (HE, x10).

Case 2.

A 41 year old man with no significant past history was diagnosed, in 2002, on a routine chest X-ray with a left pleuro-pericardial mass. Subsequently, a CT scan showed a normal thymic region and a well defined antero-inferior mediastinal mass of 50/58/39 mm with areas of attenuation suggestive of cystic lesion, which was considered at that time, a pleuro-pericardial

cyst. After seven years, in January 2009, the patient was diagnosed in Neurological Hospital with myasthenia gravis, Osserman clinical stage IIB. A repeat thorax CT scan (fig.4) showed a bigger mass of 60/60/53 mm, that was inhomogeneous and well encapsulated situated between the pericardium and left inferior mediastinal pleura. Surgical exploration revealed a large cyst measuring approximately 6 cm in greatest dimension (fig.5). On cut section, it was a large cystic mass with less solid areas. The cut surface revealed grayish pink irregular nodules on the inner surface and almost the entire tumor was cystic and filled incompletely with soft yellow gelatinous material (fig. 6).

Pathologically, we found a large cystic tumor and a normal involuted thymic tissue was present outside of the wall (fig. 7). The cyst wall was composed of hyaline fibrous tissue and was lined inside by tumoral areas and eosinophilic debris, representing extensive areas of necrosis.

Fig.4. Mediastinal cystic mass; Fig. 5. Mediastinal tumoral mass; Fig. 6. Cystic mass with solid areas; Fig.7. Normal involuted thymic tissue (HE, x20).

Microscopical examination of the solid areas showed tumoral lobules (fig. 8) separated by fibrous bands and perivascular spaces (fig**.** 9). The lobules were composed of a dual population of cells typical of thymoma, including small lymphocytes and larger epithelioid cells with round to oval nuclei surrounded by abundant slightly eosinophilic cytoplasm. There was no evidence of nuclear pleomorphism or mitotic activity of the epithelioid cells

The capsule (fig. 10) was thickened and fibrotic, presenting focally, adjacent cholesterol clefts and foamy cells. Vestiges of lymphoid tissue were present in the wall. Examination of multiple sections did not reveal any evidence of invasion through the capsule, except a point of incomplete infiltration (fig. 11) of it, where the tumor point was too small to assess capsular invasion. Indeed, there was no evidence of capsular invasion or microscopic foci in the medias-

tinal fat. There were no signs of the tumor infiltration in the lung or any other adjacent structures, as well.

Pathology was consistent with type AB thymoma according to World Health Organization Classification or mixt thymoma according to traditional schema. On the basis of these histological findings, the cystic mass was identified as an encapsulated, well differentiated thymoma, stage I Masaoka, with secondary necrotic and cystic changes.

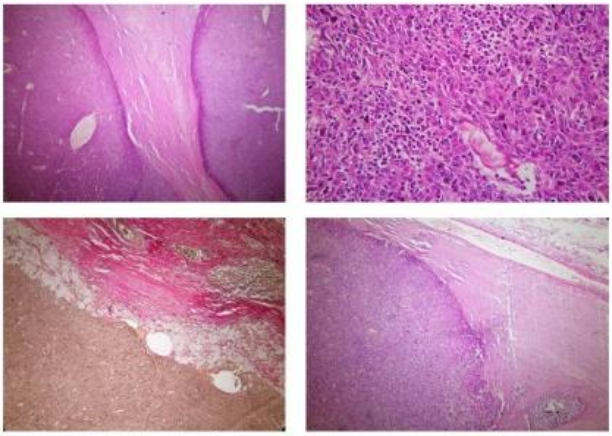

Fig.8. Tumoral lobules separated by fibrous bands (HE, x10); Fig. 9. Perivascular space and dual population of cells typical in thymoma (HE, x20); Fig.10. Thickened fibrotic capsule and subjacent foamy cells (EVG, x10); Fig.11. Point of incomplete capsular infiltration (HE, x10).

DISCUSSION AND CONCLUSIONS

Thymic cysts are relatively uncommon, but their numbers are increasing with the advent of new imagistic modalities of diagnosis, such as CT and MRI. They are most commonly classified into congenital or acquired, including neoplastic cysts (1-4). An important issue is the differentiation between thymic cysts and cystic thymomas.

Thymic cysts are believed to represent different entities, congenital, inflammatory and neoplastic cysts (9). Congenital, most of the thymic cysts can be explained as sequestrated remnants of the thymopharyngeal duct system (3). Suster and Rosai consider that the origin of thymic cysts seems to be: congenital, due to the induction of cystic transformation of ductal epithelium of the thymopharyngeal duct system or acquired, being related by an acquired inflammatory process (10). These cystic spaces are also interpreted as degenerative, probably resulting from liquefactive necrosis or fluid accumulation secondary to hemorrhage. The inflammation is a reactive process.

The same authors consider that diagnosis of inflammatory cysts may be difficult due to cystic changes and degenerative nature of these tumors. Degeneration of thymic cysts may reduce the identifiable thymic tissue, therefore extensive microscopic sampling is important.

Thymic cysts are rare and the etiopathogeny of these benign cysts is still controversial. But, their removal is often easy and the diagnosis is confirmed by the presence of Hassall's corpuscles in the cyst wall.

Cystic changes in thymoma may be the result of two pathogenetic mechanisms: (a) confluence and dilatation of perivascular spaces with creation of large cystic cavities devoid of an epithelial lining or inflammation, and (b) cystic dilatation of Hassall's corpuscles secondary to underlying inflammatory changes of residual non neoplastic thymic epithelium (11). Our case illustrates a secondary necrotic event that may supervene in thymoma that can obscure the main underlying pathological process.

Sometimes, it may be impossible to determine whether the cystic changes supervened in a preexisting thymoma (cystic transformation of the thymoma) or whether the thymoma, developed secondarily, represents an incidental finding in a thymic cyst (12). In our case, thymoma was found as mural nodules attached to the wall of the thymic cyst, pointing an initial thymoma with secondary cystic transformation.

In thymomas, more important than tumoral subtyping is to make a correct diagnosis of malignancy for avoiding confusion with other types of anterior mediastinal cystic lesions. Moreover, the most important prognostic factor of the thymomas, remain the status of capsular integrity. Adequate inking of the outer surface of the specimen and extensive sampling of the capsule are therefore of primary importance for the evaluation of these tumors.

MINIMALLY INVASIVE PERCUTANEOUS SCREWS OSTEOSYNTHESIS INDICATIONS IN TIBIAL PILON FRACTURES (Abstract): Tibial pilon fractures usually result from high energy trauma. Management of these fractures is challenging because of the complexity of the injury pattern and the risk of significant complications. Various treatment methods are available, depending not only on the fracture type but mostly on the extent of the soft tissue injury. In tibial pilon fractures AO type A and B, without intensive comminution, we can tempt orthopedic reduction and percutaneous screw fixation. This protects the soft tissues, an important factor in postoperative care of these fractures. Material and methods: We present a case of a 23 years old woman treated with closed reduction and internal fixation with percutaneous screws. Conclusions: By percutaneous osteosynthesis we avoided possible complications of extensive skin wound and skin-plate conflict. The recovery was much easier, avoiding joint stiffness and therefore osteoporosis at this level. **Key words**: TIBIAL PILON FRACTURE, CLOSED REDUCTION, INTERNAL FIXATION, PERCUTANEOUS SCREWS

Termenul de pilon tibial a fost introdus în literatura ortopedică în 1911 de către Étienne Destot (1). Aceste fracturi se produc de obicei în urma traumatismelor de energie înaltă. Tratamentul acestora este dificil nu numai prin complexitatea traiectelor de fractură, cât şi prin riscul crescut al complicațiilor.

În 1959 Jergesen considera că reducerea sângerândă şi fixarea internă a acestor fracturi este imposibilă (2). De-a lungul timpului însă lucrurile s-au schimbat datorită unei mai bune înțelegeri a importanței părților moi înconjurătoare şi diferențierii între fracturile prin energie joasă şi înaltă, ceea ce a dus la apariția unor noi concepte terapeutice (3,4,5).

MATERIAL ŞI METODE

Pacientă LI, în vârstă de 23 de ani, victimă unui accident rutier, se prezintă în urgență la camera de gardă acuzând dureri şi impotență funcțională la nivelul gleznei stângi şi coloanei dorso-lombare.

Se efectuează radiografie de gleznă în incidență antero-posterioară şi latero-laterală (fig. 1) cu evidențierea unei fracturi de pilon tibial şi maleolă internă, radiografie de coloană dorso-lombară ce evidențiază prezența unei fracturi-tasare de corp

vertebral L4 şi examen CT cranio-cerebral cu decelarea unui edem cerebral moderat.

Fig. 1. Radiografie preoperatorie de gleznă (A - faţă, B - profil) – fractura maleolei interne fără deplasare şi fractura pilonului tibial cu înfundare articulară în jumătatea anterioară.

Se imobilizează membrul inferior stâng pe atelă ghipsată gambo-podală şi fractura de coloană în lombostat, pacienta fiind dirijată spre serviciul de Neurochirurgie cu recomandarea de internare în Secția de Ortopedie după rezolvarea problemelor neurochirurgicale.

După 7 zile, pacienta revine în Secția de Ortopedie cu recomandările de consult neurologic la nevoie şi menținerea lombostatului până la 45 de zile posttraumatism.

Se efectuează examen CT de gleznă cu reconstrucție 3D ce evidențiază prezența unei fracturi de maleolă internă fără deplasare şi a unei fracturi de pilon tibial **AO 43 B2** (fig. 2).

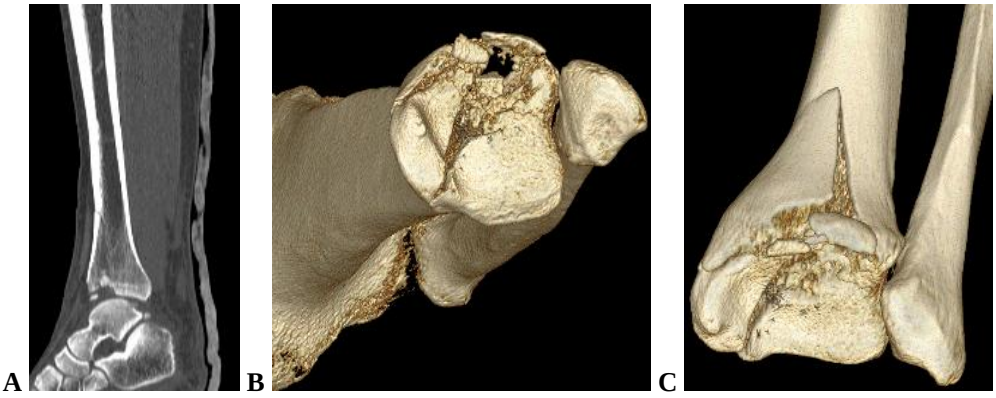

Fig. 2. **A –** CT nativ gleznă; B, C – CT cu reconstrucție 3D gleznă – fractură cominutivă pilon tibial cu înfundare (treaptă articulară de ~ 3 mm) AO 43 B2, fractură maleolă internă cu minimă deplasare.

Se intervine chirurgical, sub Rx-TV, practicându-se reducerea ortopedică a focarului de fractură şi osteosinteză percutană cu 2 şuruburi maleolare a fracturii de pilon tibial şi 1 şurub maleolar a fracturii maleolei interne (fig. 3).

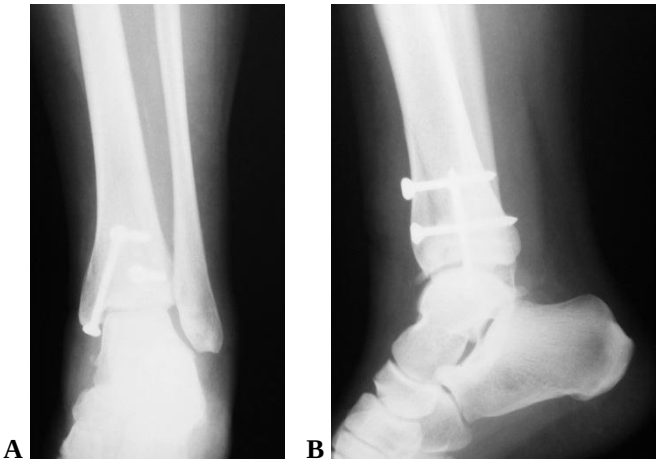

Fig. 3. Radiografie postoperatorie de gleznă (A - faţă, B - profil) – reducerea focarelor de fractură maleolar şi de pilon tibial, refacerea continuităţii suprafeţei articulare, prezenţa materialului de osteosinteză (2 şuruburi maleolare antero-posterioare pe pilonul tibial şi a unui şurub maleolar pe maleola internă).

Starea generală şi locală fiind favorabilă pacienta se externează cu recomandarea de imobilizare pe atelă gambo-podală timp de 30 de zile, timp în care evită sprijinul pe membrul inferior operat, după care revine pentru evaluare clinică şi radiologică.

DISCUŢII

Fracturile pilonului tibial rezultă dintr-o combinaţie de compresii axiale şi forţe de rotaţie. Analizarea critică a condiţiei ţesuturilor moi reprezintă un aspect crucial în managementul acestor fracturi. Poate cea mai mare realizare a tratamentului chirurgical al fracturilor pilonului tibial a fost recunoaşterea necesităţii de a amâna intervenţia chirurgicală primară.

Trebuie să facem mai întâi o distincţie între fracturile extra şi intra-articulare, cele din urmă fiind complet sau parţial articulare. Fracturile extraarticulare şi cele parţial articulare pot fi tratate prin tehnici minim invazive fie cu şuruburi canulate introduse percutan, fie cu plăci anatomice stabile angular (6,7).

Primele studii cu şuruburi canulate introduse percutan au fost publicate în 2004, pe un lot de 7 pacienţi urmăriţi 30.6 luni. Rezultatele au fost foarte bune, obţinându-se un scor de 90,8/100 (8).

Evoluţia şi prognosticul acestor fracturi depinde de severitatea traumatismului şi de acurateţea reducerii la nivel articular. Reducerea şi refacerea lungimii se poate face prin ligamentotaxis, folosind fixatorul extern, dar principiul de bază rămâne reducerea anatomică sângerândă (9,10,11).

Refacerea integrităţii mortezei este un factor determinant în succesul tratamentului acestor fracturi.

Unii autori (10,11) susțin că rata complicațiilor este mai mică când fixarea externă este folosită înaintea reducerii sângerânde, dar alți autori (12) spun că fractura de pilon tibial tratată cu fixator extern are o rată mai mare (p=0.03) de consolidări vicioase decât tratată prin reducere sângerândă şi fixare internă.

CONCLUZII

Avantajul oferit de fixarea percutană este reprezentat de prezervarea țesuturilor moi din jurul sediului fracturii; se menține astfel vascularizația din această zonă şi se reduce trauma chirurgicală, pacientul recuperându-se mult mai rapid (13).

În continuare fractura de pilon tibial reprezintă o provocare pentru chirurgul ortoped. Un plan pre-operator excelent, o atenție sporită față de țesuturile moi şi o intervenție chirurgicală bine realizată încă pot avea un rezultat defectuos datorită deteriorării cartilajului articular la momentul producerii leziunii.

Prin osteosinteza percutană am evitat posibilele complicații ale plăgilor tegumentare extensive şi a conflictului tegument-plăci. În acelaşi timp, recuperarea a fost mai facilă, evitând astfel redoarea articulară şi implicit osteoporoza de la acest nivel.

THE ROLE OF THE MOTIVATIONAL INTERVIEW IN TREATMENT ACCEPTANCE. CASE REPORT (Abstract): Treatment acceptance and subsequently treatment adherence represent the most difficult aspects of medical treatment. This is the reason why it requires the use of tools from psychotherapy and communication sciences, but also a new approach to the relationship per se. Thus, the use of the motivational interview together with the change in the perspective of the therapeutic relationship, namely the patient-centered approach from the psychosocial perspective, proved to be effective ways to overcome this obstacle. This article focuses on the case of a 45-year-old patient suffering from psoriasis since he was 30. He followed all the therapeutic steps indicated by the therapeutic protocols, reaching the critical moment of disease evolution, when the only effective therapeutic indication was biological agent therapy. Considering the adverse effects of this class of drugs, the patient exhibits a period of ambivalence before accepting therapy. **Keywords**: MOTIVATIONAL INTERVIEW, THERAPEUTIC ACCEPTANCE, PATIENT-CENTERED APPROACH.

One of the most difficult aspects of medical treatment is acceptance of diagnosis, followed by adherence to therapy and prevention of self-medication, as they are the result of the degree of information, therapeutic advice and education of the population (1, 2). At the conceptual level, accepting the diagnosis is the acceptance of a change that sometimes occurs unexpectedly and brutally in a patient's life. In the case of chronic conditions, adherence to therapy necessarily requires the existence of an important motivation. The motivational interview is a useful tool in cases when the patient essentially exhibits resistance to change.

We started from the idea that an optimal and effective therapeutic relationship is based on the concept that, starting from the individual needs of the patient, the therapist (the physician) creates a therapy plan and establishes a therapeutic relationship, placing himself/herself and the patient on the same level. This concept has the advantage of empowering the patient, who will be aware of his/her attributions in the context of the therapeutic relationship and will therefore assume his/her part (3, 4, 5, 6, 7).

Identifying the intrinsic motivation of

the patient is a difficult and long process that requires special communication skills from the physician. There are also studies that report that a wanting and difficult doctor-patient relationship can lead to non-adherence and even self-neglect, refusing medication or medical care and personal safety measures (8, 9, 10).

It is extremely challenging to establish a good medical approach, especially in severely ill patients and in elderly with multiple dietary recommendations and numerous drug regimens as one should try to reconcile the medical benefits of the treatment with the possibilities of each patient to fulfill it. Elaborating a personal, realistic therapy is the main key for providing a good compliance, an excellent evolution of the disease and quality of life at least as good as the patient's expectations. The current approach to medicine is one centered on the patient from a bio-psycho-social perspective (11).

CASE REPORT

The here presented clinical case details the adherence to therapy of a patient with psoriasis vulgaris, who was recommended to undergo biological therapy.

The 45-year-old man, with obesity, was diagnosed at the age of 15 with psoriasis vulgaris. He underwent all stages of therapy, and due to the unfavorable course and the occurrence of psoriatic arthritis at the age of 35, he was given the indication of initiation for biological therapy. Although he had accepted the diagnosis 15 years before and followed the prescribed treatments, the patient is in a state of ambivalence when recommended this last stage of therapy, invoking various reasons for postponing it (the need to quit smoking because of the possibility of infectious complications pulmonary tuberculosis).

As a result, he repeatedly performed imaging investigations and laboratory analyses included in the protocol for the inclusion of patients in the therapy program. Moreover, based on information filtered from the perspective of personal beliefs, corroborated with information assimilated by the reading of articles posted on the internet, the patient formulates diagnostic assumptions that emphasize his ambivalence (12, 13, 14).

The patient presented a state of marked anxiety during that period, which he tried to dissimulate by an exuberant attitude, in disagreement with the symptom he accuses: exhaustion, insomnia, irritability, intrusive thoughts gravitating around the same leitmotif: the need for the recommended therapy.

We considered it useful to apply the motivational interview in the context of the re-conceptualization of the disease state and the necessity of establishing the biological therapy, to obtain the situational reframing. We started from initiating the change process by trying to facilitate it (15).

The patient's profile was: increased importance given to change, but low confidence in the chances of success. We applied the technique of decisional balance that consists in producing a list of status quo (status) and benefits of change. On the other side of the balance we have positioned the costs of change and the benefits of the status quo (16, 17, 18).

Obviously, the patient was aware of the benefits of change, but we got into the *avoidance-acceptance* situation in which he was equally attracted by and scared of the benefits of treatment, the adverse effects and the need to change habits (smoking).

The situation was potentially dangerous for the patient, as psoriasis, a psychosomatic condition with an important emotional component, could be aggravated because of blocking the state of internal conflict (19).

Considering that ambivalence is a process on a continuum of change, we considered it necessary to have a meeting with the patient, explaining that ambivalence is a normal phase in the process of change and he should not be worried.

During the second session with the patient, we triggered an increase in the discrepancy between the present behavior and the perceived significance of that behavior. Thus, at the conceptual level, the patient understood that the significance he had previously attributed to the initiation of treatment could not be reduced to the treatment itself (adverse reactions or benefits) but had to be assimilated to self-destructive behavior with profound family implications, also, of social insertion and especially emotional relationships with his son. In this context, the patient admitted that, because of the extended plaques to about 90% of the body surface, he was forced to not appear in public, which caused deep suffering to his son, who was deprived of his father's presence in certain situations (feasts, visits).

The re-conceptualization of the situation was also favored by the explanation that, if the treatment is discontinued, the patient will be in a state of permanent uncertainty about the benefits of biological agents' therapy.

After four meetings, the patient realized that making personal change is a choice that belongs to him and that ambivalence is a normal state of change. Consequently, he accepted biological therapy, assuming implicitly the potential side effects.

The evolution of the patient under treatment was favorable, and he is still following the therapy with biological agents. A difficult moment was BK infection and the development of a latent form of pulmonary tuberculosis, which required additional isoniazid therapy. Thus, in this situation, the need to maintain change, as evidenced by the continuation of biological therapy, was realized by the patient.

DISCUSSION

The presentation of this case makes obvious the need for effective communication with the patient, but also the importance and benefits of using the motivational interview in increasing the adherence of the patient to treatment (20, 21). For this reason, several programs to increase the communication skills of physicians would be particularly useful. Medical tele surveillance and complex telemonitoring are considered as a promising solution for a better patient-physician communication, especially for chronic and senior patients (22, 23).

In situations of diagnostic and therapeutic uncertainty, the motivational interview and the re-conceptualization and reframing techniques used proved to be useful tools for obtaining maximum therapeutic benefits (24, 25, 26).

Specialty literature confirms the need for medical staff training on the motivational interviewing (MI)-based approach to patients with chronic diseases, particularly with psoriasis. The need for this approach lies in the importance of the physician's ability to influence the attitude of patients with psoriasis towards health in general. The Pso Well study (27) provides evidence to that effect.

Another study reveals the benefits of using MI in patients with psoriasis. It refers

to the cost-utility balance, showing that using MI "showed significant cost saving, the MI approach is cost-effective in addition to its positive effects on clinical outcomes" (28).

In the same way, the counseling of the patient with psoriasis also includes the study on motivational counseling by telephone. It puts to the forefront the lifestyle of patients with psoriasis (29, 30). A study in the USA found that MI primarily by telephone helped to improve patient activation, self-efficacy, perceived health status and promoted lifestyle changes (31). Some evidence even suggests that telephone support may be as successful as face-to-face supported self-management (32, 33).

To conclude, the literature of recent years confirms the necessity of MI implementation as a necessary tool for dealing with patients with chronic diseases, especially patients with psoriasis. The main reason is the emotional factor present in patients with chronic diseases and especially in those with affectation of aesthetic appearance, as is the case in patients with psoriasis (34).

CONCLUSIONS

This case particularly discusses the association of comorbidities (obesity, smoking) in a patient with psoriasis whose evolution had worsened over time. The peculiarity of this case resides in the fact that emotional distress was not present in a significant way at the onset of the disease, during adolescence, which is recognized as a period of psycho-biological crisis. On the contrary, the emotional impact has been determined especially by the need to give up a type of addiction, namely smoking, food addiction, issues that are being discussed more and more frequently by the medical community.

Consequently, the present study is consistent with the current concerns of the scientific community related to the impact of psoriasis, emphasizing in the same time the importance of addictions in adherence to specific therapy.

NATURAL TREATMENT IN BREAST CANCER: BENEFIC OR NOT

Breast cancer is one of the most significant health problem all over the world, despite of the high performance diagnostic procedures and the increased methods of prevention and treatment. Searching articles about herbal treatment in breast cancer on PubMed and ISI Web of Scince it was discovered that the most important plants and natural extracts used to prevent and treat breast cancer are *Echinacea sp*., *Camelia sinensis (*green tea), *Allium sativum*, *Ginseng*, vitamin A, vitamin E, omega 3. Although there are not enough in vivo studies, most studies are performed on breast cancer cell lines, many herbal products are being researched for their pharmacological activity in monotherapy or in addition to conventional cancer treatment. It is not fully known if the effects on the therapy are negative because of the numerous active ingredients and their high risk of adverse effects or positive because of their pharmacodinamyc activity: activation of metabolizing enzymes, supression of reactive oxygen species production. For example *Echinacea sp* will not affect the activity of the chemotheraputic agent, but it may cause liver damage when administrated for a long period of time. În *Allium sativum* the most effective compounds are the oil-soluble ones. Regular consumpsion of green tea seem to have also an protectiv effect against breast cancer. (C. M. Lopes, A. Dourado, and R. Oliveira. Phytotherapy and nutritional supplements on breast cancer. *Biomed Res Int*, 2017).

THE ROLE OF EEG BRAIN MAPPING IN QUANTIFICATION OF BRAIN DAMAGE IN HYPERTENSIVE DISEASE ASSOCIATED WITH PREGNANCY (Abstract): The existence of a high blood pressure during the pregnancy represents a real danger for the mother and child, responsible for damage of the kidney, brain, liver, and placenta, cardiovascular and hormonal system. Nervous system changes can include blurred vision, seeing spots, severe headaches, convulsions, brain hemorrhage, and even occasionally blindness. **Aim:** To evaluate the spatial distribution of electroneuro-pathological aspects of brain activity at pregnant women with hypertensive disease by BEAM (Brain Electrical Activity Mapping). **Material and methods:** Twenty pregnant women (week 20 to 39) with hypertensive disease were recruited. Healthy pregnant women were also recruited control group. Maternal monitoring included spectral multichannel EEG analysis (brain mapping), repeated clinical examinations and laboratory investigations. **Results:** The major EEG changes observed were focal slowing of the background activity (14 patients) - occipital lobes especially, and intermittent spike and sharp wave transients (5 patients). **Conclusions:** Our findings indicate that EEG brain mapping are probably sensitive in detecting the extent of the pathology in the brain in women with in hypertensive disease associated with pregnancy. **Key words**: PREGNANCY, BRAIN MAPPING, HYPERTENSIVE DISEASE.

High blood pressure (hypertension) during pregnancy - whether is developed before or after conception - requires a special care. Hypertensive disorders occur in 6 to 12 % of pregnancies and contribute significantly to stillbirths and neonatal morbidity and mortality, also representing the second leading cause, after embolism, of maternal mortality. There are four distinct types of high blood pressure that can complicate pregnancy: 1) chronic hypertension; 2) preeclampsia-eclampsia; 3) preeclampsia superimposed upon chronic hypertension; 4) gestational hypertension (1, 2, 3).

Expectant mothers with hypertension are predisposed to the development of potentially lethal complications, notably *abruptio placentae*, disseminated intravascular coagulation, cerebral hemorrhage, hepatic failure, and acute renal failure. The etiology of most cases of hypertension during pregnancy, particularly preeclamp-

sia, remains mostly unknown (1, 3, 4).

The central nervous system manifestations include headache and visual disturbances including blurred vision, scotomata, and rarely, cortical blindness. Occasionally, focal neurologic signs may develop, which should prompt radiologic investigation. Eclampsia, the convulsive phase of preeclampsia, remains a significant cause of maternal mortality. Hemorrhage and edema have also been documented, and has been attributed both to coagulopathy and fibrin deposition, as well as hypertensive encephalopathy (1, 4, 5).

The aim of this study is to evaluate the spatial distribution of electroneuropathological pattern of brain activity at pregnant women with hypertensive disease by quantitative EEG - also known by the acronym BEAM (Brain Electrical Activity Mapping). Topographic brain mapping is an extension of conventional electroencephalography. It involves the computerized analysis and topographic display of EEG rhythms and evoked potential data on a color video screen. A wide assortment of maps can be created to represent different measurement patterns. The purpose of this technique is to identify patterns that distinguish pathological groups from normal ones (6, 7).

MATERIAL AND METHODS

Twenty pregnant women (week 20 to 39) with hypertensive disease (gestational hypertension or preeclampsia) were recruited from Cuza-Vodă Hospital, Iasi. The patients with cerebrovascular disease, epilepsy, mass lesions, toxic exposures, head injuries, and more were excluded from our study. The control group was formed by pregnant women without hypertensive disease associated with pregnancy. Maternal monitoring included multichannel EEG recording (fig. 1), spectral analysis (fig. 2) and brain mapping (fig. 3) - also blood pressure, weight curve, diuresis, subjective complaints or blood/urine chemistries changes.

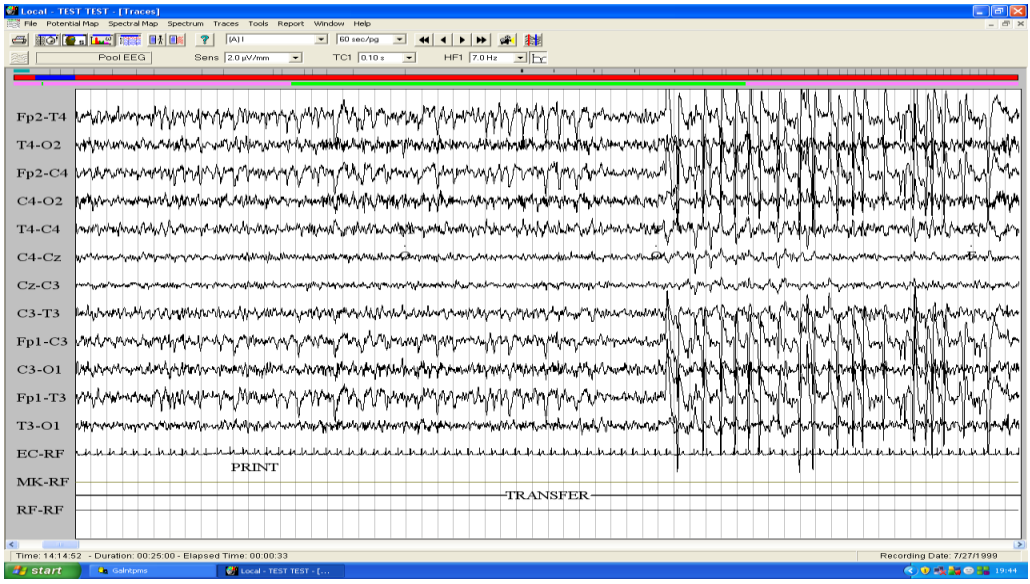

Fig. 1. Multichannel EEG recording

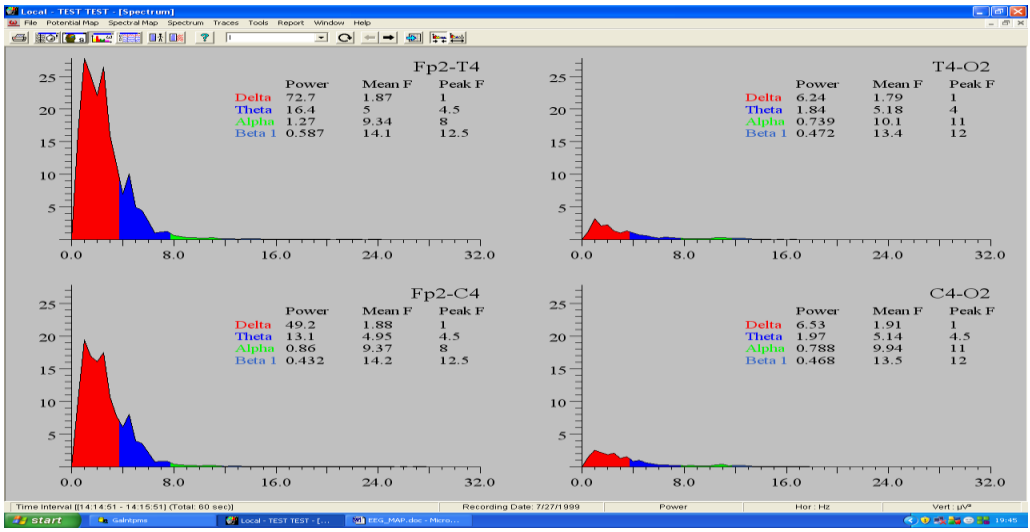

Fig. 2. Spectral analysis of EEG waves

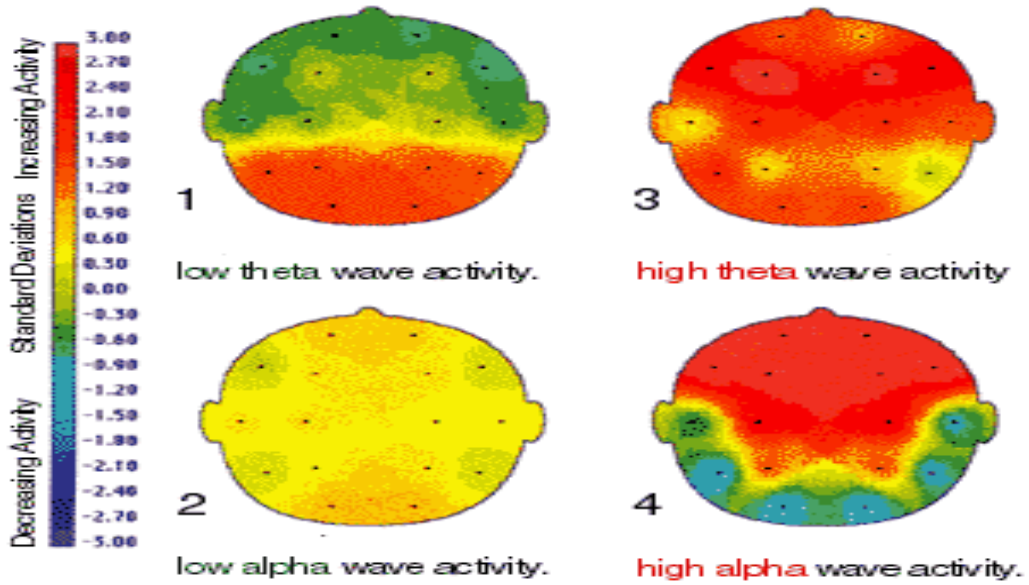

Fig. 3. EEG brain mapping

Fetal monitoring was performed by repeated clinical examinations, as well as by ultrasound assessment of fetal wellbeing, including placental maturity degree and Doppler velocimetry of umbilical /middle cerebral fetal artery- resistance index (U/C RI).

RESULTS

EEG brain mapping showed abnormalities in 14 patients compared to women in control group (fig. 4).

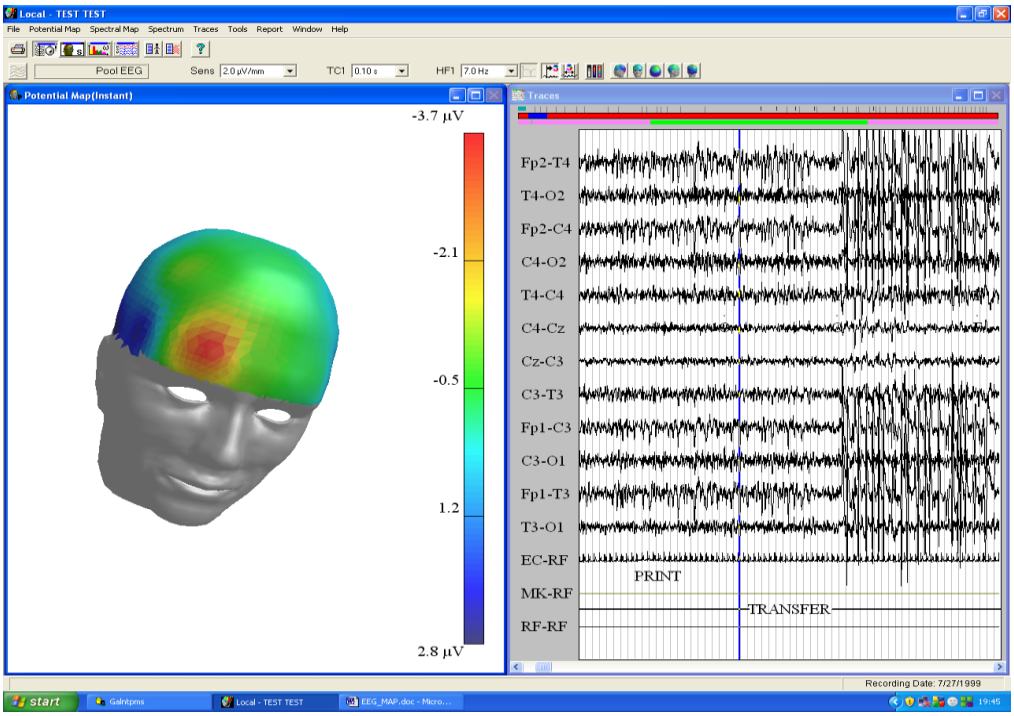

Fig. 4. Transposition of the brain electrical activity in brain mapping mode

The major EEG changes observed were focal (12 patients) or global (2 patients) slowing of the background activity-slowing of normal alpha (α) rhythms, and with the appearance of theta (θ) and continuous or non-continuous delta (δ) activities (fig. 5).

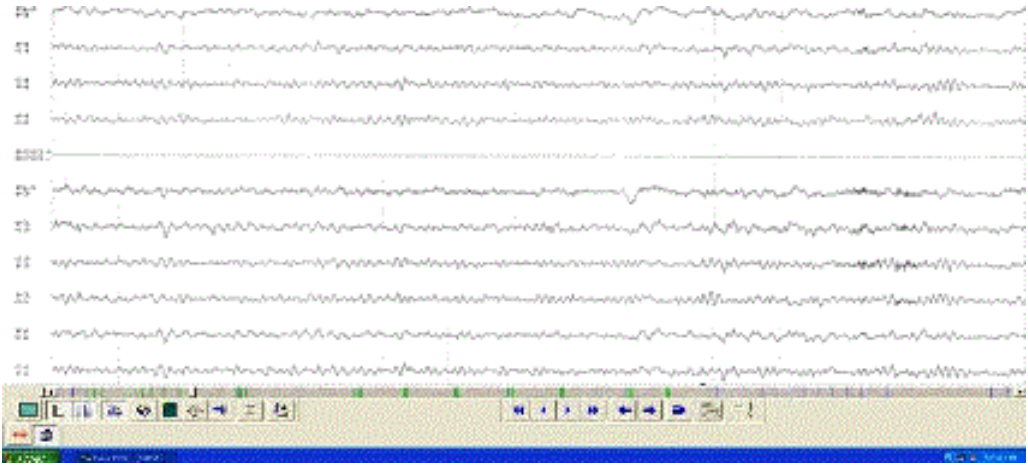

Fig. 5. Slowing of the background activity

Focal slow activity with paroxysmal or intermittent spike and sharp wave transients was also observed (5 patients) (fig. 6).

Topographic brain mapping showed these abnormalities in occipital lobes especially. Also 12 patients with EEG brain mapping changes have fetal ultrasound abnormalities: umbilical /middle cerebral fetal artery - resistance index (U/C RI) modified or abnormal placental maturity degree.

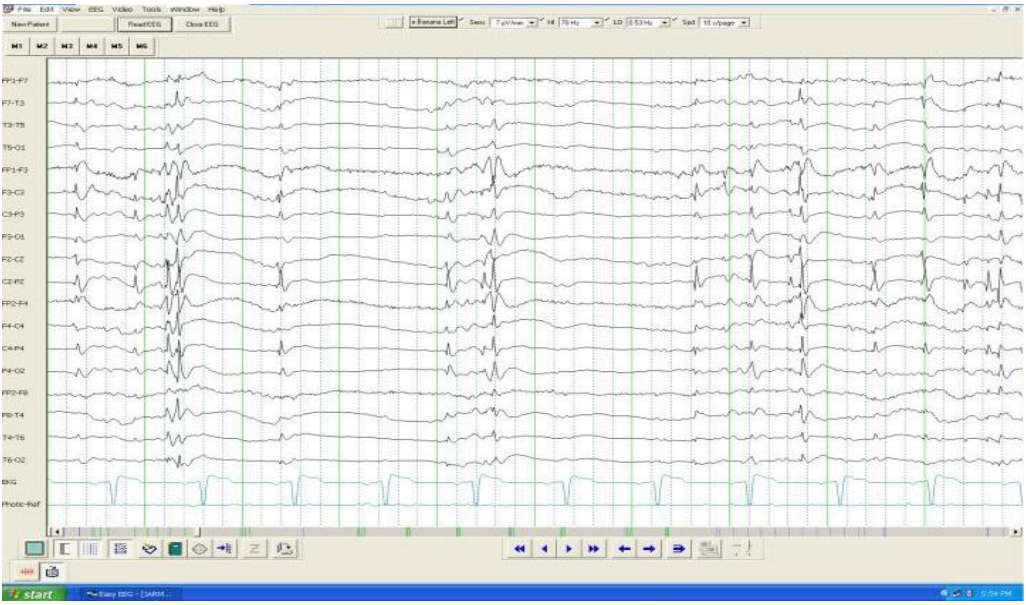

Fig. 6. Discontinuous electrical activity - high voltage electrical activity interspersed with areas of low voltage

DISCUSSION

In our study, abnormal EEG brain mapping findings were observed in the majority of the patients with hypertensive disorders, consisting of slow waves most frequently localized in the occipital lobe, as well as spike discharges. Our results are similar to the few studies on this topic so far, but little has been published on how these QEEG tests could affect the diagnosis or treatment of this patients. These changes are associated to hypertensive encephalopaty with thrombosis, fibrinoid necrosis of cerebral arterioles, diffuse microinfarcts and petechial haemorrhages (1, 2). Large changes in blood pressure (rather than the absolute blood pressure) or local metabolism can result in an imbalance of the capillary and cellular perfusion pressures, leading to vasogenic edema (1, 2, 3). Digital spike detection can identify candidate events that might develop seizures (eclampsia). Predominance of posterior lesions in our study may explain the increased incidence in preeclampsia-eclampsia of visual disturbances in the form of photophobia, diplopia, scotomata, amaurosis or blurred vision. Initially attributed to retinal arteriolar vasospasm or trombosis, these visual disturbances are now recognized to be associated with cerebral edema (1, 4, 5). When used by skilled

professionals experienced in quantitative EEG interpretation, sensitivity and specificity are high for detection of ischemia (6, 7). Ultrasound abnormalities observed at some of the patients with brain mapping changes-umbilical/cerebral flow patterns in combination with chronic placental dysfunction - are associated with fetal risk in preeclampsia. Further studies are required to determine the clinical implications of these abnormal findings in the absence of overt clinical symptoms, or possible correlations between blood pressure and aspects highlighted. A larger study is ongoing and is part of the PhD project, and the objectives are: 1) highlighting the role of EEG brain mapping in quantification of brain damage in hypertensive disease associated with pregnancy; 2) revealing statistical correlations between EEG abnormalities evidenced by mapping and pathological aspects during application maternal/fetal monitoring protocols, and if this changes can be a predictive factor for maternal-fetal risk.

CONCLUSIONS

Little has been published on how these QEEG tests could affect the diagnosis or treatment of individual patients. In summary, our findings indicate that EEG brain mapping are probably sensitive in detecting the extent of the pathology in the brain in women with in hypertensive disease associated with pregnancy, requiring more detailed studies on large groups of patients in order to obtain a clear conclusion.

PRENATAL CARE AND WEIGHT GAIN DURING PREGNANCY (Abstract): **Aim** To study the relationships between prepregancy body index mass (BMI), women's gestational weight gain and nutritional education during pregnancy. **Material and methods:** We carried a cross-sectional study on 400 women hospitalized in the maternity. Initial data included records on age, nutritional education during pregnancy and prepregnancy body mass index (BMI). The gestational weight gain was determined by using the weight registered in the obstetrics department before delivery . **Results:** In the group of overweight and obese women, 53.1% and respectively 66.7% registered a weight gain above the Institute of Medicine's recommendations, compared with 29.8% of normal weight women ($p<0.001$). Among the women with low prepregnancy BMI, 26.7% registered a weight gain below the guidelines ($p<0.001$). The nutritional education was associated with an appropriate weight gain in 44.3% women, compared with 40.7% who didn't receive any advice. The number of visits to the general practitioner and the obstetrician were associated with achieving recommended weight gain: 3.7% (no control), 38.3% (1-4 visits), 58% (more than 4 visits), and respectively 12.3% (no control), 24.7% (1 to 4 visits), 63% (more than 4 visits) ($p<0.001$). **Conclusion**s: The number of checks carried out during pregnancy plays an important role in achieving a weight gain within the guidelines. The individualized nutritional education has a positive impact on maintaining the recommended weight gain during pregnancy. **Key words**: PREPREGNANCY BMI, WEIGHT GAIN PREGANCY, PRENATAL CARE, NUTRITIONAL EDUCATION

Perioada perinatală este importantă din punct de vedere nutriţional, alimentaţia mamei înainte şi în timpul sarcinii afectând sănătatea produsului de concepţie la naştere şi pe tot parcursul vieţii (1). Creşterea ponderală în sarcină se evaluează după starea de nutriţie a gravidei, vârsta, paritatea, rasa, obiceiurile alimentare, comorbidităţile, numărul fetilor. Creşterea ponderală maternă în sarcină reprezintă unul din elementele esenţiale care influenţează greutatea nou născutului, durata sarcinii (2) şi riscul malformaţiilor congenitale (3). Metaanaliza efectuată de World Health Organization Collaborative Study (4) a relevat că indicele de masă corporală pregestaţional reprezintă un predictor al greutăţii la naştere a copilului. Baker (5) a demonstrat că întârzierea în creşterea intrauterină programează fătul spre mărirea riscului afecţiunilor cardiovasculare, a diabetului zaharat şi a sindromului metabolic.

Obezitatea maternă determină alterarea parametrilor neonatali, un scor Apgar scă-

zut, creşterea frecvenţei nou născuţilor cu greutate mare pentru vârsta gestaţională şi implicit a complicaţiilor asociate macrosomiei (distocia de umăr, traumatisme la naştere, creşterea mortalităţii perinatale). Pentru mamă, creşterea excesivă în greutate sporeşte riscul diabetului gestaţional, a hipertensiunii arteriale induse de sarcină, a bolii tromboembolice şi a infecţiilor urinare (6).

Studiile desfăşurate în România au evidenţiat o serie de deficienţe nutriţionale ale femeilor tinere, a gravidelor şi copiilor. Constatările au stat la baza elaborării unor intervenţii cuprinse în Programul Naţional de Sănătate a Femeii şi Copilului (7).

Scopul studiului a fost evaluarea indicatorilor antropometrici materni şi a efectului supravegherii prenatale şi educaţiei nutriţionale asupra creşterii ponderale în sarcină.

MATERIAL ŞI METODE

Studiul a inclus 400 de lehuze internate în septembrie 2010 în Spitalul Clinic de Obstetrică şi Ginecologie „Cuza-Vodă" Iaşi. Pentru obţinerea informaţiilor de la mame s-a utilizat un chestionar în care s-au consemnat date demografice, informaţii referitoare la utilizarea consultaţiei prenatale şi aspecte privind educaţia nutriţională în cursul sarcinii actuale.

Parametrii antropometrici materni evaluaţi au fost:

– indicele de masă corporală pregestaţional – determinat pe baza datelor consemnate de către medicul de familie în Carnetul de Sănătate al Gravidei sau prin utilizarea greutăţii autoraportate;

– înălţimea şi greutatea gravidei la sfârşitul sarcinii – determinate în maternitate înaintea naşterii;

– creşterea ponderală în cursul sarcinii – diferenţa între greutatea înregistrată la prima vizită la medicul de familie şi cea determinată înaintea naşterii în maternitate.

Pentru evaluarea stării de nutriţie înaintea sarcinii s-a utilizat clasificarea Organizaţiei Mondiale a Sănătăţii (8). În funcţie de indicele de masă corporală (IMC), femeile din lotul studiat au fost împărţite în: subponderale (IMC<18,5 kg/m^2), normoponderale (IMC 18,5-24,9 kg/m^2), supraponderale (IMC 25-29,9 kg/m^2) şi obeze (IMC>30 kg/m^2). Pentru evaluarea creşterii ponderale în relaţie cu IMC pregestaţional s-au utilizat recomandările din 2009 ale Institute of Medicine (IOM) din Washington (8) (tab. I).

TABELUL I

Creşterea ponderală recomandată în funcţie de IMC pregestaţional

IMC (Kg/m^2)	Creşterea ponderală recomandată (kg)
< 18,5	12,5- 18
18,5- 24,9	11,5 - 16
25- 29,9	7- 11,5
≥30	5 - 9

Analiza statistică s-a realizat cu ajutorul programului *SPSS 13.0*. Testul Shapiro-Wilk şi testul Kolmogorov-Smirnov s-au utilizat pentru evaluarea distribuţiei gaussiene a datelor analizate. Variabilele continue au fost exprimate ca medie, mediană, minim, maxim, deviaţie standard. Testul *Chi-Square* s-a folosit pentru evidenţierea existenţei unor diferenţe semnificative între eşantioanele formate din datele de frecvenţă.

REZULTATE

Vârsta medie a gravidelor în lotul studiat a fost de 27,53 ani, ponderea cea mai mare având-o cele cu vârsta între 19 şi 30 de ani (63,8%). Majoritatea gravidelor

(96%) au beneficiat de îngrijiri primare de sănătate, 81,4% dintre acestea prezentându-se la medicul de familie în cursul primului trimestru de sarcină, iar 83,5% au fost consultate în timpul sarcinii de medicul obstetrician. Numărul de controale la medicul de familie a variat între 0 şi 17, media fiind de 4,82, iar la medicul obstetrician a fost între 0 şi 12 vizite medicale, în medie 4,76 pe toată perioada sarcinii.

IMC pregestaţional a fost determinat la 389 persoane (97,3%), constatându-se o valoare medie de 22,31 kg/m^2, cuprinsă între 14,69 şi 44,98 kg/m^2. Creşterea ponderală în sarcină, măsurată la 95,5% dintre femeile din eşantionul studiat (382 gravide), a variat între 0 si 30 kg, având o valoare medie de 14,24 kg.

Femeile subponderale au avut o creştere a greutăţii în medie de 15,8 kg, cele normoponderale de 14,34 kg, pentru ca la cele supraponderale şi obeze să fie mai redusă (13,41 kg şi respectiv 13,11 kg), dar mai mare decât cea recomandată de IOM (tab. II).

TABELUL II

Creşterea ponderală în sarcină şi IMC pregestaţional

IMC (kg/m^2)	Creştere în greutate în sarcină						
	Nr.	%	Minim	Maxim	Media	Mediana	Deviaţia standard
< 18.5	45	11,8	4,0	27,0	15,289	15	4,9480
18.5 - 24.9	255	66,8	4.0	28,0	14,341	14	4,7742
25 - 29.9	64	16,8	5,0	30,0	13,414	12.	5.6122
≥30	18	4,7	0,0	25,0	13,111	14,5	7.5216

În grupul femeilor subponderale, 26,7% au avut o creştere în greutate sub cea recomandată, iar 51,1% în limitele indicate de IOM. Femeile normoponderale au avut o creştere adecvată a greutăţii în 42,7% din cazuri. În grupul femeilor obeze, numai 16,7% au avut o creştere ponderală optimă, iar 66,7% un câştig ponderal mai mare decât cel recomandat (Chi-Square Tests p< 0,001) (tab. III).

TABELUL III

IMC pregestaţional şi creşterea ponderală în funcţie de recomandările IOM

IMC pregestaţional	Creştere ponderală		
	sub recomandare %	normal – recomandare %	peste recomandare %
< 18,5	26,7	51,1	22,2
18,5 - 24,9	27,5	42,7	29,8
25 - 29,9	6,3	40,6	53,1
≥30	16,7	16,7	66,7

Numărul de controale la medicul de familie a fost în relație cu creşterea ponderală. Creştere optimă în greutate a fost mai frecventă la femeile cu mai mult de 4 controale (58%). Gravidele care au subutilizat consultația prenatală (56,2%) au avut mai frecvent o creştere ponderală mai mică decât cea indicată (Chi-Square Tests p=0,001) (tab. IV).

Dintre gravidele cu creştere ponderală optimă în sarcină, frecvența cea mai mare au avut-o gravidele cu mai mult de 4 controale de specialitate (63%), urmate de cele cu 1-4 vizite (24,7%) şi de cele care nu au beneficiat de consult obstetrical în sarcină (12,3%) (Chi-Square Tests p<0.001) (tab. V).

TABELUL IV

Creşterea ponderală în sarcină şi controlul la medicul de familie

		Creştere ponderală		
		sub recomandare %	**recomandată %**	**peste recomandare %**
Nr controale medic familie	fără control	3,4	3,7	1,5
	1-4 controale	56,2	38,3	29,5
	> 4 controale	40,4	58,0	68,9

TABELUL V

Creşterea ponderală în sarcină şi controlul la medicul obstetrician

Crestere ponderală	**Nr controale medic specialist**		
	fără control %	**1-4 Controale %**	**peste 4 controale %**
Sub recomandare	28,1	34,8	37,1
Normal recomandare	12,3	24,7	63,0
Peste recomandare	6,1	22,0	72,0

Gravidele care au beneficiat de educație nutrițională, au avut mai frecvent o creştere în greutate în limitele celei recomandate (44,3% față de 40,7%), fără ca asocierea întâlnită să fie semnificativă din punct de vedere statistic. Dintre femeile care au beneficiat de sfaturi legate de dietă în sarcină 69,2% au avut un număr mai mare de 4 controale, 29% au subutilizat consultația prenatală, iar 1,8% nu s-au prezentat la medicul de familie (p<0.001).

DISCUȚII

În cursul primului trimestru de sarcină, 81,4% dintre femeile din eşantionul studiat s-au prezentat la medicul de familie, în al II-lea trimestru 16,8%, iar în al treilea 1,8% din gravide. Aceste date arata o îmbunătățire a adresabilității în primul trimestru a gravidelor la medicul de familie față de studiile anterioare. În studiul desfăşurat de Institutul Ocrotirii Mamei şi Copilului "Statusul nutrițional al femeii gravide, al copiilor cu vârsta

sub 5 ani, al şcolarilor în vârstă de 6–7 ani" aproape 6% dintre femei nu au beneficiat de nici o consultaţie prenatală în cursul sarcinii, iar 68,8% s-au prezentat la prima consultaţie prenatală în cursul primului trimestru de sarcină. În „Studiului Sănătăţii Reproducerii" din 2004, 74% dintre femei au beneficiat de consultaţii prenatale în primul trimestru de sarcină (7).

Un număr mai mic de 4 consultaţii prenatale este considerat ca subutilizare, în condiţiile în care în România se recomandă minim 8 consultaţii pe durata sarcinii (7). În eşantionul nostru subutilizarea serviciilor prenatale a fost raportată de 44,3% dintre participante (3,8% fără control la medicul de familie, 40,5% cu 1-4 controale), evidenţiindu-se o deteriorare faţă de rezultatele din 2005 ale studiului „Statusul nutritional al femeii gravide", în care ponderea celor care au beneficiat de 1–4 consultaţii s-a ridicat la 33,3%, restul beneficiind de peste 4 consultaţii. În Studiul Sănătăţii Reproducerii din 2004 s-a constatat că numărul femeilor care au beneficiat de peste 4 consultaţii prenatale a crescut de la 59% în 1999 la 76% (7).

Studiile efectuate în SUA au arătat că 30-40% dintre gravide au o creştere ponderală în sarcină în afara limitelor recomandate de Institute of Medicine (9). Datele proiectului WISH (Women and Infants Starting Healthy) au arătat că 24,1% dintre femeile supraponderale şi obeze au avut o creştere ponderală mai mare decât cea recomandată, iar 51,2% dintre femeile subponderale au avut un câştig ponderal mai mic decât cel indicat. Apartenenţa la anumite grupuri etnice (hispanici), nivelul de educaţie, IMC-ul pregestaţional scăzut, lipsa sfaturilor nutriţionale au reprezentat predictori ai unei creşteri ponderale mai mici decât cea recomandată, iar supraponderea, multiparitatea şi vârsta tânără ai unei creşteri în greutate mai mari decât cea corespunzătoare IOM (10). Femeile supraponderale şi obeze din lotul studiat, au avut mai frecvent o creştere în greutate mai mare decât cea recomandată, în timp ce gravidele subponderale şi normoponderale au înregistrat mai des o creştere ponderală mai mică. Categoriile cu creştere ponderală în limitele recomandate de IOM pentru IMC cel mai frecvent întîlnite, îl reprezintă grupa femeilor normo şi subponderale (Chi- Square Tests $p< 0.001$).

Limitările studiului sunt reprezentate de:

- utilizarea greutăţii pregestaţionale autoraportate în cazul femeilor care nu au beneficiat de îngrijire prenatală constituie o sursă de eroare în cazul femeilor supraponderale, care tind să declare o greutate mai mică decât cea reală. Rezultatele studiului pot subestima relaţia dintre IMC pregestaţional şi creşterea ponderală în sarcină, dacă o parte din femeile supraponderale au fost încadrate ca normoponderale (11). OMS acceptă întrebuinţarea greutăţii pregestaţionale autoraportate în studiile epidemiologice pentru că reprezintă un indicator valoros în aprecierea creşterii ponderale şi un predictor al greutăţii nou născutului (12).;
- utilizarea informaţiilor de la gravide privind numărul de controale şi sfaturile privind dieta, determinată de lipsa documentelor medicale la toate femeile, ar putea conduce la o apreciere eronată a calităţii îngrijirilor prenatale.

CONCLUZII

Studiul a evidenţiat rolul major al IMC-ul pregestaţional asupra creşterii în greutate în sarcină, precum şi importanţa numărului de consultaţii prenatale în menţinerea unei creşteri ponderale în limitele celor reco-

mandate de ghiduri. În urma analizei efectuate, am constatat efectul pozitiv al educației nutriționale în menținerea unei creşteri în greutate în limitele indicate, dar eficiența acesteia este influențată de numărul de consultații prenatale. Femeile supraponderale şi obeze, precum şi cele subponderale, trebuie mai atent consiliate în ceea ce priveşte recomandările privind creşterea ponderală în sarcină.

BORDERLINE OVARIAN TUMORS AND GLOBAL RADIATION IN RELATION WITH CLIMATE CHANGE IMPACT **(Abstract)**: There is limited information on borderline ovarian tumor detected intra-surgically and its most favorable treatment in relation with global radiation and climate changes. **Aim:** To study the pre-surgery and intra-surgery differentiation criteria of borderline ovarian tumors from invasive carcinoma, and to make a very complex analysis of the frequency, distribution, and variation in time of global radiation, temperature, and precipitation in North-East Romania. **Material and method:** The 54 patients (age range 20-78 years, mean age 46 years) included in this study had borderline ovarian tumors surgically treated during the last 22 years (January 1988 - December 2009) at the 4th Gynecological Clinic at Iaşi, and representing 4.87% of the total 1107 ovarian tumors detected and treated during this interval. The histological types were: serous (18 cases), mucinous (27 cases), mixed (8 cases), and Brenner tumor (1 case). In order to analyze the impact of climate changes on borderline ovarian tumors a thorough study on the frequency of global radiation in relation with climate changes based on data recorded in the last 55 years was also carried out. **Results:** The distribution of these cases depending on when surgery was performed was analyzed. In our study the frequency of ovarian borderline tumors (4.87%) is lower than in similar reports in the literature being due, in our opinion, to the influence of global radiation in relation with climate changes. **Conclusions:** In our study global radiation is probably responsible for a progression to invasive carcinoma in 0.7% of the borderline ovarian tumors. **Key words:** BORDERLINE OVARIAN TUMOR, GLOBAL RADIATION, CLIMATE CHANGE

Tumorile maligne ale ovarului se găsesc pe poziția a IV-a ca frecvență a cancerului la femei, reprezentând 15% din totalitatea cancerelor feminine. Tumorile cu Potențial Malign Scăzut (TPMS) de ovar reprezintă o categorie ce numără doar între 10% şi 15%, maxim 20% dintre toate tumorile epiteliale de ovar şi sunt de multe ori diagnosticate în stadiu timpuriu. În acest caz, supraviețuirea mai mult de 5 ani este de 100% pentru pacientele diagnosticate în stadiul I şi variază între 92% şi 86% cu stadii avansate în momentul stabilirii diagnosticului (7).

Considerăm că TPMS pot fi uşor subevaluate sau supraevaluate pe latura leziunilor invazive sau non-invazive. În literatura de specialitate sunt date limitate referitor la aspectul de identificare intraoperator a tipului borderline al tumorii (2). La fel de limitată este şi baza de date despre trata-

mentul optim planificat pentru TPMS (8), cât şi referitor la impactul radiaţiei globale în evoluţia unei tumori ovariene borderline spre carcinom invaziv (9).

MATERIAL ŞI METODE

Am realizat un studiu retrospectiv pe un număr total de paciente de 1107, diagnosticate cu tumori ovariene în perioada 1 ianuarie 1988 – 31 decembrie 2009 la Spitalul Universitar "Cuza-Vodă", Clinica a –IV-a Iaşi. Studiul a fost realizat pe mai multe loturi, astfel:

- Lot A - 54 paciente diagnosticate cu tumori ovariene cu potenţial malign scăzut.
- Lot B - 575 paciente internate şi diagnosticate cu tumori ovariene benigne.
- Lot C - 478 paciente internate şi diagnosticate cu tumori ovariene maligne.

Am urmărit 5 direcţii de studiu: **1)** evidenţa din punct de vedere statistic pe loturi; **2)** asocierea tipului de tratament chirurgical aplicat cu păstrarea fertilităţii şi monitorizarea pacientei pe termen lung; **3)** urmărirea unei stadializări corecte cu scopul de a depista eventualitatea transformării unei tumori ovariene cu potenţial malign scăzut într-un carcinom invaziv; **4)** urmărirea evoluţiei post-operatorii a pacientelor pentru a depista prezenţa implantelor invazive peritoneale care reprezintă factorii majori de risc asociaţi cu recurenţa şi un prognostic mai scăzut de supravieţuire; **5)** cercetarea influenţei radiaţiei globale asupra tumorilor ovariene cu potenţial malign scăzut. Am constatat o evoluţie a TPMS spre carcinomul invaziv la un procent de 0,7% dintre paciente, ceea ce considerăm că ar avea o principală cauză în influenţa radiaţiei globale şi a impactului schimbărilor climatice asupra metabolismului pacientei.

Ca metode de lucru am folosit: Studiul foilor de observaţie, studiul registrelor de laborator, studiul imagistic în evaluarea preoperatorie şi metode statistice aplicate: a) testul $ђ^2$ cu abaterea Δ şi eroarea absolută şi relativă ε; b) testul t-Student; c) coeficient de corelaţie "Pearson"; d) testul ANOVA; e) curba de supravieţuire Kaplan-Mayer.

REZULTATE

Am considerat loturile de paciente luate în studiu focalizând pe lotul A ce conţine tumorile ovariene borderline şi am reprezentat distribuţia cazurilor pe cele 3 loturi în funcţie de caracteristicile tumorale (tab. I), cu prelucrarea statistică (fig.1, fig. 2).

Am identificat proprietăţile TPMS din lotul A şi pattern-ul intraoperator (tab. II, fig. 3) şi am realizat distribuţia pacientelor ca număr şi procent în funcţie de tipul procedurii chirurgicale (tab. III, fig. 4).

TABELUL I

Distribuţia cazurilor de tumori ovariene în funcţie de caracteristicile tumorale

Nr. Crt.	Distribuţia cazurilor pe loturi	Nr. Cazuri (n=1107)	Frecvenţa %	Caracteristici tumorale
1.	Lot A	54	4,87	TPMS
2.	Lot B	575	51,95	Benigne
3.	Lot C	478	43,18	Maligne

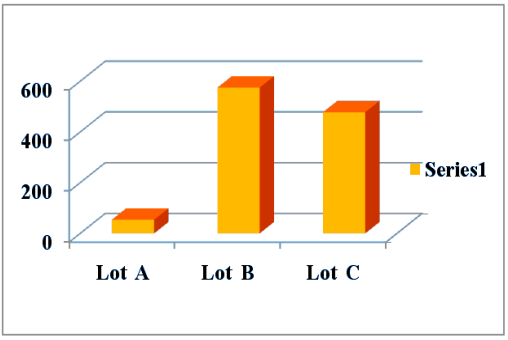

Fig. 1. Evaluarea cazurilor pe loturi A, B, C

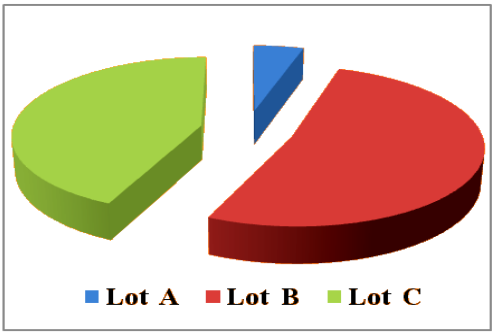

Fig. 2. Distribuția tumorilor pe loturi

TABELUL II

Distribuția TPMS după rezultatele obținute intraoperator în funcție de proprietăți şi tipuri la Clinica a-IV-a Iaşi în perioada 1988-2009.

Nr. crt.	Proprietățile şi tipurile de TPMS intraoperator	Nr. cazuri (n=54)	Frecvența %
1	Unilateral (ovarul drept)	15	27,57
2	Unilateral (ovarul stâng)	6	11,76
3	Bilateral în TPMS	33	61,12
4	Implante non-invazive	11	20,37
5	Implante invazive	6	11,76
6	TPMS mucinoasă	27	50,00
7	TPMS seroasă	18	33,33
8	Încărcare maximă tumorală în câmpul B1	42	82,35
9	Încărcare maximă tumorală în câmpul B1 şi B2	4	7,80
10	Încărcare maximă tumorală în câmpul B3	1	1,96
11	Încărcare maximă tumorală în câmpul A3	1	1,96

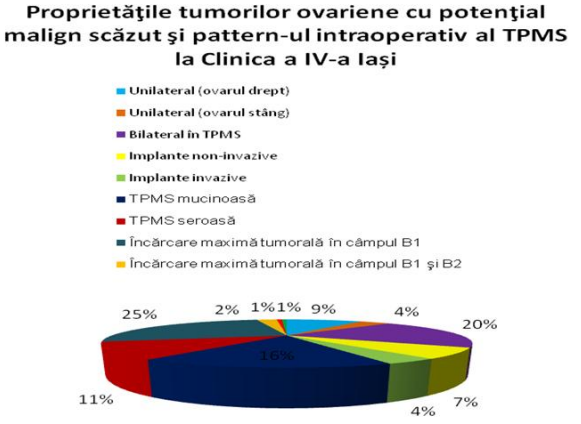

Fig. 3. Distribuția procentuală a cazurilor TPMS în funcție de proprietăți şi tipuri intraoperator.

TABELUL III

Distribuția statistică a cazurilor în funcție de tipul procedurii chirurgicale efectuate la Clinica a-IV-a Iaşi în perioada 1988-2009.

Nr. Crt.	Tipul procedurii chirurgicale efectuate	Nr. cazuri (n=54)	Frecvența %	Rezultate histo-patologic pozitive (nr. cazuri)	Rezultate histo-patologic pozitive %
1	Lavaj peritoneal	28	51.85	7	12.96
2	Omentectomie	19	35.18	9	16.66
3	Histerectomie	25	46.3	4	7.4
4	Apendicectomie	7	12.96	1	1.85
5	Rezecția nodulilor pelvici limfatici	2	3.7	4	7.4
6	Decolarea peritoneului în reducție tumorală prin impli-care macroscopică peritoneală	13	25.5	12	23.53
7	Decolarea peritoneului în reducție tumorală prin biopsie peritoneală pentru stadializare	33	64.7	--	--
8	Rezecția nodulilor para-aortici limfatici	2	3.7	0	0%
9	Mică rezecție intestinală	4	7.84	2	3.95
10	Rezecție de sigmoid/rect	4	7.84	4	7.84
11	Coagulare în infraroşu	7	13.72	--	--
12	Rezecție parțială de diafragmă	2	3.9	2	3.9

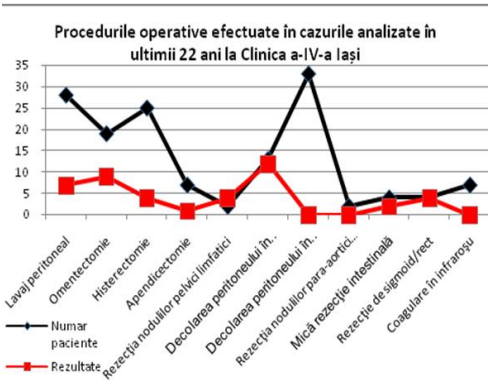

Fig. 4. Prelucrarea statistică a cazurilor de proceduri operatorii efectuate în perioada 1988-2009 la Clinica a-IV-a Iaşi.

Am realizat, de asemenea un studiu al frecvenței radiației globale şi al corelării valorilor radiației globale cu durata pentru a completa tabloul distribuției în timp şi spațiu a schimbărilor climatice în domeniul radiației globale în zona Iaşi (fig. 5).

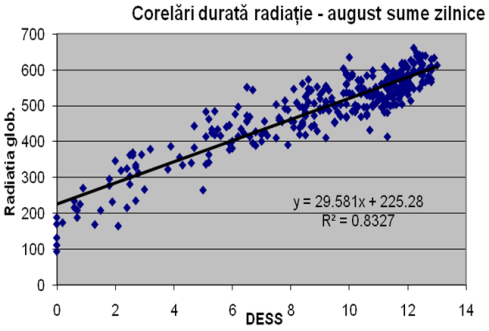

Fig. 5. Distribuția pe praguri de valori medii de radiații la Iaşi în perioada 1960-2009

Prezentăm din cazuistica personală cele mai reprezentative imagini ecografice de tumori borderline de ovar (fig. 6, 7, 8, 9) obținute prin ultrasonografie transabdominală (UTA) şi ultrasonografie transvaginală (UTV) considerată ca având o fiabilitate de 75%, iar sensibilitatea şi specificitatea 100 % (9).

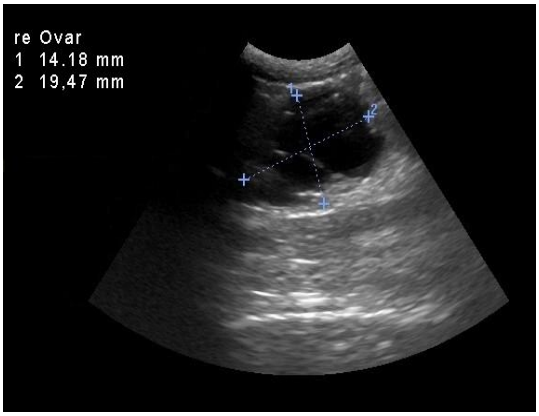

Fig. 6. UTA: ovar drept cu tumoră chistică(colecția personală)

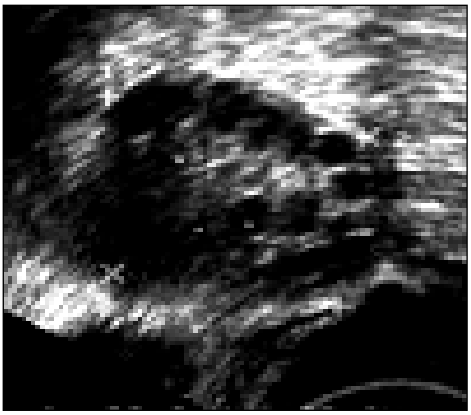

Fig. 7. UTV: ovar drept cu nuclee tumorale (colecția personală)

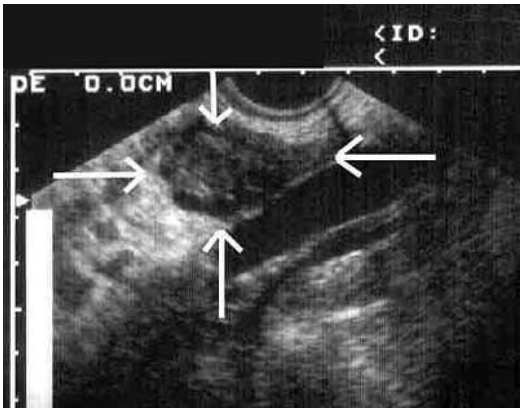

Fig. 8. UTA: ovar drept cu tumoră borderline (colecția personală)

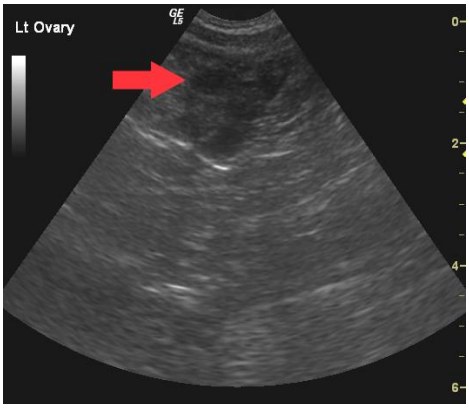

Fig. 9. UTA: ovar stâng tumoral (TPMS) (colecția personală)

În subpopulația cu TPMS recidivate, toate cele 5 paciente au prezentat implanturi epiteliale peritoneale pozitive. Analiza imuno-histologică a arătat că recurența a apărut din nou ca tumoare periferică la 2 paciente (23,53%), în timp ce la 3 paciente (60%) a apărut o conversie la tumoare infiltrantă. Metastazele extrapelvice au fost prezente la 12 paciente (23,53%).

Raportat la procentul de 0,7% calculat de noi pe baza rezultatelor studiului de cercetare, el se referă la pacientele cu tumori ovariene borderline care, din cauze necunoscute (8), trec în carcinom invaziv cu un prognostic rezervat, deşi au urmat aceeaşi schemă de tratament chirurgical şi adjuvant ca cele 99,3% paciente la care nu a apărut această evoluție a TPMS. Conside-

răm că acest procent de 0,7% poate fi explicat prin impactul radiației globale şi al schimbărilor climatice asupra unui număr mic de paciente care vor da procentul de 0,7%.

CONCLUZII

Din analiza distribuțiilor statistice ale radiației globale am constatat că acestea sunt liniare şi crescătoare pentru fiecare lună reprezentativă. Aceasta demonstrează că, în ultimii 50 ani, în perioada 1960-2009, valorile radiației globale au crescut constant şi mult, ceea ce demonstrează faptul că pot influența evoluția tumorilor în general, respectiv a tumorilor ovariene în special de la tumori borderline până la carcinoame invazive, ceea ce ar putea constitui o explicație pentru acel procent de 0,7% TPMS de ovar ce au o evoluție imprevizibilă spre carcinom invaziv.

Seriile lungi de timp cu valori numerice ale radiației globale sunt necesare ca suport pentru un studiu variat. Totuşi, algoritmul considerării datelor observaționale limitează scalele rangului determinărilor ce pot fi raportate ca fiind cu acuratețe, adică fără erori.

Impactul schimbărilor climatice şi al radiației globale asupra numărului de paciente cu TPMS se manifestă prin acel procent de 4,87% TPMS a căror evoluție postoperatorie este imprecis precizată ştiințific. Dintre ele, un procent de 0,7% TPMS vor evolua spre carcinomul invaziv, una dintre cauze fiind radiația globală şi schimbările climatice.

Considerăm că există o legătură importantă între evoluția tumorilor ovariene borderline şi radiația globală ca şi între TPMS de ovar şi impactul schimbărilor climatice asupra pacientelor, ceea ce ar putea explica evoluția într-un procent de 0,7% a TPMS spre carcinomul invaziv, dar ar putea conduce şi spre o mai bună înțelegere a unor feedback-uri între procesele atmosferice legate de cele terestre la o scală spațială şi temporală diferită şi tumorile ovariene borderline, impactul schimbărilor climatice neputând fiind neglijat.

NOUTĂȚI

CIMENTAREA LUCRĂRILOR PROTETICE PE BAZĂ DE ZIRCONIU: DIFICULTĂȚI ŞI SOLUȚII

Ceramicile fără siliciu, în special zirconiul au devenit un subiect de mare interes în protetica şi implantologia dentară datorită combinației inedite dintre calitățile estetice şi mecanice. Totuşi, acest tip de materiale prezintă o problemă deocamdată nerezolvată legată de dificultatea realizării unei adeziuni adecvate atât cu materialul sintetic asociat cât şi cu țesuturile dentare. Tehnicile tradiționale adezive utilizate cu ceramicile pe bază de siliciu nu funcționează la fel de eficient cu zirconiul. Recent au fost propuse noi tehnologii pentru soluționarea acestei probleme care urmăresc fie modificarea suprafeței ceramicilor, fie funcționalizarea chimică a suprafeței de zirconiu pentru a o face mai reactivă şi aptă pentru adeziune. Cimenturile care par să prezinte adeziune satisfăcătoare sunt materiale pe bază de rășini care care conțin monomeri fosfatați (Panavia Ex - Kuraray Medical Inc; RelyX Unicem - 3M ESPE), sau cele care conțin 4META/TBB/PMMA (Sun Medical, Moriyama City) care pare să se lege de zirconiu prin gruparea anhidridă din 4-META. În cazul cimenturilor care conțin monomeri fosfatați, adeziunea poate fi ameliorată prin adăugarea unor agenți de cuplare silanici. Mecanismul ce stă la baza acestui efect este legat de natura acidă a acestor monomeri care hidrolizează rapid agenții de cuplare, producând legăturile polisiloxanice necesare pentru adeziune. Deocamdată, cimenturile care conțin monomeri fosfatați par să reprezinte soluția preferată de practicieni pentru fixarea lucrărilor protetice din zirconiu datorită ratei de eşec reduse prin pierderea retenției (Thompson JY, Stoner BR, Piascik JR, Smith R. Adhesion/cementation to zirconia and other non-silicate ceramics: Where are we now? *Dental Materials* 2011; 27(1): 71-82).

REZECȚIA ANTERIOARĂ JOASĂ DE RECT CU EXCIZIE TOTALĂ DE MEZORECT. REZULTATE IMEDIATE

I. Radu, Gabriela Anitei, V. Scripcariu, Cr. Dragomir
Universitatea de Medicină şi Farmacie „Gr. T. Popa" Iaşi
Facultatea de Medicină
Clinica a III-a Chirurgie

LOW ANTERIOR RESECTION OF THE RECTUM WITH TOTAL MESORECTAL EXCISION – IMMEDIATE RESULTS (Abstract): **Aim:** this study was aimed at analyzing the immediate postoperative course in rectal cancer patients who underwent a low anterior resection of the rectum with total mesorectal excision. **Material and methods:** A retrospective study was carried out on a series of 75 patients operated between January, 1 2004 and December, 31 2010 at the IIIrd Surgical Unit of the Iasi "St. Spiridon" Hospital,. Low anterior resection of the rectum with total mesorectal excision was performed in all the patients. Data from medical files regarding the immediate postoperative course were analyzed. **Results:** Neoadjuvant therapy was instituted in 32 patients. There were 28 mechanical colorectal anastomoses and 47 manual anastomoses. Protective ileostomy was performed in 46 cases, including 11 manual anastomosis and 35 mechanical anastomosis cases. Anastomotic fistulas occured in 11 patients (6 with manual suture and 5 with stapler). Wound complications were identified in 5 cases, while retraction of ileostomy in 2. Two patients died from anastomotic fistula causing abdominal sepsis and multiple organ failure. In both cases ileostomy was performed at the reintervention, concomitantly with drainage of the abdominal abscesses. **Conclusions:** Healing of the colorectal anastomosis remains the major problem with low anterior resection of the rectum. Protective ileostomy reduces the risk of serious complications in the event of anastomotic fistula. **Key words:** RECTAL CANCER, TOTAL MESORECTAL EXCISION, IMMEDIATE POSTOPERATIVE RESULTS

În urmă cu 30 de ani, recurența locală după intervențiile chirurgicale pentru neoplasmul rectal varia între 20-45%. Tratamentul chirurgical în cancerul rectal are un rol primordial în vindecarea pacienților care suferă de această boală. Un studiu multicentric german publicat în 1994 arăta că rata recurenței locale variază în funcție de chirurg, de la 10 la 50%, astfel, pacienții chirurgilor cu rata de recurență de 10% au o şansă de vindecare de 80% pe când pacienții chirurgilor cu rata recurenței de 50% au şanse de vindecare doar de 40%. În acelaşi studiu s-a demonstrat că terapia adjuvantă (radio şi chimioterapia) îmbunătățeşte rezultatele, în cele mai optimiste situații, cu 20% pe când o tehnică chirurgicală corectă poate îmbunătăți rezultatele cu până la 80% (1).

În 1982, R. J. Heald publica articolul „The mesorectum in rectal cancer - the clue to pelvic recurrence?" prin care ridica problema exciziei complete a mezorectului pentru cancerele rectale. Heald susține că,

inițial, mezorectul conferă protecție contra diseminării tumorale iar extirparea sa în bloc cu rectul minimalizează riscul recidivei tumorale (2).

Infiltrația tumorală în peretele rectului este la majoritatea pacienților cu cancere diferențiate de până la un cm (3) pe când infiltrația limfatică distală în mezorect se poate detecta până la 5 cm de tumoră (2). Din acest motiv şi importanța exciziei distale a mezorectului, în cazul cancerelor rectale ampulare inferioare şi mijlocii fiind necesară excizie totală de mezorect. Recidivele la nivelul anastomozelor, sunt de fapt, recurențe în afara lumenului care invadează ulterior anastomoza.

Un alt element important în obținerea unor rezultate favorabile este reprezentat de marginile circumferențiale de rezecție. Dacă secționarea rectului se face, în marea majoritate a cazurilor în țesut neinfiltrat neoplazic, marginile circumferențiale de rezecție fără infiltrație tumorală se realizează printr-o disecție atentă îngreunată uneori de stadiul avansat al bolii neoplazice. Pentru un rezultat favorabil, marginea de rezecție trebuie să fie la peste 1mm față de frontul de invazie tumoral, fie că este vorba de adenopatie neoplazică, depozite tumorale din mezorect sau trombi tumorali intravasculari.

Rata recidivei locale este şi mai mult scăzută prin tratamentele neoadjuvante: radioterapie respectiv radiochimioterapie (4). Beneficiile potențiale ale terapiei neoadjuvante sunt reprezentate de diminuarea dimensiunilor tumorale şi sterilizarea metastazelor ganglionare din aria iradiată (down-sized, down-staged) (3).

MATERIAL ŞI METODĂ

În perioada 1 ianuarie 2004 – 31 decembrie 2010 au fost operați 566 pacienți cu neoplasm rectal şi joncțiune rectosigmoidiană. În perioada menționată au fost efectuate 75 rezecții anterioare de rect cu excizie totală de mezorect. Repartiția pe sexe a fost astfel: 45 bărbați şi 30 femei (fig. 1).

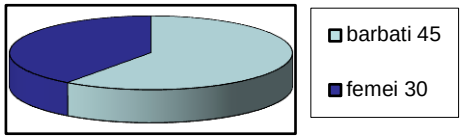

Fig.1.Repartiția pe sexe

Din cele 75 cazuri, în anul 2004 au fost 3 cazuri, în 2005 – 11 cazuri, în 2006 şi 2007 au fost câte 9 cazuri, în 2008 au fost înregistrate 15 cazuri, în 2009, 18 cazuri iar în 2010 au fost efectuate 10 rezecții anterioare joase de rect cu excizie totală de mezorect (fig.3).

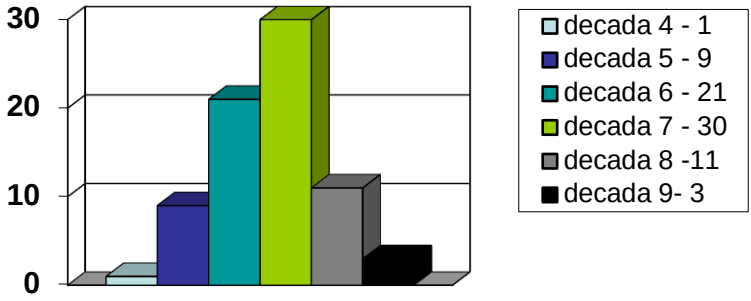

Fig. 2 Vârsta pacienților a fost situată între 39 şi 83 ani, cu o vârstă medie de 64 ani.

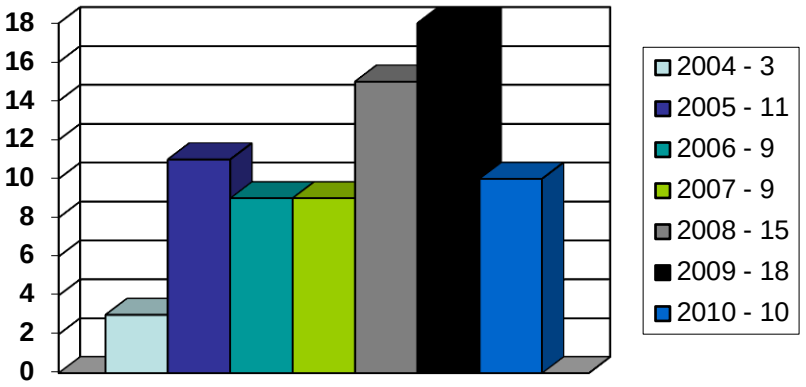

Fig. 3. Repartiția pe ani

Din punct de vedere al localizării, tumorile au fost împărțite astfel:

- neoplasm rectal superior şi joncțiune rectosigmoidiană – 27 cazuri
- neoplasm rectal ampular mijlociu – 42 cazuri (în două situații au fost identificate neoplazii sincrone de sigmoid şi de cec)
- neoplasm rectal ampular inferior – 6 cazuri

Distanța tumorii rectale față de marginea anală s-a situat între 4 şi 15 cm .

Pentru o stadializare corectă a cazurilor, pe lângă tehnicile imagistice uzuale (ecografie abdominală, radiografie toracică), 39 pacienți au beneficiat de explorare RMN, CT şi/sau ecografie endorectală:

- RMN -17
- CT - 13
- Ecografie endorectală - 13
- RMN + CT - 2

Terapia neoadjuvantă a fost aplicată la 32 cazuri, 19 pacienți beneficiind de radioterapie şi 13 de radiochimioterapie. La pacienții care au beneficiat de terapie neoadjuvantă intervenția chirurgicală a fost efectuată la aprox. 6 săptămâni de la terminarea radioterapiei/radiochimioterapiei. Doi pacienți prezentau o colostomie laterală înaintea rezecției rectale, colostomiile fiind efectuate în urgență pentru leziuni rectale stenozante.

Având în vedere vârsta de apariție a neoplasmului rectal, pacienții au o patologie asociată destul de bogată. Afecțiunile asociate întâlnite au fost:

- insuficiență cardiacă Clasa II NYHA 3 cazuri, clasa a III-a NYHA un caz
- fibrilație atrială cronică 6 cazuri
- angină pectorală de efort un caz
- hipertensiune arterială 12 cazuri
- prolaps de valvă mitrală un caz
- cardiopatie ischemică cronică 4 cazuri
- tulburări de conducere cardiacă: bloc major de ramură 2 cazuri
- hepatopatie cronică 7 cazuri (3 virus C, 2 virus B, 2 toxică)
- ciroză hepatică toxică un caz
- litiază biliară 4 cazuri (un caz cu litiază coledociană)
- astm bronşic un caz
- tuberculoză fibronodulară 3 cazuri
- bronşită cronică 2 cazuri
- emfizem pulmonar 8 cazuri

- litiază renală 9 cazuri
- diabet zaharat tip 2 , 3 cazuri
- accident ischemic vascular sechelar un caz
- boală Parkinson un caz
- fibrom uterin 2 cazuri
- ulcer duodenal cronic 3 cazuri
- infecție tract urinar 5 cazuri
- dislipidemie 3 cazuri
- hernie inghinală bilaterală 1 caz
- polip vezică urinară 1 caz
- adenom de prostată 8 cazuri
- lobectomie pulmonară pentru bronşiectazie un caz
- anemie secundară 34 cazuri

La momentul intervenției, 5 pacienți prezentau metastaze hepatice.

REZULTATE

Din cele 75 rezecții anterioare de rect cu excizie totală de mezorect, 28 au fost cu anastomoză colorectală mecanică, celelalte anastomoze 47 fiind efectuate manual, cu fire separate. Ileostomia de protecție a fost efectuată în 46 cazuri (11 ileostomii în grupul anastomozelor mecanice şi 35 în grupul pacienților cu anastomoză manuală). Ca şi incident intraoperator, a fost necesară o sutură de arteră iliacă primitivă ca urmare a unei plăgi accidentale. Datorită stricturilor uretrale, unui pacient nu i s-a putut introduce sonda urinară pe cale uretrală, inserându-se un cateter suprapubian.

Intervențiile chirurgicale asociate rezecției rectale au fost:

- hemicolectomie dreaptă un caz
- apendicectomie 2 cazuri
- rezecție cec şi ultimă ansă ileală un caz
- metastazectomie hepatică 1 caz
- histerectomie totală cu anexectomie bilaterală
- 2 cazuri – fibrom uterin
- un caz – invazie uterină
- cistectomie parțială 2 cazuri
- anexectomie bilaterală un caz
- colecistectomie, coledocolitotomie, anastomoză biliodigestivă un caz
- cura herniei inghinale un caz

Durata medie a intervenției chirurgicale a fost 162 minute. Rezecțiile cu anastomoză mecanică au avut o durată medie mai mică (145 minute față de aprox 168 minute) prin faptul că durata de efectuare a anastomozei mecanice este mai redusă, numărul ileostomiilor a fost mai mic, cât şi prin intervențiile asociate care au fost mai numeroase în grupul rezecțiilor în care anastomozele au fost efectuate manual.

Stadializarea anatomopatologică a pieselor de rezecție a adus următoarele informații:

- T0 - 1 obs N0 31 obs
- T1 - 4 obs N1 17 obs
- T2 - 15 obs N2 14 obs
- T3 - 38 obs Nx 13 obs
- T4 - 7 obs

La un pacient cu radioterapie neodajuvantă, a fost înregistrată o remisiune completă cu dispariția tumorii. Ceilalți pacienți au fost împărțiți, în funcție de clasificarea Dukes, astfel:

- Dukes A – 3 obs.
- Dukes B – 28 obs.
- Dukes C – 38 obs.
- Dukes D – 5 obs.

Numărul de ganglioni examinați a fost între 2 si 42 cu un număr mediu de 15,1. Pentru a formula un stadiu N la examenul anatomopatologic, trebuiesc examinați minim 12 ganglioni.

La 12 pacienți au fost descoperiți pe piesele de rezecție polipi adenomatoşi/ adenoviloşi.

Doar la 31 pacienți au fost descrise marginile de rezecție, la cei descrişi distanța fiind de peste 1 cm la un pacient, peste 1,4 cm la 2 pacienți şi peste 1,5 cm la 2 pacienți. La restul a fost specificat că marginea circumferențială de rezecție este „la distanță" de frontul de invazie tumorală.

Durata de spitalizare (postoperatorie) a variat între 7 şi 44 zile, durata medie fiind de 13,64 zile.

În perioada imediată după rezecție (până la externarea pacienților) au fost înregistrate 11 fistule anastomotice evidente clinic – 14,67% (6 fistule în rândul pacienților cu anastomoze efectuate manual iar 5 la cei cu anastomoză mecanică). Au fost întâlnite şi complicații ale plăgii postoperatorii – 5 obs. - 2 supurații, 2 seroame ale plăgii şi o infecție necrozantă a plăgii postoperatorii.

Ileusul postoperator prelungit (necesitatea menținerii sondei nasogastrice peste 5 zile postoperator) a fost întâlnit la 5 pacienți. Disfuncțiile urinare au fost prezente la 7 pacienți, dintre aceştia un singur pacient a fost externat cu sonda urinară revenind ulterior pentru suprimarea sondei vezicale.

La 11 pacienți s-a reintervenit, ziua şi motivul reintervenției fiind:

- ziua a 2-a remodelarea ileostomiei
- ziua a 3-a drenajul fistulei anastomotice şi ileostomie
- ziua a 4-a suspiciune necroză de colon, s-a identificat o infecție necrozantă de perete abdominal + ziua a 17- a sutură secundară
- ziua a 7-a ileostomie pentru fistulă rectovaginală
- ziua a 7-a remodelarea ileostomiei
- ziua a 9-a refacere ileostomă
- ziua a 10-a devolvularea unei anse de intestin subțire
- ziua a 10-a colostomie pentru o fistulă rectovaginală + ziua a 15 a drenajul perineal al unui hematom presacrat infectat
- ziua a 11-a colostomie laterală pe colon transvers pentru fistulă anastomotică
- ziua a 13-a ocluzie mecanoinflamatorie
- ziua a 14-a ileostomie pentru fistulă anastomotică + ziua a 31-a drenajul perineal al unei colecții presacrate

Alte complicații, fără legătură directă cu intervenția chirurgicală, întâlnite în lotul de studiu au fost:

- infecții urinare 3 cazuri
- pleurezie 2 cazuri
- ureterohidronefroză secundară litiazei ureterale un caz
- pneumonie bacteriană un caz

Au fost înregistrate 2 decese, ambii pacienți au fost de sex masculin, fără terapie neoadjuvantă. Un pacient de 69 ani care a dezvoltat o fistulă anastomotică în ziua a 7a, s-a reintervenit chirurgical în ziua a 14 a şi s-a practicat ileostomie de protecție şi drenajul unei colecții presacrate în ziua 31 postoperator, pacientul decedând prin Insuficiență Organică Multiplă. Al doilea deces a survenit la un pacient cu fistulă anastomotică precoce la care s-a reintervenit în ziua a 3 a practicându-se dirijarea fistulei anastomotice şi ileostomie de protecție. Decedează tot prin Insuficiență Multiplă de Organ în ziua a 24 a postoperator.

DISCUȚII

Excizia totală a mezorectului în chirurgia cancerului rectal are ca scop principal scăderea incidenței recidivei locale postoperatorii. Acest articol are drept scop prezentarea complicațiilor din perioada imediat postoperatorie, recidivele locale şi tulburările funcționale vor face subiectul unui

alt articol.

Marea provocare a acestei intervenții rămâne anastomoza colorectală. Bontul rectal de aproximativ 2-4 cm deasupra marginii anale are o vascularizație precară, ceea ce face ca cicatrizarea la nivelul anastomozei să fie grevată de riscul de apariție al unei fistule. Spațiul liber rămas după extirparea rectului în bloc cu mezorectul favorizează apariția hematoamelor care se pot evacua, la nivelul anastomozei, în tractul digestiv – fiind un factor în plus pentru apariția unei fistule.

Rata fistulelor anastomotice după rezecția rectului cu excizie totală de mezorect variază în literatură. Heald, în articolul inițial, prezenta o rată a fistulelor anastomotice de 13%, frecvența crescând până la 18% dacă anastomozele sunt verificate radiologic (2).

CONCLUZII

Din aceste motive, se recomandă efectuarea unei colostomii sau a unei ileostomii pentru a lăsa anastomoza să se cicatrizeze în absența tranzitului intestinal.

Ileostomia poartă şi ea riscul unor complicații (retracții, stenoze) dar riscurile sunt reduse iar rezolvarea acestor complicații nu presupune gesturi chirurgicale de amploare.

În lotul studiat, au fost înregistrate 11 fistule anastomotice (14,67%), procent comparabil cu datele existente în literatură.

Evoluția nefavorabilă a survenit la doi pacienți cu fistulă anastomotică dar fără o ileostomie sau colostomie de protecție ceea ce arată necesitatea efectuării de rutină a ileostomiei / colostomiei.

ACUTE GASTROENTERITIS IN CHILDREN. CURRENT EPIDEMIOLOGICAL AND ETIOLOGICAL CONSIDERATIONS (Abstract): Acute diarrheal disease ranks second among the causes of specific morbidity (after respiratory infections) with higher incidence values in economically undeveloped or developing countries (3 to 7 episodes of diarrhea / year / child compared to only 1-2 episodes / year / child in highly industrialized countries). Infection with *Campylobacter* globally was the most frequently reported zooanthroponosis, with 214,268 confirmed human cases in 2012. Almost any pathogen involved in the etiology of acute diarrheal disease may be involved in the occurrence of healthcare-associated infections; among these, the rotavirus and *Clostridium difficile* are most prevalent. General hygiene measures change the epidemiological aspect of acute diarrheal disease by modifying the factors which favor the transmission of pathogens. **Keywords**: ACUTE DIARRHEAL DISEASE, EPIDEMIOLOGY, HEALTHCARE-ASSOCIATED INFECTION.

Acute gastroenteritis (including acute diarrhea, acute diarrheal disease) is commonly the second cause of death worldwide (after cardiovascular diseases) and the second cause of specific morbidity (after respiratory infections) (1, 2, 3). The social and economic impact is difficult to estimate, considered to be very high: only in the United States and only for rotavirus infections the medical and social costs are over a thousand billion dollars yearly (4, 5, 6).

There are major differences between the manifestation forms of the epidemiological process in developed countries as compared to developing countries. There are also differences in terms of etiology, type of clinical forms and evolution of the disease, prognosis, therapeutics and age groups: child *versus* adult. Despite the progress made in understanding the pathogenic mechanisms and the management therapy, the acute gastroenteritis / acute diarrheal disease (AGE / ADD) remains one of the most important causes of infant morbidity and mortality.

In the early 1980s, it was estimated that the world's "biggest child killer" was diarrheal diseases, which were responsible for 4-6 million deaths every year. The latest studies show that, currently, diarrheal diseases are responsible for the death of 2 to 5 million children, mostly in poorly industrialized countries or developing countries. The annual number of diarrheal episodes

occurring in children under the age of 5 is approximated to 1 billion. It is worrying (but not unexpected) that morbidity is still in excess in developing or underdeveloped countries, with 3 to 7 episodes of diarrhea / year / child as compared to only 1-2 episodes / year / child in highly developed countries (7).

In the USA, the studies with wide coverage of the general population showed the presence of 1.05 episodes of acute diarrhea / person / year; considering that gastrointestinal signs are due to respiratory diseases for one in four people, the final figure was lower: 0.79 episodes / person / year. For the United States, the estimates indicated approximately 211 million cases of AGE / ADD for the entire population and 210,000 / year for the hospitalized pediatric population, resulting in approximately 10,000 deaths (3). From a financial point of view, these hospitalizations represent 4% of the total cost of all admissions of any cause. Acute gastroenteritis of viral etiology has a large clinical impact on children younger than 5 years old. In the United States, more than 500,000 consultations / year are reported, with about 55,000 hospitalizations and over 500 deaths / year for AGE / ADD of viral etiology.

In Australia, 15,000-20,000 children under the age of 5 years are hospitalized annually for severe acute gastroenteritis (8).

A case-control study carried out in the Netherlands, based on a "sentinel"- type surveillance system, estimated the impact of this disease on the general / family medicine network: 128,000 people call for annual family doctor consultations for acute gastroenteritis; basically 79.9 in 100,000 people have an episode of AGE / ADD / year; *Campylobacter* is by far the most frequently involved etiological agent (10%), followed by *Giardia lamblia* (5%), Rotavirus (5%), Norwalk-like virus (5%), and *Salmonella* (4%). The data varies widely depending on the territory under analysis (AGE / ADD has a lower incidence in the North) and on the degree of urbanization (a greater incidence in rural areas) (9, 10, 11).

Questions arise regarding the true extend of the spread of infections with *Campylobacter* spp. other than *C. jejuni / C. coli*, requiring more efficient diagnostic methods.

In the Czech Republic, *Salmonella* and *Campylobacter* infections are reported as early as 1951 and 1984, respectively. In 2003, they represented 92% of the etiologic spectrum of acute gastroenteritis (52% - infection with *Salmonella*, most often *Salmonella* Enteritidis and nearly 40% infections with *Campylobacter*); the most affected age group was 0-4 years. The incidence of infections with *Salmonella* in the Czech Republic recorded a steady rise until 1995, followed by a sharp decline since 1998; infections with *Campylobacter* showed an upward trend starting with 1984, with a peak in 2002 and a current slow decline (12).

A communication signed by some authors in Poland (13) states that, among the cases hospitalized in Warsaw, without generalizing to the whole territory, non-typhoid infections with *Salmonella* are common among children aged 0-5 years: 90% of the samples were positive for *Salmonella* Enteritidis. The same authors remarked the emergence of antibiotic-resistant *Salmonella*. The incidence of the antibiotic resistance of these pathogens ranged from 60% in Taiwan to 4% in Greece and 2% in Italy (14, 15).

In Norway, the incidence of AGE / ADD had a value that is like those found by FoodNet in the United States: 1.2 episodes of acute diarrhea / person / year. The risk factor often met among children less than 15 years old was water consumption from private sources; in contrast, chlorinat-

ed water consumption was not associated with AGE / ADD (16).

Ireland (Food Safety Authority of Ireland, Dublin) (17) reports 0.6 episodes of acute diarrhea / person / year; however, only 29.2% cases of the total number of reported cases presented themselves to the family physician / general practitioner and fecal samples were collected for investigation in only 2%. The authors considered that new ways of promoting prevention measures need to be found given the increased spread of AGE / ADD in the population.

A case-control study conducted in Denmark over a period of two years, with 0-5 years old children as the target population, presents in detail data regarding the etiology of AGE / ADD. In 26% of cases, the viral etiology was determined; in 17%, the etiology was bacterial; in 4%, the etiology was parasitic. The most frequent pathogen was rotavirus, followed by *Salmonella*, *Norovirus*, *Campylobacter*, and *Adenovirus*. Rarely, *Giardia lamblia*, *Blastocystis hominis*, *Cryptosporidium*, *Ascaris spp*. were found. Agents such as *Yersinia enterocolitica* (3% of samples), *Shigella*, *E. coli* are highly prevalent in Denmark (18).

Salmonellosis. In 2003, Germany reports an epidemic outbreak of *Salmonella enterica* serotype Agona infection among children with the average age of 13 months. 42 cases were diagnosed; after an epidemiological investigation, the route of transmission was identified: contaminated anise tea imported from Turkey. Rarely isolated, *Salmonella* Agona is involved in human pathology especially in relation to the consumption of powdered milk, snacks and industrially processed cereals. In similar situations, other serotypes were also involved in various food categories (in 2001-2002 there was an outbreak of epidemic scale, impacting several European countries; *Salmonella* Oranienburg was involved, which was isolated from samples of chocolate produced in Germany) (19, 20).

A study conducted in France in 2003 focused on estimating the number of cases hospitalized for AGE / ADD in children less than 5 years old and the costs associated with their hospitalization. The results showed that 51,125 children were hospitalized with this diagnosis; 56% of cases were "probably infectious", 36% had viral etiology (of these, 43% were coded as "rotavirus") and 8% had bacterial etiology (60% of which were coded as "*Salmonella*"). Complications (particularly acute dehydration) followed "viral" gastroenteritis in 21% of cases and "bacterial" gastroenteritis in 17% of cases, followed by 14 deaths. The mean length of stay was 3.2 days and the costs were estimated to reach 62 million EUR (21).

The report of the European Food Safety Authority (EFSA, Parma, Italy) and of the European Centre for Prevention and Control (ECDC, Stockholm, Sweden) published on July 17th, 2014 based on the information presented by 27 EU member states shows that the number of diseases caused by *Salmonella* continued to decrease in 2012. Thus, a total of 92,916 cases diagnosed with salmonellosis were reported by the 27 EU member states, with 91,034 confirmed cases, representing a 4.7% decrease in the confirmed cases compared to 2011. In 2012, the Czech Republic and Slovakia reported the highest number of cases of contracted diseases caused by *Salmonella* ($\geq$85 cases per 100,000), while Portugal, Greece and Romania reported the lowest figures ($\leq$4 in 100,000 cases). The proportion of endemic cases versus imported cases (favored by population movement) varies significantly from one country to another: most cases associated with travels (>70%) were reported by the Nordic countries, Finland, Sweden, and Norway. The

seasonal trend of salmonellosis is confirmed by the 2008-2012 Reports, with most cases reported during the summer months. The downward trend in the number of salmonellosis cases in the EU is significant; this has been noted for several years and continued in 2012 as well ($p < 0.001$ with linear regression), particularly in the 15 member states and in two non-EU countries: Austria, Belgium, Cyprus, Denmark, Estonia, Finland, Germany, Greece, Iceland, Ireland, Lithuania, Norway, Portugal, Slovakia, Slovenia, Sweden, and the United Kingdom (14, 22).

Ten EU Member States have reported data according to which 45% of the hospitalized cases were admitted for *Salmonella* infection: 45.1% of the confirmed cases of salmonellosis were hospitalized; the highest rates of hospitalization have been reported in Greece, Romania, Cyprus, and Portugal (73-91% of cases). It was revealed that three of these countries also reported the lowest rates of notification for infections with *Salmonella*, which indicates that the surveillance systems in these countries capture the most severe cases first. A total of 61 fatal cases have been reported by eight EU member states (23).

Contaminated food that was most often involved in causing *Salmonella* infections are: meat and meat products (intended to be eaten as such or heat-treated), mechanically separated meat, gelatin, collagen, cheese, butter, cream, powdered milk, whey powder, ice cream, eggs and products containing raw eggs, crustaceans, shellfish, sprouted grains, fruit and pre-cut fruit, vegetables, unpasteurized juices, dehydrated diet foods (24) .

Among infectious diseases, including those of the gastrointestinal tract, such as some types of food poisoning, they are currently considered as “emerging” diseases either because they are too frequently encountered or because they are caused by recently discovered pathogens, or because the role of contaminated food or water has recently been determined for the transmission of etiologic agents. For example, there have always been outbreaks of salmonellosis; however, in the last 25-30 years, their incidence has greatly increased in almost all regions of the globe. In Western Europe, *Salmonella* Enteritidis has become the dominant strain (23, 25).

Salmonellosis has stood out over the last decades; it is the first among the pathogens which can contaminate food and the external environment, and which have also been involved in the occurrence of sporadic cases of AGE / ADD as well as in the appearance of foodborne outbreaks. Morbidity and mortality data are inaccurate: there is no system for reporting isolated cases of salmonellosis in humans, animals or foods of animal origin. In addition, regarding the cause of death, the etiology of salmonellosis is not always detected. Only the investigation of foodborne salmonellosis outbreak can provide a clearer picture of this public health issue. Given the wide spread and the possibility of outbreaks, several types of surveillance and control programs for *Salmonella* infections have been proposed, such as those in Denmark, the USA, Australia, etc. Since 2003, a Control Program for these diseases has been implemented for the EU states, with the focus on food quality (especially for poultry and pork) (13, 19, 20).

Campylobacteriosis today tends to rank on the same position as the infections caused by non-typhoid *Salmonella*. The incidence is higher in summer in temperate zones; there are no differences related to seasons in the tropics. The morbidity assessment is made based on bacteriologically-confirmed cases.

The reported data generally come from

laboratories and hospitals but also from epidemiological surveys carried out in foodborne outbreaks; some countries have "sentinel"- type systems of supervision and reporting. CDC reports show values of incidence of 5-6%000 for these infections in the USA. *Campylobacter* infections can be hyperendemic, endemic or epidemic outbreaks (almost characteristic of economically developed countries with high sanitary standards). In Thailand, *Campylobacter* infections seem to dominate bacterial etiology, *Campylobacter jejuni* serotypes 36, 4, and 11 are found quite frequently, rather than *Salmonella* and *Shigella* infections (26).

In 2012, at a worldwide level, campylobacteriosis was the most frequently reported zooanthroponosis, with 214,268 confirmed human cases. In developed countries, *Campylobacter spp* was the most important cause of AGE / ADD; thus, in 2009, in England and Scotland, there were over 64,000 cases but due to the phenomenon of underreporting, the actual number of cases is estimated at 450,000; about 10% of all reported cases are hospitalized; variable percentage of patients experience complications – severe abdominal pain and impaired musculoskeletal, neurological or articular functions, Guillain-Barré syndrome (15% of all cases are due to infection with *Campylobacter spp*) and others (25). Epidemiological studies have shown that 50-80% of diseases in humans are caused by the consumption of contaminated poultry (21, 22, 27, 28).

Young children in rural areas are the category at the highest risk of catching the disease due to their lifestyle that is why prevention should be promoted everywhere the world. In 2006-2007, New Zealand recorded the highest incidence ever reported in the world (12,778 cases); however, after the implementation of the new regulations concerning the marketing and consumption of fresh poultry, the figures fell dramatically in 2008 (6,693 cases) (23).

Among the measures limiting the occurrence AGE / ADD, the following are included: the proper handling and operation of water supply stations and the reduction of bacterial load in the poultry destined for consumption (*E. coli* O 157, *Cryptosporidium*, *Campylobacter spp* and *Salmonella*).

In Iceland, before 1996, the consumption and marketing of refrigerated poultry was banned, and only frozen meat was allowed; the measure was established to control *Salmonella* infections (23), but it also led to fewer cases of *Campylobacter* infection; after 1996, the ban was withdrawn, and refrigerated meat products were allowed for consumption once again. The reports have shown a significant increase in the number of people who caught the diseases caused by both *Salmonella* and *Campylobacter* (29, 30).

The highest rates of hospitalization for infections with *Campylobacter* (74 -78%) were reported by Cyprus, Latvia, Lithuania, Romania and the UK. At the same time, Cyprus, Latvia and Romania have the lowest number of reported cases, revealing that the surveillance in these areas includes only the severe cases. In 2012, the UK reported 20 of the 31 deaths reported by the EU member states (23, 31).

In the United States, the incidence of campylobacteriosis decreased in the late '90s and still remains at low levels due to the establishment and revision of hygiene measures on decontamination of drinking water and on the chlorination of the water used for washing chicken carcasses – the latter is still highly controversial in the European Union (32).

Listeriosis. In the European Union countries, *Listeria monocytogenes* has seldom been detected above the legal safety

limit when the food distributed for consumption was analyzed. However, the number of confirmed cases of human listeriosis increased in 2012 to 1,642 (compared to 1,583 cases in 2006, considered the largest number of cases in the EU up to that moment) (22, 23). Relatively rarely reported, listeriosis is a zooanthroponosis which causes high morbidity, hospitalization and mortality especially for the population at risk; the most vulnerable are fetuses, newborns, immunosuppressed patients of any age, seniors (especially men) over 74 years old. Symptoms range from mild, flu-like, with associated diarrhea, life threatening such as septicemia and meningoencephalitis; in pregnant women, *Listeria* can affect the conception product, usually causing severe diseases of the fetus, premature birth or miscarriage. The incriminated foods were not only milk products (soft varieties of cheese were often involved) but also fish and derivatives (4 samples reported in 2012 by Slovenia, but also by Austria, Belgium, Bulgaria, Cyprus, the Czech Republic, Germany, Hungary, the Netherlands, Latvia, Poland, Romania, Estonia, Spain) (38). Mollusks and crustaceans have been identified as contaminated in Bulgaria, Hungary, Poland, Portugal and Spain (23). There were additional red flags concerning the foods for consumption (pre-cut vegetables and fruit, sandwiches, pasta, salads, dishes based on eggs); however, in the last EFSA / ECDC Report, there are relatively few laboratory investigations in this regard and the results are virtually insignificant (23).

Colibacillosis. Many *Escherichia coli* serotypes are said to produce verotoxin (VTEC), yet those with the ability to cause severe diseases in humans are found in a limited number of serotypes; of these, *E. coli* O157 is the most frequently reported (synonymous terms: VTEC - verotoxin-producing *E. coli* and STEC - *Shiga* toxin-producing *E. coli*). It is normal to see occasional manifestations; in humans, the evolution of the infection includes bloody diarrhea and abdominal pain, usually without being accompanied by fever; the appearance of the hemolytic-uremic syndrome (HUS) aggravates the clinical picture (renal failure, hemolytic anemia and thrombocytopenia); about 10% of cases of infection with *E. coli*-VTEC will develop into SHU. In 2012, a total number of 5,671 confirmed cases of infection with *E. coli* VTEC were reported in the EU (23).

Since 1982 (when it was first described) until today, the infection with *Escherichia coli* serotype O157: H7 is considered a major cause of acute bloody diarrhea and acute renal failure, sometimes progressing to death, especially in children.

In Japan, in 1996, the largest outbreaks of infection with *Escherichia coli* serotype O157: H7 was reported and it involved almost 10,000 people, mostly school children (14 outbreaks). The largest outbreak included 6,300 children. There were 2 deaths (30).

Spain was faced with several outbreaks of infection with VT2 verotoxin-producing *Escherichia coli* O157: H7, first reported in 1986, 1994, 1997, which involved only foreign tourists. In 2000, the infection with *E. coli* O157: H7 affected 158 people (children from 6 schools), and 6 of them had the hemolytic uremic syndrome (23).

Cyclosporidiasis. An emerging pathogen in the United States is *Cyclospora cayetanensis*. Recently, it has been categorized as an enteropathogenic in humans. It causes outbreaks, some of which can be quite extensive. In 1997, in the USA and in 1998, in Canada, *Cyclospora cayetanensis* caused many diseases (over 1,500 cases in the USA); all the cases were related to the consumption of raspberries imported from Guatemala. There were no fatalities; the

infection was self-limiting in immunocompetent patients. In patients with HIV / AIDS, there is the risk of massive dehydration and unfavorable evolution or chronicization of diarrhea. Again, the most vulnerable age group is represented by children aged 0-2 years (33).

In the USA, the prevalence of the infection with *Cyclospora cayetanensis* in the community outside outbreaks is below 1%. In Peru, among the children from disadvantaged environments, the prevalence is estimated to be between 6% and 18%, where most cases are symptomatic (27). Two outbreaks reported in two successive voyages of an Australian cruise ship, affecting 73 passengers (confirmed with the laboratory) of the total number of 241 suspects required investigation using a case-control study, which failed to incriminate a certain food product or a food product available aboard that ship (41). In some areas (Egypt), 10-17% of the immunocompetent child population, with or without clinical signs of AGE / ADD, had fecal samples positive for *Cyclospora cayetanensis* (28, 34, 35).

Cholera, endemic in Asia and Africa and in some South American countries, was no longer an issue for the USA in the twentieth century. *Vibrio cholera* got into the South Coast waters of the United States in 1991, when a cargo unshipped contaminated ballast; basically, the first case of cholera reported in South America after 1900 was recorded in 1991 in Peru; an extensive epidemic broke out and lasted for almost five years; it extended to other countries in South America, Mexico and Central American countries and it resulted in 1,099,882 cases and 10,453 deaths. In 1993, a new serotype was identified, O139 (Bengal), which was involved in outbreaks of cholera in India and Bangladesh. A history of infection with *V. cholerae* O1 does not confer immunity, which explains the endemic manifestation of serotype O139 cholera (36, 37).

Shigellosis manifests endemically worldwide and it is extremely prevalent in undeveloped countries. Shigellosis is a highly contagious disease, especially for children younger than 5 years old, who are very receptive to it and who can die because of it. Even today, the United States still must deal with a prevalence of 6-10%$_{000}$ of the population. The most affected age group is 0-4 years (where there were 10 times more isolations compared to people over the age of 20). In Romania, the incidence of infections with *Shigella* has a downward trend, from 130.6%$_{000}$ in 1975 to 31.8%$_{000}$ in 1990 and 6.7%$_{000}$ in 2004. The most frequent in Romania are *S. flexneri* followed by *S. sonnei* (especially in Banat and Transylvania). It can be noted that, at a worldwide level, the circulation of *S. sonnei* is more intense in the areas that are better developed economically. In Romania, the disease remains endemically manifested; there is a certain summer-autumn seasonality. In the territories where the epidemiological process manifests epidemically, the most affected is the age of childhood. Infants who are exclusively breastfed are rarely affected. Receptivity decreases with age, in parallel with the increase in the number of anti-LPS antibodies and a higher concentration of these antibodies. Epidemiological observations suggest the installation of a serotype-specific immunity (24, 38).

Yersiniosis. *Yersinia enterocolitica* causes gastroenteritis or enterocolitis with self-limiting evolution; it is a frequent cause of acute infectious diarrhea and abdominal pain syndrome, especially in children, who are most receptive to it between 5 and 15 years old; the ratio boys: girls is 1: 3. The emergence of outbreaks in schools or other centers for children is possible. *Yersinia enterocolitica* is univer-

sally widespread (cases have been reported in tropical areas, as well); the prevalence of these infections is higher in Northern European countries, where the climate is cooler, and in North America, in winter. The Report for 2003 on the evolution of zooanthroponosis in the EU includes 9,399 reported cases of AGE / ADD with *Yersinia enterocolitica*. A study on the prevalence of acute gastroenteritis in children, conducted in Iran, places the infections with *Yersinia spp.* right after the infections with the enteropathogenic *E. coli* and *Shigella spp*. There was no reported antibiotic resistance (24).

Enteroviruses. In economically developed countries like the United States, Japan, Great Britain, countries in Northern Europe, the pathogens causing AGE / ADD with sporadic manifestation are caliciviruses (Norwalk, Sapporo) in patients of all ages, except for infants and toddlers in who rotaviruses are the most common. Adenovirus serotypes 40, 41 and astroviruses are also found quite frequently. Coronaviruses, picornaviruses and picotrirnaviruses, pestiviruses, and toroviruses are considered pathogens that cause acute gastroenteritis, being associated with AGE / ADD in animals; however, they have not yet been isolated from the fecal samples collected from the people who had specific symptoms. Caliciviruses are considered responsible for 50% of the foodborne outbreaks (39) and 90% of the outbreaks in the United States, with approximately 23 million cases of AGE / ADD each year; the estimates also based on questionnaires applied to the general population show much higher numbers, nearly 74 million cases / year in the USA. The small inoculum (less than 100 viral particles), the very short incubation period (12-48 hours), the resistance to the environment and to usual decontaminants correlate with the high incidence attack rates (estimated value in practice: 41%; experimentally obtained value: 50-80%). The transmission can take place indirectly through food and contaminated water or directly through the phenomenon of aerosolization during emesis (40, 41).

In the Iasi County, acute gastroenteritis recorded averages values, comparable to other counties from Romania (2.3 - 3% of all cases reported nationwide). The etiologic diagnosis was not possible for most laboratory tests, but the 0-1 age group positivity rate is higher (42).

CONCLUSIONS

Acute diarrheal disease ranks second among the causes of specific morbidity (after respiratory infections). Morbidity has higher values in economically undeveloped or developing countries, with 3 to 7 episodes of diarrhea / year / child compared to only 1-2 episodes / year / child in highly industrialized countries.

There are numerous etiological bacterial agents which cause acute diarrheal disease globally, but the infection with *Campylobacter* was the most frequently reported zooanthroponosis, with 214,268 confirmed human cases in 2012.

Almost any pathogen involved in the etiology of ADD may be involved in the occurrence of healthcare-associated infections; among these, the rotavirus and *Clostridium difficile* are most prevalent.

In our opinion, general hygiene measures could change the epidemiological aspect of ADD by modifying the factors which favor the transmission of pathogens: crowds (number of children in care), the occurrence of a case of disease (or more), the presence of sick children in the community (without isolation), two or more children sharing the same bed, common areas for changing diapers, lack of personnel's compliance.

THE IMPORTANCE OF EDHF IN ENDOTHELIUM – DEPENDENT RELAXATION INCREASES DISTALLY IN MESENTERIC ARTERIES DEPENDING UPON THE CONTRACTING AGENT

THE IMPORTANCE OF EDHF IN ENDOTHELIUM - DEPENDENT RELAXATION INCREASES DISTALLY IN MESENTERIC ARTERIES DEPENDING UPON THE CONTRACTING AGENT (Abstract). **Aim** : The importance of endothelium-derived hyperpolarizing factor (EDHF) in endothelium-dependent relaxation (EDR) is influenced by multiple factors, including vascular territory and caliber, pre-existing tone and its determining factors. **Method** : Using isometric myography we noticed that in rat mesenteric resistance arteries (RMA2 ; 2nd order branches) EDHF-mediated relaxation is increased when precontraction is induced by prostaglandin F2 (PGF) compared to phenylephrine (PHE) and we investigated the participation of certain K channels. Here we extend the study on more proximal vascular fragments ; from mesenteric arcade and from 1st order branches. **Results** : The EDHF component of EDR is stronger distally only when precontraction is induced by PHE. Moreover, morphometric analysis shows a strong inverse correlation between the magnitude of EDHF response and arterial caliber. **Conclusions** : Other authors have shown that EDHF increases in relative importance distally, but we show that this change in EDR profile depends upon the contracting agent used, with implications regarding the physiological relevance of accumulated data refering to EDHF and nitric oxide as mediators of EDR in resistance arteries. **Key words :** ENDOTHELIUM-DERIVED HYPERPOLARIZING FACTOR ; ENDOTHELIUM--DEPENDENT RELAXATION ; SMALL MESENTERIC ARTERIES.

The complex picture of EDR shows differences related to species, sex, age, hormonal status, territory and vessel size, mechanical or chemical vasodilators, pre-existing tone and its factors (1, 2, 3, 4). There are few explicit studies of the latter (1, 4). NO may be the main mediator of EDR on the vascular tree wide scale, but EDHF largely mediates the NO-independent EDR which predominates in small arteries. Of the many candidates (1), EDHF in RMA seems to be C-type natriuretic peptide (5), while gap junctions also play a critical role (6), yet another line shows that EDR induced by acetylcholine in RMA is mediated by an S-nitrosothiol (7). We noticed (3) that when NOS and COX are blocked EDHF-mediated EDR induced by carbachol in RMA2 is enhanced with precontraction by PGF vs. PHE. Here we extend the isometric myography study upon RMA1 and mesenteric arcade.

MATERIALS AND METHODS

Proximal jejunal loops were removed from adult male Wistar rats (~200 g body weight, decapitated) and placed in solution (PSS)

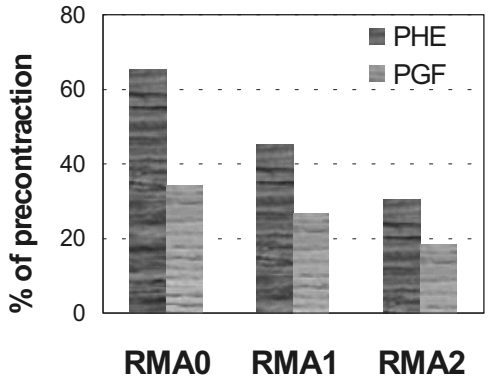

Fig. 1. Effects of 10^{-5} M carbachol upon contraction of rat mesenteric artery (RMA0) and branches (RMA1, RMA2) induced by 10^{-5} M PHE or 10^{-5} M PGF, in presence of 10^{-5} M L-NAME and 10^{-5} M indomethacin (residual active tension; % of precontraction; mean ±SEM; n=6; *p<0.01).

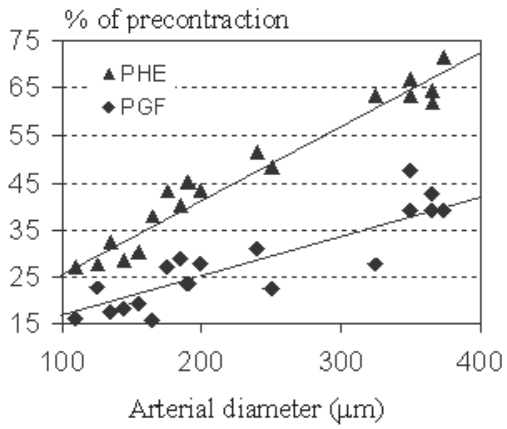

Fig. 2. Effects of 10^{-5} M carbachol upon contraction of rat mesenteric arteries induced by 10^{-5} M PHE or 10^{-5} M PGF, in the presence of 10^{-5} M L-NAME and 10^{-5} M indomethacin (residual active tension; % of precontraction; regression lines for PHE vs. PG; data pooled for all vessel types).

containing (mM): NaCl 118; KCl 4.7; $CaCl_2$ 2.52; $MgSO_4$ 1.64; $NaHCO_3$ 24.88; KH_2PO_4 1.18; glucose 5.55. Rings (Î1 mm) from mesenteric artery (RMA0) and its first and second order branches (RMA1 and RMA2) were mounted in wire myographs, in oxygenated PSS at 37°C (pH 7.2-7.4) and equilibrated for 1 h under 1 g tension. We evaluated the EDHF component of EDR induced by 10^{-5} M carbachol (e.g. in the presence of 10^{-5} M L-NAME and 10^{-5} M indomethacin); results expressed as residual active force, % from precontraction by PHE (10^{-5} M) or PGF (10^{-5} M); all drugs from Sigma. All data are presented as mean ± SEM (n=6) and differences are considered significant if $p<0.01$ (Student's t-test for grouped data). Correlation analysis was performed based on individual values for the EDHF effect and the external diameter of the mounted ring, as measured with the ocular micrometer at zero parietal tension.

Ethical aspects were evaluated and protocols were approved by local Committee on Research Animal Use, in agreement with ECC 609/24.11.1986.

RESULTS

There is a general tendency of increased EDHF towards periphery (fig. 1), but significant differences occur only with PHE; with PGF this is obscured by an already strong EDHF in RMA0. Thus, EDHF participation in EDR in this territory displays an increase with branching (and smaller size; fig. 2), more or less abrupt depending on the contracting agent.

DISCUSSIONS

Our data are in agreement with the few existing studies which use PGF in RMA (8), showing that both NO and EDHF are involved in EDR, and also with the many studies on EDHF in these vessels using a_1-adrenoceptor stimulation (1, 2, 4, 7, 9).

In RMA small and intermediate conductance calcium-dependent K^+ channels do increase in expression and function towards periphery (10), where EDHF is more pronounced (2).

While carbachol-induced global EDR in RMA is complete (6, 11), irrespective of

the artery caliber and of the contracting agent, the EDHF component of EDR varies significantly ($p < 0.01$) with the contracting agent (fig. 1).

CONCLUSIONS

EDHF component of EDR is stronger distally when contraction is induced by PHE but not by PGF. Others have shown that EDHF importance increases towards periphery, but we show that this may depend on the contracting agent.

This finding may influence the interpretation of existing data on EDHF and NO as mediators of EDR in resistance arteries (12), including human small mesenteric arteries, which behave similarly ; EDR is based on NO & EDHF but not on prostaglandins (13).

PREVALENCE OF NASAL CARRIAGE OF STAPHYLOCOCCUS AUREUS WITH SPECIAL REFERENCE TO NUMBER OF METHICILLIN RESISTANCE AND ANTIMICROBIAL EVALUATION AMONGST APPARENTLY PEOPLE WITH GOOD HEALTH STATUS (Abstract): The emergence and spread of *Staphylococcus aureus* (*S. aureus*) strains that are resistant to some first line and supplementary group of antibiotics is a matter of public health importance. *S. aureus* is ubiquitously found in the environment as a commensal organism, but pathogenic strains of the bacterium that are resistant to some commonly available antibiotics puts antimicrobial therapy at risk. **Objectives:** To determine the number of nasal carriers of *S. aureus* among apparently healthy people from Iasi and to assess the antibiogram profile of isolated strains, with special reference to methicillin sensitivity. **Material and methods**: This study was conducted in Biodev Medical Center, Iasi, Romania, during 2014 - 2018, where a total of 757 apparently healthy patients (men, women and children) were tested for *S. aureus* infection. The samples were collected from their anterior nares and incubated on culture media for isolation and antibiotic susceptibility testing in microbiology department. The data was compiled and analyzed for the prevalence of *S. aureus* carriers, the number of MRSA strains and the antibiotic resistance pattern. **Results and discussion:** Our study has shown that from 757 people involved, 229 of them were carriers of *S. aureus* strains and 22 of them were MRSA strain carriers. Additionally, we found that the male / female portability ratio is similar and also the fact that the most carriers are in the group of age over 18, followed by school age people (age 8-18 years old). **Conclusions:** This study will help raise awareness regarding the danger of developing antibiotic resistance and in the same time also reduce or prevent self-medication and antibiotics abuse without medical recommendation. **Keywords:** STAPHYLOCOCCUS AUREUS, METHICILLIN-RESISTANT *S. AUREUS*, STAPHYLOCOCCAL INFECTIONS, ANTIBIOTIC RESISTANCE.

S. aureus is a gram-positive, round-shaped bacterium, member of the Firmicutes phylum and it is a member of the normal flora of the body, frequently found in the nose, respiratory tract and on the skin. *S. aureus* is the most common species of the genus *Staphylococcus* that causes staphylococcal infections in humans (1). The carriage of *S. aureus* is an important source of nosocomial infections, community acquired infections and antibiotic resistant infections due to the organisms including but not limited to methicillin-resistant *S. aureus* (MRSA). Frequently, *S. aureus* can be present on the skin of the host, but a large proportion of its carriage is through the anterior nostrils of the nasal passages. The nose is one of the few openings thorough which bacteria has direct access to the body. Thus, the nose and nasal passages can be perfect environments for some bacteria. *S. aureus* has been recognized as one of the most important bacterial pathogens, significantly contributing to hospital and community-acquired infections all over the world (2). The ability of the nasal passages to host *S. aureus* results from a combination of a weakened or defective host and the ability of bacteria to evade host innate immunity. It was estimated that 20 - 30% of the human population are long-term carriers of *S. aureus* (3, 4). It is the most frequently isolated pathogen causing bloodstream infections, skin and soft tissue infections, and pneumonia. Diseases caused by *S. aureus* include folliculitis, boil, furunculosis, scalded skin syndrome, conjunctivitis and toxic shock syndrome (4, 5, 6, 7, 8). In attempts to control these diseases through the use of antimicrobial agents particularly antibiotics have led to increased prevalence of resistance to these agents. *S. aureus* diseases and their high mortality were greatly reduced after Alexander Fleming discovered the effects of penicillin, but success was short-term because the bacteria immediately gained resistance to penicillin by secreting an enzyme called beta-lactamase, that breaks the antibiotic beta-lactam ring thus inactivating antimicrobial action. A group of narrow spectrum antibiotics (Nafcillin, Oxacillin, Methicillin), which are resistant to beta-lactamase activity secreted by *S. aureus*, offered new treatment options for staphylococcal infections, but the occurrence of methicillin-resistant *S. aureus*, determined its resistance to all beta lactam antibiotics.

MRSA (**M**ethicillin-**r**esistant ***S***. ***a****ureus*) strains have gained resistance not only to beta-lactam antibiotics, but also to several other classes of antibiotics (9) MRSA strains play a crucial role in disease acquisition from the community and there has been a global increase in the number of infections caused by MRSA (9, 10). However, data concerning the frequency of MRSA nasal carriage in Iasi community is unknown. The aim of this study was to determine the prevalence of MRSA in *S. aureus* carrier individuals, from Iasi area and to determine the pattern of antibiotic resistance.

MATERIAL AND METHODS

This study was conducted in Biodev Medical Center, Iasi, Romania and was planned in the year 2014. The studied subjects were people with apparently good health status, from Iasi city and nearby villages. With their agreement, a total of 757 of people were included in this study, 348 males and 409 females, from which 508 persons were under the age of 18 and 249 over this age.

Microbiology

All 757 Specimens were collected during January 2014-June 2018 from anterior nostrils with sterile cotton swabs (the same swab being used for both nostrils of the patient). Swabs were cultured on 5% blood agar and Mannitol-salt agar, incubated at +37°C (±1°C) and examined for the growth of characteristic colonies after 24-48 hours of aerobic incubation. The organism was identified by microscopy, using Gram staining technique and colony characteristics: colonies are large (2-4mm in diameter), circular, convex smooth, and show hemolysis on blood agar. After colony smear and Gram staining of bacterial colonies, the biochemical identification was carried out by following tests: catalase test, slide coagulase test and tube coagulase test, Mannitol salt agar for fermentation and latex agglutination kit (Prolex^{TM} Staph Latex Kit).

Antibiotic susceptibility test

Antibiotic susceptibility of the isolates was performed on Muller Hinton agar plates and interpretation was done according to Clinical and Laboratory Standard Institute (CLSI) testing guidelines. We used Kirby-Bauer Disc diffusion technique, using following antibiotics: Penicillin G (10 units/disc), Oxacillin (OX 30mcg/disc), Cefoxitin (CX 30 mcg/disc), Ciprofloxacin (CIP 5mcg/disc), Clindamycin (CD 2 mcg/disc), Erythromycin (E 15mcg/disc), Doxycycline Hydrochloride (DO 30mcg/disc), Tetracycline (TE 30mcg/disc), Kanamycin (K 30 mcg/disc), Chloramphenicol (C 30 mcg/disc), Vancomycin (10 mcg/disc), all produced by HiMedia.

Screening for methicillin resistance was done using Oxacillin (OX 30 mcg/disc) antibiotic or Cefoxitin (CX 30 mcg/disc, surrogate for Oxacillin). Inducible resistance to Clindamycin in *S. aureus* was tested by 'D test' also as per CLSI guidelines. For the preparation of the bacterial suspension, the scale of 0.5 on McFarland was used. The entire surface of the plate medium was inoculated using sterile cotton swab soaked in inoculum and antibiotic discs (HiMedia) were applied, then the plates were inverted and incubated at +37°C (±1°C) for 24 hours. Quality control of the test was done by Standard Strain (Staphylococcus aureus ATCC 25923). The Zone diameter around the disk is measured using a measuring scale and the results were interpreted as susceptible, moderately susceptible or resistant as per recommendations.

Analysis: All data was compiled using MS Excel and presented in tabular form. A Visual Basic script was used to process data.

Ethical consideration: Data collection permission was obtained from the subjects before results were used in the study.

RESULTS AND DISCUSSION

The prevalence of *Staphylococcus aureus* (carrier state) was 30.25% (fig. 1) observed in apparently healthy people (in line with specialty literature), with a percent of 90.39% MSSA (**M**ethicillin-**s**usceptible ***S***. ***a****ureus*) strains and 9.60% MRSA (**M**ethicillin-**r**esistant ***S***. ***a****ureus*) strains (fig. 2).

The incidence of MSSA strains carriers of female (fig. 3) compared to male (fig. 4) individuals were similar: we found 106 (46.28%) female and 101 (44.10%) male respectively, compared to MRSA strain carriers, where the female carrier rate was lower (fig. 3), with a number of 9 infec-

tions (3.93%), versus 13 male (fig. 4) infections (5.67%).

Regarding age incidence, we noticed that the highest rate was found in adult patients over 18 years (31.87%), followed by school age people between 8 - 18 years with 26.63% (tab I, II). Although the number of patients from rural environment was not equal to those in the urban area, as a percentage of the number of individuals tested, we found 29 carriers (38.66%) of *S. aureus*, from which 25 had MSSA strains (86.30%) and 4 had MRSA strains (13.70%). In comparison, among urban residents 200 persons where we found carrying *S. aureus* (29.32%), of which 182 MSSA strains (91%) and 18 with MRSA strains (9%) (fig. 5).

TABLE I

Female carriers' ratio between MSSA and MRSA strains, according to age

Age group (Years)	Female tested	S. aureus carriers	Methicillin susceptibility (%)	Methicillin Resistance (%)
0 - 3	94	19 (4.64%)	18 (94.73%)	1 (5.26%)
4 - 7	85	29 (7.09%)	25 (86.20%)	4 (13.79%)
8 - 18	75	23 (5.62%)	22 (95.65%)	1 (4.34%)
> 18	155	44 (10.75%)	41(93.18%)	3 (6.81%)
Total	409	115 (28.11%)	106 (92.17%)	9 (7.82)

TABLE II

Male carriers' ratio between MSSA and MRSA strains, according to age

Age group (Years)	Male tested	S. aureus carriers	Methicillin susceptibility (%)	Methicillin Resistance (%)
0 – 3	108	25 (7.18%)	20 (80.0%)	5 (20.0%)
4 - 7	69	22 (6.32%)	21 (95.45%)	1 (4.54%)
8 - 18	81	38 (10.91%)	34 (89.47%)	4 (10.52%)
> 18	90	29 (8.33%)	26 (89.65%)	3 (10.34%)
Total	348	114 (32.75%)	101 (88.59%)	13 (11.40%)

DISCUSSION

Development of resistance to antimicrobial agents by staphylococci is a major concern primarily because they are still frequently associated with hospital and community - acquired infections (11). The organisms exhibit remarkable versatility in their behavior towards antibiotics, with some strains having become resistant to most commonly used antibiotics (12). The higher percentage of people with antibiotic resistance in rural areas can be attributed to self-medicine due in principle to the lack of medical education (people do not know the risks and mechanisms of acquiring antibiotic resistance, e.g. incomplete treatments or the prescribing of broad-spectrum antibiotics as a preventive measure).

MRSA is a common pathogen in many healthcare facilities and communities worldwide. It causes mild to severe infections which is sometimes difficult to treat due to its resistance to multiple antibiotics and carriage of multiple virulence factors. The highest percentages of resistance of MRSA strains were shown to Oxacillin and Cefoxitin (100%), followed by Penicillin (90.90 %), Erythromycin and Clindamycin with 72.72%, Vancomycin (9.09%), Kanamycin and Chloramphenicol (4.54%) (Fig.4). This finding is in accord with other studies that show the predominance of MRSA strains resistant to Oxacillin and Cefoxitin (13,14,15). The most susceptible antibiotic for treating MRSA strains was Ciprofloxacin and Doxycycline with a percentage of 100%. Regarding the inducible resistance to Clindamycin, we found that it appeared in 52 of the MSSA strains and in 16 of the MRSA strains.

Clinical infections with *S. aureus* will likely remain both common and serious. Not only have there been waves of increasing antimicrobial resistance (16,17,18,19) but the spectrum of clinical diseases also continues to change (20).

CONCLUSIONS

There is no doubt that there will continue to be a shifting landscape in the interactions between host and pathogen in the decades to come. We have the belief that this study, will help to raise awareness regarding the danger of developing antibiotic resistance and at the same time to reduce and eventually prevent self-medication and abuse of antibiotics without medical recommendation.

TAMOXIFEN AND ENDOMETRIAL PATHOLOGY (Abstract): Tamoxifen is a non-steroid antiestrogen, used as adjuvant therapy for carcinoma breast in women with positive estrogen receptor (ER+). In this report we evaluated endometrial histological changes in the women treated with Tamoxifen for breast carcinoma ER+. **Material and method**: We performed transvaginal ultrasonography for the endometrial thickness and biopsy of endometrium on a group of 125 symptomatic women with Tamoxifen therapy for breast carcinoma ER+. The endometrial specimens were histologically processed for histological diagnosis. **Results**: Of all patients, 49.6% had endometrial pathology (women with functional hemorrhage), and 32% had atrophic endometrium. Endometrial pathology was represented by endometrial simple hyperplasia 17.6%, and endometrial complex hyperplasia 8.8%. Endometrial complex hyperplasia with atypia was found in 5.6%, endometrial polyps in 11.2%, endometrial carcinoma in 4.8% and müllerian mixt tumor in 1.6%. **Conclusions**: Endometrial pathology was more likely to be diagnosed in gynecological symptomatic postmenopausal and premenopausal women with breast carcinoma treated with Tamoxifen. Therefore, it is necessary that these patients to be supervise, first, with transvaginal ultrasonography for endometrium, and after, with biopsy of endometrium. All pacients on long term Tamoxifen therapy should be annually screened by endometrial biopsy for endometrial pathology. **Key words**: BREAST CARCINOMA, TAMOXIFEN, ENDOMETRIAL PATHOLOGY

Incidenţa adenocarcinomului endometrial este în creştere, determinat de obezitate, de înaintarea în vârstă şi mai recent de terapia adjuvantă cu Tamoxifen.

Tamoxifenul, un antiestrogen, nonsteroidian de sinteză a fost utilizat cu succes ca terapie adjuvantă, efectuată după tratamentul primar, la femeile în postmenopauză cu cancer de sân, cu receptor estrogen + (ER+). Efectul său benefic în reducerea recurenţei şi creşterea supravieţuirii a fost confirmat de mari trialuri clinice (1).

Actualmente este evaluat ca agent chemoprotector pentru tratamentul femeilor sănătoase, care prezintă un risc crescut de a dezvolta cancer de sân (2).

De-a lungul timpului, în literatura de specialitate, au apărut numeroase rapoarte care au indicat, prin cazuistica studiată, apariţia de modificări endometriale în urma tratamentului de lungă durată cu Tamoxifen (3). Una dintre cele mai semnificative complicaţii ale folosirii Tamoxifenului pe termen lung este dezvoltarea cancerului de endometru, evidenţiindu-se o creştere a riscului cu 7,5% faţă de populaţia generală (4).

Studiului nostru a încercat să evidenţieze modificările histopatologice la nivelul endometrului, apărute la femeile diagnosticate cu cancer de sân şi aflate sub tratament hormonal cu Tamoxifen, concomitent cu analiza leziunilor histopatologice endome-

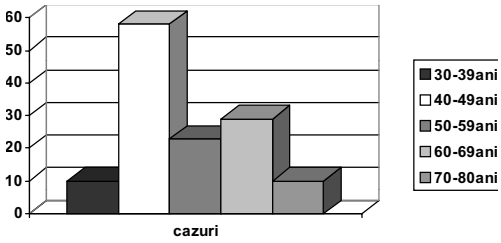

Fig. 1. Distribuţia cazurilor pe grupe de vârstă

triale curente în raport cu durata tratamentului hormonal.

MATERIAL ŞI METODĂ

S-a realizat un studiu în perioada 1995-2009, care a cuprins 125 de paciente prezentate în acest interval de timp, în cadrul Clinicii de Obstetrică şi Ginecologie „Cuza Vodă" din Iaşi, pentru hemoragie disfuncţională apărută sub terapie cu Tamoxifen.

Pacientele au fost diagnosticate anterior cu cancer mamar in stadii diferite, dar cu receptor ER+, pentru care s-a instituit terapie hormonală cu Tamoxifen, post intervenţie chirurgicală în doză de 20-40 mg/zi.

Tehnicile de investigaţie au constat din echografie endovaginală, urmată de recoltare de biopsie endometrială. Produsele de chiuretaj au fost fixate în formaldehidă 10% tamponată şi prelucrate prin includere în parafină. Secţiunile histologice de 4-5μ au fost colorate prin metode uzuale (colorare hematoxilin-eozină şi van Gieson) pentru interpretare şi diagnostic histopatologic.

REZULTATE

Dintre cele125 paciente cu cancer de sân tratate cu Tamoxifen, 104 (87,2%) erau la postmenopauză şi 16 (12,8%) la premenopauză. Grupul de vârstă a fost cuprins între 36-83 de ani, iar media de vârstă a fost de 56 de ani (fig. 1).

Diagnosticul clinic, la toate pacientele din studiu, a fost în momentul recoltării biopsiei endometriale, de hemoragie disfuncţională. Ecografic, s-a observat o creştere în grosime a endometrului peste 8mm

TABELUL I

Modificările histopatologice

Modificări histopatologice	Nr. paciente	Procent (%)
Endometru normal	23	18,4%
Endometru atrofic	40	32%
Polipi endometriali	14	11,2%
Hiperplazie simplă	22	17,6%
Hiperplazie complexă	11	8,8%
Hiperplazie complexă cu atipii	7	5,6%
Adenocarcinom de endometru	6	4,8%
Tumoră mixtă mezodermică	2	1,6%

(cu excepţia cazurilor de atrofie endometrială) cu aspect eterogen şi lacune anecogene difuze în grosimea endometrului, iar uterul a fost mărit de volum.

Durata tratamentului până la apariţia simptomatologiei a fost cuprinsă între 8 şi 72 de luni.

La 23 de paciente (18,4%) nu s-au constatat modificări endometriale. Hiperplazia simplă s-a observat la 22 paciente (17,6%) cu aspect tipic cu numeroase glande cu epiteliu de tip proliferativ pseudostratificat (tab. I).

Histologic, s-a evidenţiat endometru atrofic la 40 de paciente în postmenopauză. În cursul tratamentului cu Tamoxifen, 14 paciente au prezentat polipi endometriali, care histologic prezentau glande, în general neregulate cu epiteliu atrofic sau cu metaplazie eozinofilă. Stroma a fost fibroasă, cu condensări periglandulare (strat cambium).

Cea mai frecventă leziune a fost hiperplazia endometrială (40 de cazuri), din care hiperplazie simplă (22 de cazuri), hiperplazie complexă (11 cazuri) şi hiperplazie atipică (7 cazuri). În hiperplazia complexă fără atipii, glandele prezentau o arhitectură neregulată cu muguri intraglandulari şi în stromă (fig. 2), dar cu epiteliu pseudostratificat cu nuclei uniformi, alungiţi şi polarizaţi. Stroma a fost uşor redusă, mai

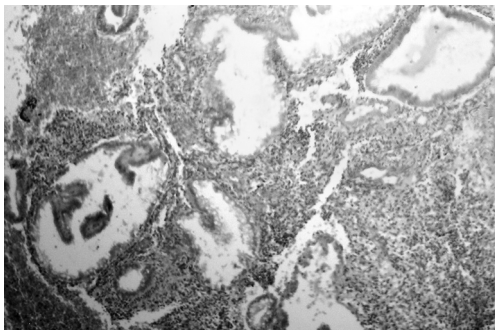

Fig. 2. Hiperplazie endometrială complexă cu muguri epiteliali intraglandulari şi în stromă

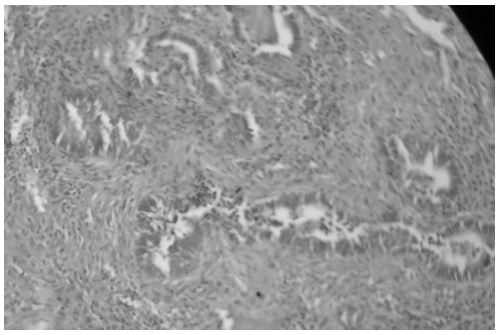

Fig. 3. Hiperplazie endometrială atipică

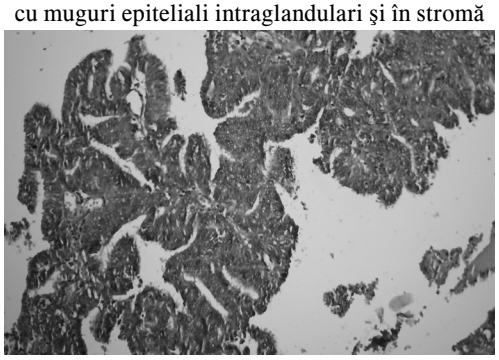

Fig. 4. Adenocarcinom endometrioid papilar

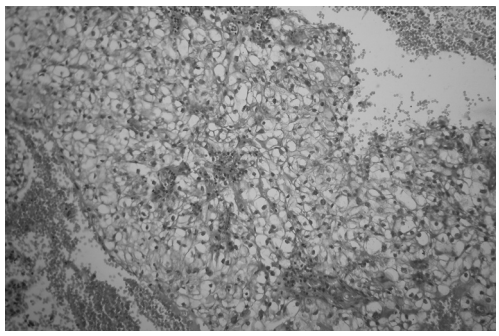

Fig. 5. Adenocarcinom endometrial de tip seros cu tablou histologic solid

ales în focarele cele mai bogate glandular. În hiperplazia atipică (fig. 3), diagnosticul histopatologic s-a bazat pe atipia citologică a epiteliului glandular, ce prezenta pierderea polarităţii nucleare axiale, anizocorie, nucleoli proeminenţi şi cromatină clară sau densă. Aceste aspecte atipice s-au observat în focar, iar stroma a fost redusă, dar prezentă. În cele 6 cazuri de carcinom endometrial, histologic s-au diagnosticat 4 cazuri de adenocarcinom endometrioid de tip I şi II , de tip papilar (fig. 4) şi adenocarcinom de tip seros cu tablou histologic solid (fig. 5).

În două cazuri, transformarea malignă a apărut sub formă de tumoră mixtă mezodermică de tip heterolog cu aspecte carcinomatoase – carcinom seros-papilar cu focare de carcinom scuamocelular keratinizat, asociate cu sarcom stromal, leiomiosarcom, fibrosarcom, condrosarcom şi celule multinucleate, posibil rabdiomioblaste.

DISCUŢII

În literatura de specialitate există numeroase argumente documentate pentru asocierea terapiei cu Tamoxifen şi dezvoltarea de numeroase aspecte patologice endometriale (5).

O astfel de asociere a fost bazată pe observaţia că ratele de incidenţă a endometrului proliferativ, hiperplaziilor endometriale, polipilor endometriali şi carcinomului endometrial au fost mai mari la pacientele cu carcinom de sîn tratate cu Tamoxifen decât la pacientele similare netratate, deşi diferenţa nu a fost statistic semnificativă (5,6,7,8,9,10,11).

În grupul de 125 paciente vârsta medie a fost 56 de ani, cu un maximum grup de vârstă 40-49. Toate pacientele au prezentat sângerări uterine în momentul recoltării,

iar în produsul de chiuretaj s-au constatat 81,6% leziuni endometriale - din care 32 % atrofie, 11,2% polipi, 26,4% hiperplazie simplă şi complexă, 5,6% hiperplazie atipică, 4,8% carcinom şi 1,6% tumoră mixtă mezodermică. Cele mai multe leziuni au fost decelate în grupul 40-49 ani, iar chiuretajele au fost efectuate după 24-36 luni de la începutul tratamentului cu Tamoxifen.

În studiul nostru incidenţa de 49,6 % a patologiei endometriale detectată la pacientele simptomatice tratate cu Tamoxifen este mai redusă decât cea din studiile lui Cohen et al., care a utilizat doza de 40mg/zi (11).

Cel mai mare risc cumulativ al dezvoltării leziunilor endometriale a survenit la 36 luni de utilizare a Tamoxifenului, iar leziunile frecvente au fost polipi endometriali, hiperplaziile simple, complexe şi cu atipii. În cazuistica noastră cazurile de apariţie a carcinomului endometrial a fost după 5 ani de administrare zilnică a 40 mg de Tamoxifen.

Studiul prezent confirmă datele din literatură legate de efectul inductiv lezional al terapiei cu Tamoxifen, administrat pe termen lung, asupra endometrului.

CONCLUZII

După maxim 36 luni terapie cu Tamoxifen, toate pacientele ar trebui supravegheate prin sonografie transvaginală, urmată de chiuretaj biopsic, dacă aspectele sonografice sunt patologice. Beneficiile utilizării tratamentului cu Tamoxifen sunt deosebit de importante, deoarece reduce recurenţa şi apariţia de noi carcinoame în sânul controlateral.

EVALUATION OF FREE RADICAL SCAVENGING ACTIVITY OF *CRATAEGUS MACRACANTHA LODD* FLOWERS (Abstract): The antioxidant activity of biological products has been demonstrated by various "in vitro" and "in vivo" studies. **Aim**: To measure the capacity of an extract obtained from *Crataegus macracantha Lodd* flowers to capture free radicals from chlorpromazine (radical indicators), in order to evaluate the entire antioxidant activity. **Material and methods**: The lyophilisate from *Crataegus macracantha Lodd* flowers were obtained in the Department of Pharmacognosy of the Iaşi "Grigore T. Popa" University of Medicine and Pharmacy. The radical indicators were obtained through oxidation of chlorpromazine with potassium persulphate in acid environment. The diminution of radical solution color was determined by means of spectrophotometry (maximum absorbance at ƛ=525 nm), according to the amount of lyophilisate. Ascorbic acid was used as a standard antioxidant. **Results**: The antioxidant activity was evaluated by using the calibration curve, obtained by plotting the radical solution absorbance variation according to ascorbic acid concentration. Due to the fact that antioxidant activity is simultaneously influenced both by the antioxidant concentration and response time, a variant of the method using the calibration curve obtained by plotting the area under the curve (AUC), against ascorbic acid concentration. AUC was calculated for each ascorbic acid concentration by graphic representation of the absorbance inhibition percentage at every two predefined time frames. The antioxidant activity of the sample is calculated by using the regression line equation (r^2=0.999) and was expressed in micromolar equivalents ascorbic acid/g product (59,70 µM/g). **Conclusions**: The obtained results confirm the capacity to capture free radicals and, implicitly, the antioxidant activity of *Crataegus macracantha Lodd* flowers. **Keywords:** FREE RADICAL SCAVENGING, SPECTROPHOTOMETRIC ANALYSIS, CHLOR-PROMAZINE RADICAL CATION.

The reactive oxygen and nitrogen species (free radicals or non-radical compounds) interfere in various oxidative processes, which are produced both in the human body and other systems: food, medicine, cosmetics, petroleum products etc.

The interference of antioxidant substances ensures a balance between the prooxidative processes initiated and catalyzed by the reactive species and normal metabolic processes.

Exogenous antioxidants supplied

through foods or drug intake are extensively studied, of which herbal products play an essential role.

Finding new sources of natural antioxidant substances represents a challenge for researchers (1-10).

At the same time, methods of analyzing the antioxidant activity of biological products have expanded and diversified (11-15).

The aim of this study was to determine the ability of lyophilisate obtained from *Crataegus macracantha Lodd* flowers to capture free radicals resulting from the oxidation of chlorpromazine with potassium persulfate and to evaluate their antioxidant action by means of spectrophotometry.

Crataegus macracantha Lodd, fam. *Rosaceae* is a widespread species in North America (south of Canada and USA), but a rare species in Europe.

Unlike *Crataegus monogyna* (leaves and flowers), extensively studied and with a demonstrated antiarrhythmic and antioxidant action, *Crataegus macracantha* was less analyzed due to its reduced distribution area. The indicator radical cation chromophore of chlorpromazine has a maximum absorbance at 525 nm. In the presence of the antioxidant, the color of the solution diminishes proportionally with the amount of lyophilisate. Ascorbic acid was used as a standard antioxidant and the antioxidant activity of the sample was expressed in molar equivalents (micromolars) of ascorbic acid per gram of dried product.

MATERIAL AND METHODS

The lyophilisate was obtained in the Department of Pharmacognosy, Faculty of Pharmacy, Iasi "Grigore T. Popa" University of Medicine and Pharmacy, as it follows: 10 g of plant product (flowers) was treated with 100 mL of 70% methanol (v/v); the mixture was stirred for one hour (FALC F-30 ST magnetic stirrer), filtered, concentrated (Rotavapor, BUCHI R-210) and lyophilized (UNICRYO TFD 5505 freeze-dryer).

Of the 10g of plant product, 2.66g of crude extract were obtained.

Radical preparation. The preformed radical of chlorpromazine obtained by oxidation of chlorpromazine by potassium persulfate in an acid environment was used for measurements (16). The optimum molar ratio between chlorpromazine and potassium persulfate, where the radical absorbance remains constant, was established (fig. 1).

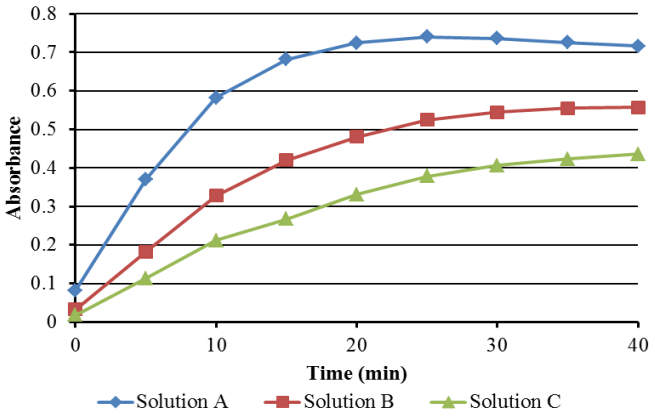

Fig. 1. Stability over time of the $CP^{\bullet+}$ radical

It was found that solution A (molar ratio chlorpromazine/persulfate of 20:1) reaches its maximum absorbance 20 minutes after the addition of persulfate and remains constant for approximately 20 minutes.

Thus, the optimal time frame to carry out the measurements is 20 to 40 min after adding the potassium persulfate. An excess of chlorpromazine ensures radical stability.

Sample preparation. Approximately 0.05 g lyophilisate are dissolved in 10 mL of distilled water. After 30 minutes, the obtained suspension is filtered, and the resulting solution is diluted to 25 mL (V).

Procedure. To 2 mL radical solution a certain amount of lyophilisate solution diluted to 1 mL with distilled water was added. The solution absorbance was measured 10 and 20 minutes after the initiation of the reaction, at λ=525 nm, in 1-cm cuvette, with distilled water as a control.

Statistical analysis

The micromolar equivalents of ascorbic acid/g product values were calculated by linear regression on six different gross extract and the results were expressed as average, standard deviation (SD) and relative standard deviation (RSD%).

RESULTS AND DISCUSSION

In order to express the antioxidant activity in molar equivalents (micromolars) of ascorbic acid, we used a calibration curve obtained by plotting the radical solution absorbance according to the concentration of the standard antioxidant, namely, ascorbic acid. The method was validated for a concentration of ascorbic acid in the range of 10-100 µM/L. The linearity of response function, linearity of results, detection limit (LOD=3.13 µM/L), quantification limit (LOQ=9,49 µM/L), system and method accuracy (16) were determined.

Using the equation of the calibration curve (Absorbance = –0.001944 × calculated concentration (µM/L) + 0.5192514), we calculated the concentration of the samples taking into account the dilutions made.

Micromolar equivalents ascorbic acid/g product = a × V × C calculated /v × b × 10^4

a = 2.66 g lyophilisate

b = g lyophilisate involved in the working process (~0.05)

V = 25 mL

v = volume of the analyzed lyophilisate solution

The results refer to 1 g of dried plant product.

The measurements were carried out 10 minutes (tab. I) and 20 minutes after the reaction was triggered (tab. II).

The RSD values of measurements at 10 and 20 minutes, respectively, fit the RSD values for method.

It is concluded that radical capture speed by the antioxidants from the plant product depends both on the antioxidant concentration and the set time frame for the determination (fig. 2).

The two factors influencing the measurements were reunited in one parameter – area under the curve (AUC), calculated for each concentration in ascorbic acid (10-100 µM/L) by plotting the variation of percent inhibition at 10 and 20 minutes against ascorbic acid concentration,

% Inh = $A_r - A_s/A_r.100$, *where*

A_r – radical absorbance;

A_s – sample absorbance.

A_r = 0,53103 (17) (tab. III)

Taking into consideration that the lyophilisate obtained from *Crataegus macracantha Lodd* flowers contains substances with different antioxidant activity, hence with a different capacity of capturing the radicals, it is very important to carry out the measurements at a set time.

4	0.16555	0.14038	68.82	73.56	711.95	182.37	58.08
5	0.32447	0.30067	38.90	43.38	411.39	102.83	61.88
6	0.24425	0.22843	54.00	56.98	554.94	140.82	60.53
Statistical data						Average	61.23
						SD	2.4339
						RSD	3.9751%

In order to evaluate the entire antioxidant activity, it is recommended to use the area under the curve as an indicating parameter, since it combines the two variable factors influencing the kinetics of the reaction between radicals and antioxidants: set time for determination and antioxidant concentration.

CONCLUSIONS

In our study, the obtained results show that *Crataegus macracantha Lodd* flowers have a remarkable antioxidant activity. The proposed methods can be used for a qualitative assessment of radical absorption capacity by this plant, and by optimizing these methods a quantitative estimate of total antioxidant activity can also be made.

NEWS

THE RELATIONSHIP BETWEEN LOW INCOME AND PHYSICAL CAPACITY IN COPD

The capacity to exercise effort depends on the degree of chronic obstructive pulmonary disease (COPD) and on the lung recovery program to which the patient is subject. The prognosis of COPD is associated with the use of health care and quality of life. The 6 minutes' walk test (6MWT) and the cardiopulmonary effort test (CPET) are two methods of measuring effort capacity. Studies suggest that socio-economic status in COPD can also be associated with physical activity effort. For this study, two groups of patients with higher and lower annual incomes of $ 30,000 were formed. Lower-income patients had generally lower outcomes at 6MWT ($p < 0.0001$). An association between income and 6MWT was seen at patients with severe COPD after they were matched by age, gender, pulmonary function, dyspnea and living conditions ($p < 0.0007$). Our research confirms and extends previous hypotheses that conduct to importance of approaching social factors in health, such as income at patients with COPD (Ana Sofia Porta, Nyanjok Lam, Paul Novotny, *et al.* Low income as a determinant of exercise capacity in COPD. https://doi.org/10.1177/14799 72318809491).

SMALL MEDICAL CYCLOTRON PRODUCED RADIOISOTOPES: FROM CLASSIC TO NOVEL RADIOTRACERS

SMALL MEDICAL CYCLOTRON PRODUCED RADIOISOTOPES: FROM CLASSIC TO NOVEL RADIOTRACERS (Abstract): Positron emission tomography (PET) has become a widespread and indispensable tool for non-invasive oncological, cardiological and neurological diagnosis. With its increase use, there has been a surge in medical cyclotron facilities to answer this demand as well as a continuous research into novel radiopharmaceuticals. Although the high demand for new and efficient radiotracers has spurred the use of new radioisotopes, the classic PET isotopes such as fluorine-18, carbon-11, nitrogen-13 and oxygen-15 have still widespread use, due to their fast ease of synthesis, when compared with other isotopes. The purpose of this mini-review is to present both old and novel radiopharmaceuticals, based on the aforementioned radionuclides, used in clinical diagnosis and biomedical research. **Keywords**: POSITRON EMISSION TOMOGRAPHY, MEDICAL CYCLOTRON, RADIOPHARMACEUTICALS.

Small medical cyclotrons are generally characterized by a small energy range (less than 20 MeV), located in or near hospitals, to answer the daily radiopharmaceutical needs of local PET centers (1). Ease of operation, low cost and minimal preparation of target material is a characteristic of most PET cyclotrons, but these limitations are meant to provide a fast and reliable production of very specific and highly utilized isotopes.

Radioisotopes used in PET need to have specific physical properties, such as a mostly β^+ decay, with adequate energy emission, that will not negatively affect the resolution of the image, a small half-life to ensure a low exposure to the patient and medical personnel but long enough to make the synthesis, quality control and diagnostic procedure feasible (2, 3). From a radiopharmaceutical point of view, the radioisotopes need to be easily labeled, preferably to a variety of molecules that in turn have high specificity, to increase their diagnostic use.

TABLE I
Common isotopes produced by small PET cyclotrons

Radioisotope	Half-life (min)	Max Energy (MeV)
^{18}F	109.8	0.633
^{11}C	20.4	0.980
^{13}N	9.97	1.19
^{15}O	2.06	1.73

As small medical cyclotrons are generally aimed for the production of only the most common radioisotopes, such as the ones presented in first table, the energy output and beam current are relatively small. This, coupled with the target handling system, makes the production of other isotopes difficult if not impossible. In spite of this, we will show that, although the isotopes production by small medical cyclotrons is limited, the radiopharmaceuticals derived from these isotopes can more than satisfy the daily clinical diagnostic needs of local PET centers as well as for biomedical research.

FLOURINE-18

Fluorine-18 (^{18}F) is one of the oldest and most common used PET radioisotopes, especially in oncology, but also in cardiology, neurology and in the diagnostic of infectious diseases (4). ^{18}F is produced by irradiating an ^{18}O enriched water target with a proton beam, with energies from near threshold (3 MeV) up to 20 MeV (5). The $^{18}O(p, n)^{18}F$ reaction yields fluorine in aqueous solution which is then transferred to the synthesis module for extraction, purification and labeling.

The vast majority of PET investigations are conducted using [^{18}F]-Fluorodeoxyglucose ([^{18}F]-FDG), which enables the study of glucose metabolism, especially for the early diagnosis of cancerous cells (6). [^{18}F]-FDG can also be used for myocardial viability studies but due to glucose competition in cardiomyocytes, the specificity is generally low, which may lead to false positive results (7). [^{18}F]-FDG has further limitations when it comes to the diagnosis of malignant cells in tissues with high glucose metabolism which also may cause false positive results, prompting the development and use of other ^{18}F based radiotracers (8).

Neuro-oncological diagnosis also makes use of [^{18}F]-Fluoro-ethyl-L-tyrosine ([^{18}F]-FET), for the detection of brain tumors (9). The higher metabolic activity of malignant cells leads to an abnormal uptake of certain amino acids, such as L-tyrosine, which can be detected. Clinical studies have shown [^{18}F]-FET to have a high sensitivity (87%) in the diagnosis of brain tumors but limited specificity (68%), due to the passive influx and limited uptake in tissues (10).

[^{18}F]-Fluorothymidine ([^{18}F]-FLT) is another PET radiotracer used in oncology, especially in therapy response evaluation and in brain tumors. FLT acts as a cellular proliferation biomarker, that is transported inside the cell in the same way as thymidine, but due to the overexpression of the TK-1 enzyme in tumors, FLT undergoes phosphorylation and it predominantly accumulates inside them (11).

[^{18}F]-Fluorocholine ([^{18}F]-FCH) is used to signal rapid cellular metabolism, as the lipid choline is the precursor for the biosynthesis of phosphatidylcholine (PC) and thus for many PC rich cellular membranes, such as cancerous cells (12). [^{18}F]-FCH has been used extensively to image prostate cancer and to monitor the effects of therapy (13, 14).

Beyond oncological applications, certain ^{18}F based PET radiopharmaceuticals have been developed for the diagnosis of Alzheimer's disease, such as [^{18}F]-Florbetaben and [^{18}F]-Flutemetamol (15, 16). Both of these tracers help visualize the presence of β-amyloid plaques (Aβ) in the brain and have recently received approval for medical use by the FDA and the EMA. As with all radiopharmaceuticals, the drug is only produced when needed, in limited quantity, due to the high cost and time consuming nature of the synthesis and quality control procedures, that reduces the useful ^{18}F radioactivity (17).

The use of positron emission tomography has also found widespread use in medical research, as it enables the *in vivo* examination of cerebral functions, especially concerning the activity and role of certain neural receptors (18).

[^{18}F]-Mefway is 5-HT_{1A} serotonin receptor antagonist, that has shown high stability and selectivity in both animal and human studies (19, 20). These initial results make ^{18}F-Mefway a highly useful tool to quantify the serotonin 5-HT_{1A} receptor distribution, which may assist the diagnosis and evolution of various central nervous system disorders, such as depression, anxiety and Alzheimer's disease (21). Similar to [^{18}F]-Mefway, MPPF is also a serotonin receptor antagonist with increased use in academic and medical centers, for preclinical and clinical studies (22).

[^{18}F]-Nifene is a PET radiotracer that acts as an agonist to α4β2* nicotinic acetylcholine receptors (23). These receptors have been shown to be involved in the evolution of certain brain disorders such as Parkinson's, Alzheimer's and schizophrenia, and a precise and reliable technique to analyze their distribution and activity *in vivo*, could hold the key to early diagnosis and treatment (24-27).

CARBON-11

Due to the natural abundance of carbon in organic matter, ^{11}C can be attached to various organic molecules without disrupting their function within the target organism. There are a number of possible reactions that yield ^{11}C, but the most common and the most relevant for routine production in small medical cyclotrons is the $^{11}N(p, \alpha)^{11}C$ nuclear reaction. ^{11}C decays 98.1% by β^+ and 0.19% by electron capture, with a half-life of 20.3 minutes, making it a useful radionuclide for PET imaging. Using natural nitrogen gas with a small percentage of O_2 (0.1-0.5%) will yield [^{11}C]-CO_2, while using nitrogen gas with a small percentage of hydrogen (5-10%) will yield [^{11}C]-CH_4. Due its short half-life the time available for the labeling and diagnostic procedures is limited, but this also means that the dose received by the patient is lower when compared to ^{18}F based radiotracers (28).

Beyond $^{11}CO_2$ and other simple molecules, like ^{11}CO and $^{11}CH_3I$, ^{11}C labeled organic molecules are widely available for PET investigations, such as amino acids, enzymes, tumor specific receptors and drugs (29). As with ^{18}F, a comprehensive study of all the different ^{11}C based radiotracers would be beyond the scope of this review, thus we will focus instead on the most common and widely used tracers available.

[^{11}C]-Acetate was found to be highly versatile and it has widespread use in many PET centers, for oncological applications, such as for the diagnosis of brain tumors

(30) and prostate cancer (31, 32). The use of [^{11}C]-acetate for hepatocellular carcinoma (HCC) was proven very effective and it exhibited a higher sensitivity when compared to ^{18}F-FDG (33). Outside of oncology, [^{11}C]-acetate has been used in cardiology, for the study of myocardial blood flow (MBF), cardiac input and cardiac efficiency (34, 35).

[^{11}C]-Choline is one of the most important PET imaging radiotracers. The use of choline labeling was stated previously, when we presented [^{18}F]-choline, but the use of ^{11}C is more advantageous, as it offers a lower radiation exposure to the patient. In this regard ^{11}C-Choline has been used to study prostate (32, 36) and breast cancer (37) as well as brain tumors, where it was shown to have a higher specificity than ^{18}F-FDG (38).

[^{11}C]-Methionine ([^{11}C]-MET) is another commonly used PET tracer for the imaging of brain tumors, due to specific upregulated amino acid transporters (39). [^{11}C]-MET has a high specificity and sensitivity in detecting most malignant tumors (40), having a greater ability to outline the region of low-grade glioma when compared to [^{18}F]-FDG (41).

Several other ^{11}C radiotracers are used in biomedical research, on animal or human studies.

[^{11}C]-DASB has been used for PET neuroimaging, for the study and treatment of major depressive disorder (42, 43). Due to its high selectivity for serotonin transporter, imaging during treatment with selective serotonin reuptake inhibitors (SSRIs) allows for the evaluation of their effectiveness on patients (42, 44).

25B-NBOMe is a derivative of the psychedelic drug 2C-B, that acts as an agonist of the $5HT_{2A}$ serotonin receptor, which through radiolabeling with ^{11}C becomes a valid PET radiotracer, named [^{11}C]-Cimbi-36 (45). [^{11}C]-Cimbi-36 may act as a functional marker for the $5HT_{2A}$ receptors in the human brain, involved in the pathophysiology of a variety of brain diseases such as depression, Alzheimer's disease, and schizophrenia (46).

[^{11}C] labeled Flumazenil is a selective $GABA_A$ antagonist used as a radiotracer to assess the distribution and function of these receptors in relation to epilepsy evolution (47).

NITROGEN-13

Nitrogen-13 is generally produced by irradiating a water target with a proton beam, by way of $^{16}O(p, \alpha)^{13}N$ nuclear reaction. The reaction produces nitrate (NO_2^-) and nitrite ions (NO_3^-) which are later converted into ammonia ([^{13}N]-NH_3), either directly in the target by using a reducing agent (48) or a radical inhibitor, or later following a reduction reaction (49).

Due to its short half-life (9.97 min), the use of ^{13}N in nuclear medicine is limited to facilities that have access to a cyclotron, the production and labeling procedures needs to be fast and efficient to ensure minimal loss and the biological half-life of the radiopharmaceutical needs to match the radionuclide's physical half-life. Currently ^{13}N labeled ammonia (NH_3) is the only viable radiotracer used in clinical practice. [^{13}N]-NH_3 is taken up by the myocardium and the brain, where it is used for the imaging and measuring of the myocardial and cerebral blood flow (50) while the use of simple [^{13}N]-N_2 has been applied for nitrogen fixation and ventilation studies (51). Although the use of [^{13}N]-NH_3 has become

more common, ^{13}N has limited use, which is unfortunate when considering the large variety of complex and biologically active molecules that contain nitrogen. Fortunately, several studies have reported the synthesis of more complex molecules.

The synthesis of [^{13}N] labeled amino acids has been reported, such as L-[^{13}N]-asparagine L-[^{13}N] glutamate, L-[^{13}N]-valine, L-[^{13}N]-alanine and L-[^{13}N]-leucine through either chemical or enzymatic techniques but the fast synthesis procedures provided limited purification which made it unacceptable for human use (52).

^{13}N based amines and amides, such as [^{13}N] labeled amphetamine, β-phenethylamine (PEA) and [^{13}N]-adenosine have been produced but none demonstrated any significant use (53-55).

The use of microfluidic systems, which have been employed for other PET radioisotopes, my offer an useful alternative to traditional synthesis methods (56).

Thus, it is important to understand that although ^{13}N is currently much less developed than the previous radioisotope-based tracers, research is being conducted on faster and more reliable labeling and synthesis techniques that could provide more versatility to this PET radionuclide in the near future.

OXYGEN-15

^{15}O was one the first artificial radioisotopes produced using low energy cyclotrons either through the $^{14}N(d, n)^{15}O$ or the $^{15}N(p, n)^{15}O$ nuclear reactions, depending on the cyclotron capabilities (deuteron or proton beam). The ^{15}N production reaction is the only feasible reaction for small energy medical cyclotrons but the expensive enriched nitrogen-15 gas limits the use of ^{15}O based radiotracers. In both scenarios, a nitrogen gas target is used - which yields ^{15}O in gaseous form. Having the shortest half-life (2.06 min) when compared to the previous PET radioisotopes, the processing available is minimal and certain circumstances being carried out inside the cyclotron target system.

^{15}O is mainly used for the synthesis of [^{15}O]-water, either by adding 5% hydrogen directly in the target or by transferring the ^{15}O to a 400°C oven, where it undergoes platinum catalysis in the presence of high grade hydrogen (57). [^{15}O]-water is used for measuring cerebral (58) and myocardial blood flow, undergoing free-diffusion across cellular membranes, and having a 100% extraction rate, which makes it superior to other PET radiotracers (59). But practical limitations, due to its low resolution and low half-life, combined with the previously mentioned high production costs, make the use of [^{15}O]-water generally rare, even though its usage has been approved by both the FDA and EMA.

Although not very common, studies using ^{15}O labeled gases have been reported. ^{15}O-CO_2, ^{15}O-O_2 and ^{15}O-CO_2 have been used for *in vivo* measurements of cerebral oxygen metabolism, cerebral blood flow and cerebral blood volume in animals that may pave the way for their use in human research and clinical practice (60, 61).

CONCLUSIONS

As small medical cyclotrons designed for routine PET isotope production will become more efficient, more automated and accessible, PET imaging for either clinical or research purposes will become even more common and thus it is important to understand the full diagnostic potential

of the most readily available radioisotopes: ^{18}F, ^{11}C, ^{13}N and ^{15}O. The aim of this mini review was to highlight that these nuclides are highly versatile and with the development of novel synthesis techniques their potential is ever expanding.

NEWS

CANCER: "OFF-THE-SHELF" STEM CELL TREATMENT ENTERS CLINICAL TRIAL

Now, researchers at the University of California (UC) San Diego School of Medicine are running a clinical trial with industrial collaborator Fate Therapeutics to investigate NK cells both alone and in combination with checkpoint inhibitors in people with advanced solid tumors. One particular factor sets this study apart from others using NK cells for similar purposes. This "off-the-shelf" NK immunotherapy trial is the first in the U.S. to use cells that the researchers have derived from induced pluripotent stem (iPS) cells. The use of iPS cells allows researchers to produce a never-ending stream of cells. All that they need is a robust method to turn iPS cells into the particular cell type that they require. A single iPS cell can thus become an "off-the-shelf" source of cells for therapy, which it is easy to produce time and time again. In 2013, Dr. Dan Kaufman - professor of medicine in the Division of Regenerative Medicine and director of cell therapy at UC San Diego School of Medicine - and his team developed a method of expanding large numbers of NK cells from human iPS cells for cancer therapy. They published the method in the journal Stem Cells Translational Medicine. After extensive preclinical testing, the Food and Drug Administration (FDA) gave Dr. Kaufman and Fate Therapeutics the go-ahead last November to set up a phase I clinical trial to test their iPS-derived NK immunotherapy in people with advanced solid tumors. The phase I trial started in February and will include up to 64 people with advanced, untreatable cancer. The main aim of the trial is to assess the safety of the treatment. The other objectives are to determine the extent to which the tumors respond to NK cell therapy and to find out how long the cells stay in the participants' bodies. The team will administer the cells once per week for 3 weeks, either on their own or in combination with one of three checkpoint inhibitors, namely nivolumab, pembrolizumab, or atezolizumab. The study is an open-label trial, which means that all of the study participants will know which treatment they are receiving. "This is a landmark accomplishment for the field of stem cell-based medicine and cancer immunotherapy" explains Dr. Kaufman in a press release. "This clinical trial represents the first use of cells produced from human-induced pluripotent stem cells to better treat and fight cancer". "Together with Fate Therapeutics, we've been able to show in preclinical research that this new strategy to produce pluripotent stem cell-derived natural killer cells can effectively kill cancer cells in cell culture and in mouse models" he continues. The first person to receive treatment as part of the trial was Derek Ruff. After 10 years in remission, Mr. Ruff has stage 4 colon cancer, which is progressing despite aggressive treatment. It will be a while before the results of the trial are available, with expectations being that the study will run into 2022. However, it paves the way not only for a new generation of immunotherapies to treat cancer but also for other iPS-derived cell therapies to follow (https://www.medicalnewstoday.com/articles/324916.php).

EARLY RECURRENCE IN FAVORABLE STAGE II BREAST CANCER-WHICH APPROACH IS THE BEST ? (Abstract) : **Aim** : Changing the sequence of therapeutic options in stage II breast cancer : first, a core biopsy, followed by the evaluation of the tumoral markers, adaptation of the chemotherapy scheme and finally, surgical approach. Thus would be possible to improve the hope of life in some stage II breast cancer patients, in whom survival is poorer than in some stage III patients. **Material and method** : 144 patients in stage II breast cancer were included in this study, over a period of 5 years (2000-2004). In all these patients the first therapeutic option was surgery (radically modified mastectomy type Madden), followed by systemic chemotherapy-FAC or FEC, 6 cycles, and finally Tamoxifen. **Results** : 34 out of them developed metastases in a period between 6 and 72 months, most of them in the first 26 months ; 25 out of these 34 didn't have metastases in the axillary lymph nodes, and in 18 patients estrogen - and progesterone - receptors were highly positive. HER 2 neu was negative or low expressed in patients with metastases. CD 34 wasn't evaluate in the whole group. **Conclusions** : Early onset of metastases in the studied patients, in whom tumoral aggressiveness markers were not obvious, impose the evaluation of the angiogenesis markers and, when positive, chemotherapy as the first therapeutic option. **Key words** : STAGE II BREAST CANCER, CORE BIOPSY, TUMORAL MARKERS, NEOADJUVANT SYSTEMIC CHEMOTHERAPY

Stage II breast cancer, considered as a curable clinic stage, benefits today of surgery, as the first therapeutic sequence, followed by radiotherapy (for those operated conservative), and chemo-hormono-therapy, monoclonal antibodies, depending on the tumoral markers.

The last WHO classification-2008-, includes in stage II the following categories : St. IIA : T0-1 N1 M0 ; T2 N0 M0, and St.IIB : T2 N1 M0 ; T3 N0 M0 (1). Most of the patients with stage II breast cancer have a better prognostic in comparison with patients in stage III, as well known for many years. Meantime, it is a reality that some patients in stage II have a disease-free survival and overall survival shorter, comparative with patients in stage III. Tumoral markers'analysis should, theoretically, find the explanation of certain more aggressive biological tumors, thus explaining the negative evolution of some stage II breast cancers in the first five years after the beginning of treatment : the presence of tumoral emboli, the presence of different histological types in the same tumor, positive axillary lymph

nodes, type III histological gradding, mitotic index greater than 1,2, estrogen receptor (ER) and progesterone receptor (PR) negative, HER-2 neu negative(triple negative). It is true the fact that some patients in stage II with positive tumoral markers have an unexpected prolonged survival, while part of the patients in the same stage II, with negative tumoral markers-axillary lymph nodes without metastases, estrogen and progesterone receptor positive in high percentage- develop in a period of months-years after the onset of adjuvant therapy, metastatic disease and death. This evolution could be explained by the incomplete evaluation of the tumoral aggressiveness with the actual tumoral markers, thus avoiding to use more specific therapeutic options in such cases; another explanation could be the delay in starting the systemic therapy when the first sequence was surgery; on the other hand, surgery itself, when applied first, could be considered as a "whip" for the systemic disease, favoring the installation of the metastatic disease.

MATERIAL AND METHOD

Between January 2000 and December 2004, 455 patients were operated for breast cancer in our unit; 66 were stage I, 144 stage II, and 245 were stage III. Patients in stage II were submitted to surgery as the first therapeutic option, including a radically modified mastectomy type Madden; axillary dissection was performed with an en-bloc removal of the connective tissue, and the three levels of the axillary lymph nodes. Adjuvant therapy was applied after 14 days from the surgical excision in patients with positive axilla it consisted in chemotherapy FAC or FEC (considered standard after 1990), 6 cycles in 6 months, and Tamoxifen for 5 years, in patients with high levels of estrogen and progesterone receptors. Fourteen patients in the group with negative axilla couldn't benefit of standard chemotherapy, due to severe myocardiopathy.

RESULTS

Our study analyses almost exclusively patients with unfavorable evolution. Thirty four patients out of 144 in stage II breast cancer developed metastases in a period between 6 and 72 months postoperatively, most of them in the first 26 months: 11 -pulmonary metastases, 8 –bone metastases,

	PATIENTS
pulmonary metastasis	11
bone metastasis	8
pulmonary and bone metastasis	5
hepatic metastasis	3
cerebral matastasis	1
local recurence	3
bone metastasis and local recurence	3

Fig. 1. Developed metastasis in a period of 6-72 months postoperatively for patients in stage II

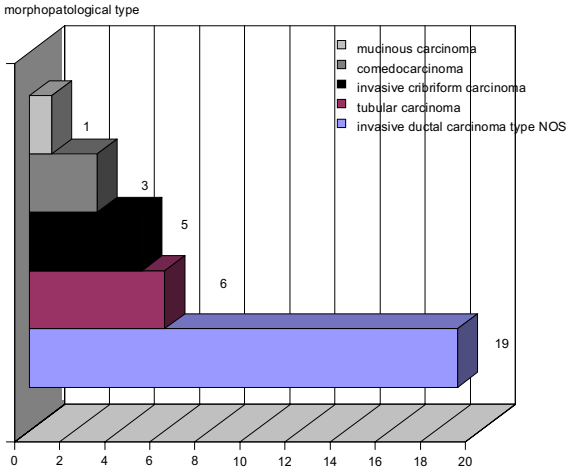

Fig. 2. Morphopatological types for patients in stage II breast cancer with unfavorable evolution

5-pulmonary and bone metastases, 3-hepatic metastases, 1-cerebral metastases, 3-bone metastases and local recurrence and 3 with local recurrence (fig.1).

As from morphopathological point of view, most of the tumors were ductal invasive carcinoma (one third of the patients), followed by tubular carcinoma and invasive cribriform carcinoma (fig.2).

Patients with pulmonary, cerebral and hepatic metastases were not alive at the moment of the evaluation, death occurring between 3 and 14 months from the onset of metastases. Patients who died of metastatic disease were aged between 49 and 81 years, with a median of 61,47 years. Sixteen patients with pulmonary metastases and pulmonary plus other metastases, as well as 2 patients in the group with hepatic metastases didn't have metastases in the axillary lymph nodes; estrogen and progesterone receptors were > 70%, HER- 2neu was negative or poor expressed (fig. 3) Seven patients in the group with bone metastases didn't have invasion in the axillary lymph nodes, and the receptors for estrogen and progesterone were in low percentage.

CD 34 wasn't evaluated in the whole group of the patients included in the study, so that we can't make any comments for the patients that had a good evolution. CD 34 was moderated or over-expressed in 8 patients who developed pulmonary metastases,

pT2	60-96
pT1,pT2,pT3	60-117

3 patients with hepatic metastases, 5 patients with bone metastases and in 2 patients with bone metastases and local recurrence (fig. 4).

Out of the patients with tumors greater than 2 cm, 39 were alive, without clinical recurrence in the moment of evaluation (between 60 months and 96 months) (tab. I) and the disease – free survival in all patients ranged between 60 and 117 months (tab. I).

DISCUSSIONS

The benefit of adjuvant chemotherapy in breast cancer was established in many prospective randomized trials, started in the last 40 years. A comprehensive meta-analysis of all randomized trials prior to 1985 (Early Breast Cancer Trialist's Collaborative Group) and published in 1992, including 75.000 patients, showed the advantages of poly-chemotherapy in terms of survival, especially in women aged under 50. Before 1990, standard chemotherapy in breast cancer consisted in Cyclophosphamide plus Methotrexate and Fluorouracil. The association of anthracyclines (Doxorubicin or Epirubicin) with Fluorouracil and Cyclophosphamide (FAC or FEC) for a period of 3-6 months, after 1990, was correlated with the improving of the clinical results, thus becoming the standard therapy (2). For patients in stage II with positive axilla, chemotherapy reduces the risk of death with 15%. The association of Paclitaxel to the standard treatment of Doxorubicin and Cyclophosphamide, improved the 5 years disease-free survival to 70%, and the overall survival to 80%, in comparison with 65% and respectively 77%, reached in anterior studies (2). More recently, the association of another Taxane-Docetaxel with Doxorubicin and Cyclophosphamide, improved the efficacy of chemotherapy in comparison with FAC(3).

Another problem is represented by the patients with negative axilla, as one third of them will develop metastatic disease, thus negative axillary lymph nodes cannot preclude the systemic treatment. In this group, patients with tumors greater than 2 cm have a recurrence risk equivalent to those with one or two positive lymph nodes (4,5). Most of the studies consider that the most important, reliable and simpliest indicator in assessing the risk of recurrence in stage II patients with negative axilla is the volume of the tumor. In our database, more than 30% of the patients with tumors greater than 2 cm were alive in the moment of evaluation. Another useful criteria in evaluating the recurrence in patients with negative axilla is represented by a series of histopathological types, considered to have a lower tumoral aggressiveness. Thus, a study conducted in Sloan-Kettering Memorial Center on 767 women with negative axillary lymph nodes have demonstrated that the ductal invasive carcinoma type NOS, found in tumors less than 1cm, had a recurrence of disease of 13% at 21 years of follow-up (6). Despite all these data, many prognostic factors were not identified up to now for clinically curable breast cancers, as showed by Donegan 20 years ago (7).

It is known today that certain fenotypes of cells, structuring the tumor, present some aggressiveness factors, thus offering a lower or higher risk for developing the systemic disease. These prognostic tumoral markers have also the role in adjusting the therapeutic protocol to be followed by the patient: the status of steroid hormones, the expression of HER 2neu, CD 34 or other angiogenesis tumoral markers. Around 15 years ago, some medical centers have proposed the utilization of computerized programs which incorporate the effects of the prog-

nostic factors, thus establishing an individual risk (8).

The first therapeutic option in patients with positive estrogen- and progesterone-receptors is Tamoxifen, which is less toxic comparative with chemotherapy.

The benefit of Tamoxifen in cases with negative axilla is pointed out by the results obtained in large series of patients with positive receptors, treated over a period of 5 years ; thus, recurrence was reduced with 47% per year, and the absolute benefit at 10 years of follow-up was of 5-7% (9). More recently, aromatase inhibitors, such as anastrozole (10), letrozole (11), aromasin (12), have improved the clinical benefit for patients with positive receptors. The value of combined chemo-hormono- therapy in patients with negative axilla isn't yet well established by the clinical trials.

Based on data published in literature by the different trials, our study tries to analyze the rapid unfavorable outcome of some patients with stage II breast cancer, who didn't have lymph node metastases, hormone receptors were positive, Her 2 neu negative or low expressed. This group of patients, who rapidly evoluted unfavorable, included women in late menopause, who presented T 2 tumors (most of the patients--32 cases), and histologically was confirmed the common type of breast cancer (28 cases). The tumoral aggressiveness factors were not presented in these cases (the triple negative character, positive axilla, the association of combined histological types in the same tumor, the presence of emboli in peritumoral vessels), exception making the size of the tumor (T2).

Patients in whom recurrence early occurred and died of metastatic disease were adjuvantly treated with chemotherapy and Tamoxifen, excluding those with myocardiopathy, who couldn't benefit of chemotherapy due to its cardiotoxicity (13,14).

The unfavorable outcome of these patients can be also explained by the heterogenous aspect of tumors in the same stage of disease, which have molecular differences even they are histological similar ; it is known in literature the new molecular classification of breast cancer, based on gene expression profile (15). We consider that the early onset of metastases in our cases could be also favored by the delay in the beginning of chemotherapy, due to surgical treatment (as first therapeutic option), and, on the other hand, surgery acted as a "whip" for the systemic disease, favoring the early onset of the hepatic, pulmonary and bone metastases.

These unfavorable conditions in the evolution of the disease could be counterbalanced by changing the sequence of the therapeutic options ; thus, a core biopsy is to be initially performed, followed by an evaluation of the tumoral markers, adaptation of the therapeutic scheme with systemic target, and finally, the surgical approach. In this manner, we could improve the hope for a prolonged survival for these patients.

The value of this hypothesis will or not be confirmed in the future by studies on larger groups of patients, continuing the efforts of identification of risk factors which will allow a better selection of patients for treatment.

NOUTĂŢI

PEPTIDUL GALANIN-LIKE : UN FACTOR CHEIE IN REGLAREA HOMEOSTATICĂ A ALIMENTAŢIEI ŞI A METABOLISMULUI ENERGETIC

Hipotalamusul deţine un rol cheie în reglarea comportamentului alimentar, a reproducerii şi a metabolismului energetic. Peptidul galanin-like este un neuropeptid alcătuit din 60 de aminoacizi, produs de o populaţie discretă de neuroni din nucleul arcuat bazomedian şi eminenţa mediană, trimiţând proiecţii spre nucleul anterior paraventricular. În prezent se consideră că acest peptid exprimă receptori pentru leptină, care intervine direct în controlul saţietăţii şi implicit în instalarea obezităţii. Stimularea constantă a producerii peptidului galanin-like acţionează la distanţă asupra altor peptide reglatoare, inclusiv asupra leptinei, întrucât neuronii care îl sintetizează formează reţele care se regăsesc pe spaţii extinse. La animale de laborator, peptidul galanin-like induce o scădere a consumului alimentar, putând reprezenta o soluţie de viitor în terapia obezităţii (Shioda S, Kageyama H, Takenoya F, Shiba K. Galanin-like peptide : a key player in the homeostatic regulation of feeding and energy metabolism. *Int J Obes* 2010 ; 12 : 132-136).

NOVEL APPROACHES IN THE PHARMACOTHERAPY OF RHEUMATOID ARTHRITIS (Abstract): Rheumatoid arthritis is an autoimmune disease, a chronic inflammatory disease that affects more than the joints. There is currently no cure for rheumatoid arthritis, but remarkable progress has been made over the last two decades in therapeutic regimens, with the possibility of long-lasting remission and in particular, prevention of sequelae (joint deformities, ankylosis, reduced mobility and functional capacity). Various drugs are used in the pharmacological treatment: nonsteroidal anti-inflammatory drugs, corticoids, disease-modifying anti-rheumatic drugs, biological agents (acting on the immune system, reducing its erratic activity, with maximum efficacy combined with disease-modifying anti-rheumatic drugs). **Keywords:** RHEUMATOID ARTHRITIS, NON-STEROIDAL ANTI-INFLAMMATORY DRUGS, BIOLOGICAL AGENTS.

Rheumatoid arthritis (RA) represents an inflammatory disorder that particularly concerns extremity joints (hands, legs) causing injuries, swelling, deformities of the regions and pain. Statistical data show that this disease can occur at any age, even in children (juvenile RA), but usually affects individuals aged 25 to 50 years, with a higher incidence in women compared to men (1, 2).

Over time, degenerative manifestations worsen, the erosions and destructions of cartilages, ligaments and bones causes local fibrosis that progressively deforms the extremities, generating from mild to particularly severe disabling disease forms. Moreover, pain, local deformities and functional impotence affect the day-to-day, domestic and occupational activity of patients (2). In parallel, existing autoimmune reactions induce extra- articular manifestations, affecting other systems such as the connective tissue, the cardiovascular system or respiratory system. There are situations in which the pain is particularly intense and limits the joint movements, significantly affecting their functionality and implicitly the motor activity of the person, who will present various degrees of disability.

The mechanisms involved in the etiopathogenesis of this disease have not been fully elucidated yet, but the most viable pathophysiological hypothesis implies the intervention of autoimmune processes, especially in susceptible individu-

als (3). An idea that has been raised is that under the conditions of particular predisposing genetic factors, the action of certain triggers (such as trauma, stressful situations, infections, smoking, alcohol consumption) induces an autoimmune reaction, causing a series of articular changes with chronic inflammation and synovial hypertrophy, as well as extra-articular manifestations (in the pulmonary and circulatory system) (4, 5).

Nearly all compartments of the lung structure are potential sites of injury, common pulmonary manifestations of rheumatoid arthritis being interstitial lung disease (ILD), airways disease (bronchiolitis, bronchiectasis), nodules, pleural and vascular disease (6, 7). ILD is a significant cause of morbidity and mortality which can arise before and throughout lifetime after the diagnosis of RA (6), therefore patients presenting risk factors for ILD or with ILD should be closely monitored for lung function (pulmonary function tests and/or high-resolution computed tomography) (8).

Furthermore, conventional immunosuppressant or biologic drugs (methotrexate, anti-tumor necrosis factor alpha agents, leflunomide, sulfasalazine, rituximab) used in RA therapy are associated with an increased incidence of pulmonary toxicity (7, 8).

CLASSIC PHARMACOTHERAPY

In 2008, recommendations and algorithms were developed for the use of disease-modifying anti-rheumatic drugs, non-biological and biological agents, corticosteroids, non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics for the management of RA; an updated version of these algorithms was later published in April 2012.

Immediately after diagnosis, the main goals of treatment are to control disease activity and to reduce the rate of joint damage, while minimizing pain, joint stiffness, inflammation, and complications (2).

The disease-modifying anti-rheumatic drugs can be classified into non-biological agents and biological agents. Non-biological agents include hydroxychloroquine, azathioprine, sulfasalazine, methotrexate, leflunomide, cyclosporine, gold salts, D-penicillamine, minocycline (2). Gold-injected salts and penicillamine rarely induce sustained disease remissions, which is why their frequent use in the therapy of this condition has largely been replaced by other more effective anti-rheumatic agents.

In October 2013 the USA Food and Drug Administration (FDA) approved for therapeutic use a single-dose methotrexate with a disposable subcutaneous autoinjector for self-administration of the drug. This therapeutic agent is indicated for use in adults with severe active rheumatoid arthritis who have an inadequate response or cannot tolerate the first line of treatment, as well as for children with juvenile idiopathic rheumatoid arthritis.

Corticosteroids are potent anti-inflammatory drugs habitually used in patients with RA in the first stages of the disease, until treatment with disease-modifying anti-rheumatic drugs is necessary (9). These agents can also be effective adjuvants of therapy with disease-modifying anti-rheumatic drugs (2). Administration of corticosteroids as well as NSAIDs may be advantageous, as it allows reduction of required doses of anti-rheumatic drugs modifying the disease (9). There are a few dozen NSAIDs available on the market, but those commonly used in the treatment of RA include ibuprofen, keto-

profen, naproxen, piroxicam, diclofenac, celecoxib. Treatment with chelating agents in RA can suppress inflammation and arthritis by inhibiting the T cell activity.

MODERN PHARMACOTHERAPY

The debate concerning the involvement of tumor necrosis factor alpha (TNF-α) and interleukin-1 (IL-1) as central pro-inflammatory cytokines has led to the development of biological agents that block or inhibit these cytokines (tab. I). In addition to alleviating disease symptomatology and improving the quality of life, all biological agents significantly delay the progression of joint erosions, action that has been radiologically demonstrated (10). It has been highlighted that biological agents are meaningfully more effective than non-biological treatments in improving the joints physical function in patients with RA (11). It is fundamental not to recommend the use of these agents until the failure to treat the disease with at least one non-biologically-modifying antirheumatic drug, usually methotrexate.

The following rheumatic disease modifying agents are mentioned: adalimumab, certolizumab, etanercept, golimumab and infliximab (2, 12). For patients with incipient RA (less than 3 years of development), who have not previously administered methotrexate, the beginning of monotherapy with methotrexate, adalimumab or etanercept effectively controls the symptoms of the disease (11, 13). Combining a biological agent with methotrexate usually improves better the clinical manifestations than monotherapy (10). Rituximab is the most commonly used anti-rheumatic drug in combination with methotrexate in the treatment of RA (14). On the other hand, for patients with incipient RA, the combination of methotrexate and sulfasalazine does not bring significant benefits compared to the use of any of these drugs alone (13).

There is not sufficient evidence to show that combining two biological agents has superior efficacy to the use of any biological agent alone; in addition, it has been pointed out that concomitant use of two biological agents has been associated with an increased risk of complications (the administration of methotrexate and most biological agents increase the probability of a severe infection), but without a clear benefit (11, 12).

In 1998, *etanercept* was the first TNF inhibitor to receive approval from FDA and the European Medicines Agency (EMA) for the treatment of moderate to severe RA and remains a first-line biologic disease-modifying drug therapy for RA worldwide. Other indications for etanercept are psoriatic arthritis, plaque psoriasis, axial spondylo arthritis, ankylosing spondylitis and polyarticular juvenile idiopathic arthritis (15,16). It was found that combination treatment with methotrexate improves functional capacity, disease control and remission compared with monotherapy with either etanercept or methotrexate; discontinuation and side effects are similar (17).

Tocilizumab represents an inhibitor of the IL-6 receptor, and it is indicated for the treatment of moderate to severe active RA in adults with no response to one or more TNF antagonists (2). It has been approved for intravenous infusion or subcutaneous injection and can be used alone or in combination with methotrexate or other disease-modifying antirheumatic drugs (18, 19). The treatment with tocilizumab produces significant improvements in clinical trials in patients with inadequate response to TNF inhibitors, therefore showing that

the association of methotrexate with tocilizumab is more clinically effective than association of methotrexate with adalimumab in rheumatoid arthritis (20).

Anakinra, a recombinant non-glycosylated form, is derived from the antagonist of the receptor for human IL-1 and can be disposed alone or in combination with other disease-modifying anti-rheumatic drugs other than TNF blockers. It is indicated to reduce the symptomatology and reduce the progression of structural damage in moderate to severe active RA unresponsive to treatment with one or more disease-modifying anti-rheumatic drugs (2, 21).

Abatacept is a selective costimulatory modulator that inhibits T lymphocyte activation by binding to CD80 and CD86 (which are proteins, differentiation clusters), thus blocking their interaction with CD28 (22,23). This agent has been approved for the reduction of clinical manifestations because it produces significant inhibition of structural damage progression and improves physical function in adult patients with moderate to severe RA (22). It can be administered in monotherapy or in combination with disease-modifying anti-rheumatic drugs other than TNF antagonists (23). It has been emphasized that in patients with RA with previous failure of treatment with anti-TNF agents, abatacept administration had increased efficacy and safety over long periods of treatment (6 months to 5 years) (22, 24).

TABLE I

Biological agents used in RA therapy (28,29)

Target	Drug	Mode of action	Starting dose	Usual dosage or Maintenance dose
Soluble TNF	Adalimumab	Immunoneutralization		40mg SC every 2 weeks
	Certolizumab		400 mg SC at weeks 0, 2, 4	200mg every other week
	Etanercept	Neutralization		50mg SC once weekly or 25mg twice weekly
	Golimumab	Immunoneutralization		50mg SC once monthly
	Infliximab		3mg/kg IV at 0, 2, 6 weeks	3-10 mg/kg IV every 4-8 weeks
Soluble IL-1	Anakinra	Neutralization		100mg SC daily
Soluble IL-6	Tocilizumab	Neutralization	4 mg/kg IV q 4 weeks	4-8mg/kg IV every 4 weeks
T cells	Abatacept	Prevents co-stimulation of T cells	IV: <60kg = 500 mg; 60-100kg = 750mg; >100 kg= 1000mg at 0, 2, and 4 weeks or initial IV dose followed by 125 mg SC within 24 h	IV: dose based on weight every 4 weeks SC: 125 mg once weekly
B cells	Rituximab	Causes B cells lysis	1000mg IV infusion given twice, 2 weeks apart	Initial dose may be repeated every 16-24 weeks based on response

Adverse effects associated with biological agents include production of antibodies against these compounds, the emergence of antinuclear antibodies, occasional drug-induced lupus syndromes and infections. Rarely, demyelinating disorders, as well as bone marrow suppression (25) may occur. The presence of acute and chronic infections, demyelinating disorders, NYHA class III and IV cardiac insufficiency, recent malignancies, contraindicates the use of TNF inhibitors (2, 24, 26).

Tofacitinib, an inhibitor of the pathogenic pathway of Janus kinase (a non-receptor tyrosine kinase family that mediates the transmission of cytokine-mediated signals), is indicated as a second treatment line for moderate to severe active RA in patients with inadequate or intolerant methotrexate response. It may be administered as a monotherapy or in combination with methotrexate or other non-biological anti-rheumatic agents but is not used in combination with anti-rheumatic biological agents or with potent immunosuppressive agents (for example, azathioprine and cyclosporine) (2, 27).

EXPERIMENTAL THERAPIES IN RHEUMATOID ARTHRITIS

Despite significant progress over the past decades, RA continues to be a chronic disease. It remains active in many patients whose general condition does not partially, or completely respond to disease-modifying anti-rheumatic drugs. Therefore, efforts are continually being made to discover new effective therapeutic agents.

Experimental research and clinical studies include:

- new biological agents with B cell targeting for CD20, including: atacicept, AMG 623, B3-fcc, Br3-Fc, belimumab, epratuzumab, ofatumumab, ocrelizumab and TRU-015 (30);

- small molecules directed on enzymes, involved in signal transduction of TNF and other pro-inflammatory cytokines are also studied in RA (31);

- a Phase II clinical study reported that, compared with placebo, examatinib, a spleen tyrosine kinase inhibitor, reduced disease activity in patients with RA unresponsive to methotrexate therapy. However, additional investigations are needed to determine the safety and efficacy of this agent in patients with RA (31, 32);

- the administration of agents that produce matrix metalloproteinase inhibition, or agents that inhibit osteoclast activity, although initially failed to be effective, may still be taken into consideration in the treatment of RA (30);

- immunosuppressive drugs in high dosage combined with autologous stem cell transplant have been used in study protocols for patients with resistance to other therapies (2).

CONFLICT OF INTERESTS

There are no conflicts of interest. All authors made equal contribution to the paper, to that of first authors, and thus share main authorship.

TRADITIONAL CHINESE MEDICINE USED ON PATIENTS WITH RHEUMATOID ARTHRITIS: ALTERNATIVE OR COMPLEMENTARY TREATMENT?

The use of traditional Chinese medicine (TCM) on patients with rheumatoid arthritis (RA) had a magnitude of 30% as compared to the general population of Taiwan, according to the results of retrospective cohort study used the Longitudinal Health Insurance Database (LHID) 2000. The authors, Ming Chi-Lu and colleagues, aimed to describe the utilization of TCM and determine the factors related to TCM usage among RA patients. Herbal remedies (49.6%) constituted the most commonly used therapeutic approach, followed by combined therapy (32.7%) and acupuncture or traumatology manipulation alone (17.7%). The profile of the patients who used TCM is female, younger age, higher monthly income and higher Charlson-Deyo co-morbidity index scores, living in urbanized areas, in higher TCM physician density. The top three reasons for seeking TCM services were diseases of the musculoskeletal system and connective tissue, the respiratory system, and the digestive system.(Lu MC, Livneh H, Chiu L M, Lai NS, Yeh CC, Tsai, TY 2019. AGNOGENIC MYELOID METAPLASIA IN PREGNANCY. CASE REPORT (Abstract): Idiopathic myelofibrosis is a rare myeloproliferative disorder characterized by excessive accumulation of connective tissue in the bone marrow in association with anemia, splenomegaly and extramedullary hematopoiesis. A rare case of pregnancy in a patient with agnogenic myeloid metaplasia who carried a term pregnancy is described. In spite of the increased perinatal risks, a favorable outcome was possible with close antepartum surveillance. Conclusion: Idiopathic myelofibrosis was once thought to be a contraindication to pregnancy. With careful management, successful pregnancies can be achieved. **Key words**: AGNOGENIC MYELOID METAPLASIA, PREGNANCY, VENOUS THROMBOEMBOLISM

STUDY ON THE PREVALENCE AND RISK FACTORS FOR CARIES ADJACENT TO POSTERIOR COMPOSITE RESIN RESTORATIONS

STUDY ON THE PREVALENCE AND RISK FACTORS FOR CARIES ADJACENT TO COMPOSITE RESIN CORONAL RESTORATIONS (Abstract). **Aims** of the study were as follows: to determine the prevalence of caries adjacent to direct posterior composite resin restorations (CARS); to analyze the distribution of caries adjacent to coronal restorations in relation to socio-demographic, individual, and local parameters; to identify significant risk factors associated with caries adjacent to composite resin coronal restorations. **Materials and methods**: The retrospective study included 45 patients (mean age: 23.40 ± 4.027 years; gender: 31 males, 29 females) with 305 direct nanohybrid composite restorations aged 1-5 years. Univariate analysis was used to identify risk factors and odds ratios for the occurrence of CARS. Multivariate analysis was performed to identify combinations of risk factors that significantly increased the probability of CARS. The association between CARS and marginal integrity was assessed by the Spearman test. **Results:** According to FDI criteria, 8.9% of restorations had a score of 12.4 (micro-cavitated CARS extended to dentin), 3.9% had a score of 12.5 (cavitated CARS). Odds ratio for CARS were 2.135 for high caries risk, 2.179 for female gender, and 19.19 for impaired marginal integrity (scores 6.2-6.5) (OR 19.19). **Conclusions:** The prevalence of CARS in micro-cavitated and cavitated stage was 26.6%. Risk factors for CARS in direct posterior composite resins restorations were high cariogenic risk, female gender, and impaired marginal integrity. Risk predictors for caries adjacent to posterior composite resin coronal restorations, identified in multivariate analysis, were female gender and impaired marginal integrity. The risk of developing CARS increases progressively with the degree of marginal integrity impairment. **Keywords:** COMPOSITE RESTORATIONS, CARS, PREVALENCE, RISK FACTORS.

INTRODUCTION

Caries adjacent to restorations are considered the most common biological criteria leading to decisions for repair or replacement, significantly affecting the longevity of the involved teeth and increasing healthcare costs (1). Epidemiological studies report wide variations in the prevalence of caries adjacent to coronal restorations, depending on geographic regions and the demographics of the investigated population groups. A prevalence of 3.6% for caries adjacent to restorations (CARS) was reported in a study involving clinical and radiographic examination of 4,036 restorations in a cohort of 450 patients (2), while another research group found a prevalence of 12% for caries adjacent to coronal restorations made of nanohybrid or micro hybrid composite resins at 15 years post-treatment (3). A system-

atic review reported an average annual failure rate of 1.8% after five years and 2.4% at ten years post-treatment, with most failures attributed to CARS (4). In a population-based study conducted in the North-Eastern region of Romania, prevalence of CARS was between 13.5% (5) and 23.23% (6) of posterior composite-based restorations within 2-5 years post-treatment. Since the primary goal of clinical and therapeutic management of caries adjacent to coronal restorations is to control etiological factors and halt the progression of active lesions through non-operative or minimally invasive preventive methods, understanding the processes involved in the pathogenesis of these carious lesions is essential for selecting and developing the most effective approaches to avoid repeating the restorative cycle. Patient-related risk factors that can significantly contribute to the failure of composite resin coronal restorations include high cariogenic risk, smoking status, and periodontal involvement of teeth with Class II or Class V cavities (7). Material-related factors are critical and can lead to different scenarios of recurrent caries incidence (8). Regarding the influence of composite resin type on the likelihood of marginal defects, hybrid composites, nanofilled composites, and condensable composites exhibit the lowest polymerization shrinkage values (9). The elasticity modulus of composite resins materials can affect the marginal adaptation and stress distribution, resin composite with the highest modulus of elasticity resulting in the highest number of gap-free enamel margins but with an increased incidence of enamel fractures (10, 11). Regarding the clinician's role, their competencies are partially associated with the occurrence of caries adjacent to coronal restorations, influencing significantly the decisions of repair *vs.* replacement (12).

AIM OF STUDY

The objectives of the study were as follows:

- to determine the prevalence of caries adjacent to composite resin coronal restorations;
- to analyze the distribution of caries adjacent to coronal restorations in relation to socio-demographic, individual, and local parameters;
- to identify significant risk factors associated with caries adjacent to composite resin coronal restorations.

MATERIALS AND METHODS

The retrospective study included 45 patients (mean age: 23.40 ± 4.027 years; gender: 31 males, 29 females; p=0.091) who presented for various treatments at the Clinical Base of the Faculty of Dental Medicine, "Grigore T. Popa" U.M.Ph. Iași (Romania). A clinical examination was conducted to evaluate 305 direct nanohybride composite restorations aged between 1 and 5 years. The research was carried out in accordance with the ethical principles of the Declaration of Helsinki and received approval from the Ethics Committee of "Grigore T. Popa" U.M.Ph. Iasi. All patients were informed about the study objectives and provided written informed consent.

Inclusion criteria: occlusal and occluso-proximal posterior composite restorations; cavities classified as ICDAS 05-06; vital molars/premolars; age ≥ 18 years.

Exclusion criteria: non-carious lesions; bruxism; high consumption of cola beverages, coffee, or black tea.

The independent variables evaluated as risk factors for CARS were:

- Black's classification (Class I *vs.* Class II);
- gender (male *vs*. female);
- restoration age (1-2 yrs. *vs*. 3-5 yrs.);

- cariogenic risk (high *vs*. low);
- arch location (maxilla *vs*. mandible);
- dental group (molar *vs*. premolar).

CARS diagnosis and the assessment of CARS stage were performed according to FDI criteria (13). The patient's caries risk was determined by assessing anamnesis and intraoral risk factors, as well as caries disease indicators. The presence of at least two risk factors and one caries disease indicator classified the patient as high cariogenic risk.

Statistical analysis. The statistical analysis was conducted using *SPSS version 29.0*. The analyzed parameters were described using frequency distributions and descriptive statistics. Univariate analysis was performed to identify risk factors and odds ratios for the occurrence of CARS. Multivariate analysis was employed to identify combinations of risk factors that, when present in the same patient, significantly increased the probability of CARS. The identified risk factors were incorporated into a logistic regression model to determine their cumulative effect on risk of CARS. The association between CARS and marginal adaptation was characterized by calculating Spearman's nonlinear correlation coefficients.

RESULTS

Distribution of posterior composite resins direct restorations was as follows (table 1):

- By gender: 47.9% of restorations were evaluated in male patients, while 52.1% were evaluated in female patients.
- By restoration age: 47.5% of restorations were evaluated at 1-2 years post-treatment, while 52.5% were evaluated at 3-5 years post-treatment.
- By arch location: 46.6% of restorations were maxillary, while 53.4% were mandibular.
- By dental group location: 81% of restorations were located in molars, while 19% were in premolars.

TABLE I.

Distribution of direct posterior composite resins restorations related to analyzed parameters

Gender	male	146	47.9
	female	159	52.1
Age	1-2 yrs.	145	47.5
	3-5 yrs.	160	52.5
Arch	MX	142	46.6
	MD	163	53.4
Dental group	PM	58	19.0
	M	247	81.0
Cariogenic risk	low	217	71.1
	high	88	28.9
Black Class	Class I	246	80.7
	Class II	59	19.3
FDI score	12.1	198	64.9
	12.2	26	8.5
	12.3	42	13.8
	12.4	27	8.9
	12.5	12	3.9
Total		305	100.0

• By cavity type: 80.7% were occlusal restorations (Class I), while 19.3% were proximo-occlusal restorations (Class II).

• By patient caries risk: 71.1% of restorations were evaluated in low-caries-risk patients, while 29% were in high-caries-risk patients.

CARS indices distribution (tab. I):

• 64.9% of restorations were classified as score 12.1 (no caries adjacent to restorations)

• 8.5% were classified as score 12.2 (non-cavitated CARS).

• 13.8% were classified as score 12.3 (micro-cavitated CARS clinically limited to enamel, non-intervention or preventive intervention).

• 8.9% were classified as score 12.4 (micro-cavitated CARS clinically extended to dentine, repair needed).

• 3.9% were classified as score 12.5 (cavitated CARS extended to dentin, replacement required).

Study on correlation between CARS and marginal integrity

The Spearman test demonstrated a strong, positive, and statistically significant correlation (r=0.559) between the quality of marginal integrity of composite resin restorations and CARS diagnosis (tab. II). 100% of coronal restorations with score 12.5 were evaluated with marginal integrity score 6.5. 96.5% of coronal restorations that were not diagnosed with CARS (score 12.1) were evaluated with marginal integrity score 6.1 (tab. III).

Univariate and Multivariate Analysis Studies on Risk Factors for CARS

The results of univariate analysis for risk factors of CARS in table IV. Coronal restorations in female patients have a 2.179 times higher risk of CARS occurrence. High caries risk increases the CARS risk by 2.135 times. Restorations with marginal integrity scores of 6.2-6.5 have a 19.19 times higher risk of CARS compared to coronal restorations with unaffected marginal integrity (score 6.1). The results of the multivariate analysis of predictors for caries adjacent to composite resin coronal restorations are presented in table V.

TABLE IV.

Univariate analysis of risk factors for CARS

		CARS				Pearson Chi-squared	OR (95% CI)
		ABSENT		PRESENT			
		N	%	N	%		
Gender	male	108	54.5%	38	35.5%	$Chi^2 = 10.082$	2.179
	female	90	45.5%	69	64.5%	p = 0.001**	(1.342 ÷ 3.538)
Cariogenic risk	low	152	76.8%	65	60.7%	$Chi^2 = 8.684$	2.135

Black class	Class I	165	83.3%	81	75.7%	$Chi^2 = 2.593$	-
	Class II	33	16.7%	26	24.3%	p = 0.107	
Age	1-2 yrs.	91	46.0%	54	50.5%	$Chi^2 = 0.566$	-
	3-5 yrs.	107	54.0%	53	49.5%	p = 0.452	
Arch location	MX	92	46.5%	50	46.7%	$Chi^2 = 0.002$	-
	MD	106	53.5%	57	53.3%	p = 0.965	
Dental group location	PM	38	19.2%	20	18.7%	$Chi^2 = 0.011$	-
	M	160	80.8%	87	81.3%	p = 0.915	
Marginal integrity	6.1.	53	26.8%	2	1.9%	$Chi^2 = 88.913$	
	6.2.	137	69.2%	60	56.1%	p <0.001**	
	6.3.	2	1.0%	19	17.8%		
	6.4.	6	3.0%	10	9.3%		
	6.5.			16	15.0%		
Marginal integrity	Healthy	53	26.8%	2	1.9%	$Chi^2 = 29.134$	19.190
	Microleakage	145	73.2%	105	98.1%	p <0.001**	(4.574 ÷ 80.507)
Total		198	100.0%	107	100.0%		

Multivariate analysis of CARS risk factors

The Hosmer-Lemeshow goodness-of-fit test indicates that the constructed model is viable. Initially, the prediction accuracy for CARS is 64.9%, while using the model improves the prediction accuracy for CARS to 81.6%. The model explains 44.2% of the variation in CARS (Nagelkerke R coefficient). The predictors included in the model show the following progression:

TABLE V.

Predictors in binary logistic regression model

	Coef. B	p-value	OR	95% C.I. / OR
Age	-0.098	0.025*	0.907	0.832 ÷ 0.987
Gender (1)	0.961	0.004**	2.615	1.368 ÷ 4.996
Cariogenic risk (1)	-0.715	0.070	0.489	0.226 ÷ 1.061
Marginal adaptation		<0.001**		

	Coef. B	p-value	OR	95% C.I. / OR
Marginal adaptation (1)	2.512	<0.001**	12.329	2.853 ÷ 53.276
Marginal adaptation (2)	5.683	<0.001**	293.910	35.499 ÷ 2433.384
Marginal adaptation (3)	4.553	<0.001**	94.938	14.532 ÷ 620.237
Marginal adaptation (4)	25.450	0.998	1.1294E+11	
Constant	-1.474	0.216	0.229	

Equation for binary logistic regression model is as follows: Ln(p/1-p) = -1.474 - 0.098*Age + 0.961*Gender- 0.715* Cariogenic risk + 2.512* Marginal adaptation 6.2. + 5.683* Marginal adaptation 6.3. + 4.553* Marginal adaptation 6.4. + 25.450* Marginal adaptation 6.5.

Based on this equation, the probability of patients developing CARS in the combined presence of the identified risk factors can be calculated, considering the following observations:

- The risk of CARS is 2.615 times higher in women than in men.
- The risk of CARS is 12.329 times higher in patients with marginal adaptation score 6.2 compared to those with marginal adaptation score 6.1.
- The risk of CARS is 293.910 times higher in patients with marginal adaptation score 6.3 compared to those with marginal adaptation score 6.1.
- The risk of CARS is 94.938 times higher in patients with marginal adaptation score 6.4 compared to those with marginal adaptation score 6.1.

DISCUSSION

The identified risk factors in our research included high caries risk, female gender, and marginal adaptation impairment. High caries risk has been classified as a significant risk factor for the occurrence of caries adjacent to composite resin restorations (14). High-risk and non-compliant patients regarding etiological therapy have a significantly higher risk of developing caries adjacent to direct coronal restorations (15). A high caries risk increases the risk of restorative failure by 2-3 times (16). The higher prevalence of caries adjacent to restorations located in molars (*vs*. premolars), as found in our study, is supported by literature data (17). High-caries-risk patients had failure rates of 3.2% at five years and 4.6% at ten years post-treatment, while low-risk patients had significantly lower failure rates of 1.2% at five years and 1.6% at ten years post-treatment (18). Krämmer *et al*. (2015) also reported that direct Class I and II restorations in molars had inferior clinical performance compared to premolar restorations regarding marginal integrity at four years post-treatment (19). The significantly higher prevalence of Class II restorations, noted also in our study, can be explained by the fact that biofilm removal is more difficult at proximal and cervical margins, the enamel in these areas is thin and aprismatic (making acid etching ineffective), access is challenging, and these regions are predominantly subjected to flexural forces (20). A high C-factor can contribute to stress accumulation at the adhesive interface, favoring the occurrence of marginal microleakage (21). In Class II cavities, adapting composite resin to the dentinal margin is difficult, and the formation of microgaps along this margin can, in the medium and long term, lead to post-operative sensitivity and microleakage

associated with caries development adjacent to composite resin coronal restorations (22). We found that the risk of caries adjacent to composite resin restorations progressively increases with the degree of marginal impairment, from OR 12.329 for restorations with marginal adaptation scores of 6.2 to OR 94.938 for restorations with marginal integrity scores of 6.4, compared to coronal restorations with optimal marginal integrity (scores 6.1). The likelihood of caries developing adjacent to posterior composite resin coronal restorations correlates with both the size of marginal gaps at the interface between the cavity walls and the external surfaces of the restoration, as well as with the functional loading specific to occlusal and proximal-occlusal restorations (23). Microgaps may appear over time due to the hydrolytic degradation of the hybrid layer, followed by adhesive failure at the adhesive restorations (24). Polymerization contraction stress can also cause crack formation, marginal microleakage, margin discoloration, and postoperative hypersensitivity (25). Adhesive failure leads to nano-metric-sized microleakages that serve as pathways for bacterial penetration into the hybrid layer, facilitated by occlusal forces and deep-water penetration (26). A limitation of these studies is related to the performance of composite resins in real-world conditions, where dentists are time-constrained and treat populations different from those investigated in dental schools (27).

CONCLUSIONS

The prevalence of CARS in micro-cavitated and cavitated stage was 26.6%. Risk factors of CARS for direct posterior composite resins restorations were high cariogenic risk, female gender, and impaired marginal integrity. Risk predictors for CARS were female gender and impaired marginal integrity. The risk of developing CARS increases progressively with the degree of marginal integrity impairment.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding.

EVOLUTION OF BIOLOGICAL PARAMETERS IN THE METABOLIC SYNDROME (Abstract)**:** The metabolic syndrome is responsible for the threefold increase of the atherosclerotic cardiovascular diseases and for the increase of the mortality due to these disorders compared to the general population. **Aim:** To evaluate the biochemistry dynamics and the specific medication in patients diagnosed with metabolic syndrome. **Materials and methods**: The study was carried out in the 3rd Medical Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital of Iasi, being a retrospective study and including 250 patients which fulfilled at least three of the five defining criteria of the metabolic syndrome. **Results**: It was obtained the improvement of the inflammatory metabolic syndrome through the decrease of the fibrinogen and of the C-reactive protein (p=0.001). It was observed the fact that, both in men as well as in women, serum value of the uric acid proved to be significant in hypertensive subjects, a statistically significant decrease being observed in the patients treated with Candesartan. **Conclusions**: Obesity and especially the central adiposity is the dominant risk factor for the development of the type 2 diabetes mellitus, which usually is accompanied by the arterial hypertension due to a common physiopathology. Although the pharmacologic therapy is often necessary, a very important element remains the lifestyle change which represents the only full therapeutic approach which can reduce the resistance to insulin and visceral obesity. **Keywords**: METABOLIC SYNDROME, CARDIOVASCULAR DISEASES, BIOLOGICAL PARAMETERS, PHARMACOLOGICAL THERAPY.

The metabolic syndrome (MetS) is defined as being a group of interdependent metabolic factors which together represent a cardiovascular multiple risk. MetS is characterized by the presence of at least three of the following risk factors: central obesity, increased serum triglycerides, the decreased value of the high molecular density lipoproteins (HDLc), increased arterial tension (AT) and hyperglycemia. A variable number of organizations such as the World Health Organization, European

Group for Study of Insulin Resistance, National Cholesterol Education Program, International Diabetes Federation and American Association of Clinical Endocrinologists have defined the criteria for its diagnosis.

The prevalence of obesity and of the MetS has increased in epidemic proportions at the global level. According to the World Health Organization, the obesity rate has doubled since 1980, with 600 million persons, representing 13% of the global population. Metabolic syndrome is responsible for the threefold increase of the atherosclerotic cardiovascular disease (CVD) risk and for the increase in the mortality due to its disorders, compared to the general population (1).

Taking into consideration the relation with the obesity, CVD and the type 2 diabetes mellitus (DM), the prevalence of the MetS varies according to the geographic region at the global level. The general prevalence in adults in the United States of America is of 34,7%**,** compared to the urban India of 33.5%, Malaysia with 27.5%, Brazil with 29.6% and 7.3% in China (2-4). From the point of view of the prevalence on gender, it varies, predominating in men during adolescence (10.9% *vs.* 6.29%), the ratio being inverted during the ages 20-39 (18% *vs.* 20%), reaching the adult age with a ratio predominant in women (42% compared to 51%) (2, 5).

It is known the fact that the major cardiovascular events at the hypertensive patients are preceded by the development of the structural anomalies and the cardiovascular and asymptotic renal functions, of which the majority are recognized as significant independent predictors of the adverse cardiovascular results (6).

According to the appreciations of the European Cardiology Society, the European Atherosclerosis Society and the Hypertension European Society, the plasmatic cholesterol increase, especially of the low molecular density lipoproteins (LDLc) and of the low plasmatic level HDL cholesterol represents the risk factors for the atherosclerotic cardiovascular diseases.

It was shown statistical differences according to sex, in situations of HDLc's decrease, being lower in male patients, and in case of hypertriglyceridemia, the triglycerides level was significantly higher in women (7).

It was proven that the hepatic transaminases, alanine aminotransferase (ALT), aspartate aminotransferase (AST) and, to a lower degree, the gamma-glutamyltransferase (GGT) represents markers of the hepatic disorder due to the infiltration of the fatty acids and of the inflammatory stimulations, these being associated with several components involved in the MetS physiopathology.

The ALT's increased values are associated with the MetS's components (increase of the triglycerides, glycaemia, abdominal circumference, diastolic arterial pressure and low levels of the HDLc) (8). GGT is a sensible indicator, but with a low hepatic disorder specificity, suggesting the possibility of a link between it, the endothelial dysfunction and the cardiovascular risk (9).

The study carried out by Music M. et al (10) has shown that GGT was significantly higher in patients with type 2 DM and MetS than in type 2 DM without, while the ALT and AST did not present significant variations. Monitoring studies are required to determine if the hepatic enzymes can be used as hepatic component of the MetS.

The increased serum levels of the uric acid were observed as being a prediction

factor, independent from the apparition of the coronary arterial disease, thus indicating the involvement of its presence in the development of the vascular inflammation (11, 12).

The hyperuricemia is frequently associated with the arterial hypertension and it is present in 25 % of the patients with non-treated arterial hypertension, 50 % of the patients under treatment with diuretics and more than 75% of the patients which suffer from malignant arterial hypertension (13).

To reach the therapeutic objectives, the European Society of Hypertension / European Society of Cardiology recommends as treatment: four classes of antihypertensive medication: inhibitors of the angiotensin-converting-enzyme inhibitors / angiotensin II receptor blockers, calcium channel blockers, beta blockers and diuretics. It is important the initiation of the MetS treatment for the reduction of the increased cardiovascular risk. The administered medication addresses the individual components of the syndrome. However, although the pharmacology therapy is often necessary, a very important element remains the lifestyle change, which represents the only full therapeutic approach which can reduce the resistance to insulin and the visceral obesity (6).

Robinson *et al.* (14) carried out a meta-analysis which has proven that the HMG-CoA reductase inhibitors medication, such as statins and fibrates, used in the monotherapy, generate an approximate relation of 1:1 between the LDL-c lowering and the reduction of the risk of the coronary disease apparition.

MATERIAL AND METHODS

The aim of the study was to evaluate the biochemical dynamics and the specific medication in patients diagnosed with the metabolic syndrome.

The study was carried out in the 3rd Medical Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital of Iasi, it being a retrospective study. 250 patients were included in the study, patients which fulfilled at least three of the five criteria for defining the metabolic syndrome according to the American Heart Association/National Heart, Lung and Blood Institute and World Health Organization. From the total of patients, 57% returned to the clinic for re-evaluation after 12 months of treatment.

To carry out this study, it was used as working instrument the patient's clinical observation sheet, with the drafting of some special sheets relating to the: clinical, biochemical and treatment aspects. The following inclusion criteria were: age above 18 years, presence of the metabolic syndrome, absence of the chronic renal disease in the terminal stage and absence of the severe hepatic insufficiency.

The exclusion criteria were represented by: pregnancy, patients with neoplasm or patients with major psychic/ cognitive disorders, acute or chronic inflammatory disorders, which could have influenced the results of the laboratory investigations, the hormone treatment.

The study protocol was applied according to the recommendations of the Ethics Committee of the "Sf. Spiridon" County Clinical Emergency Hospital of Iasi, abiding with the ethic norms of the European Community about the investigations carried out on the patients.

Data statistical analysis. The data was centralized and statistically handled using the *SPSS version 22.0* for Windows 10 and the ANOVA method. In the statistical anal-

ysis were used not only descriptive methods, but also the analytical ones at the 95 % confidence interval (CI 95 %). When calculating the significant difference between the two averages it was used the t-student test or the F test (ANOVA) used for the comparison of the average values, in three or more groups with normal distribution. Moreover, it was used the Microsoft Excel program for the generation of graphics using the values obtained in *SPSS version 22.0.*

RESULTS AND DISCUSSION

The clinical proof related to the inflammatory nature of the atherosclerotic process is represented by the increase of the circulatory levels of the inflammatory markers at the patients with cardiovascular diseases. Numerous epidemiologic studies have reported positive associations between the risk of the atherosclerotic and the fibrinogen's plasmatic levels, this parameter's high level being significantly associated with the cardiovascular risk, independent of the lipid profile. Thus, we can observe an improvement of the inflammatory process through the markers' decrease ($p = 0.001$) (tab. I).

It has shown a statistically significant relationship between elevated C-reactive protein and fibrinogen levels and the presence of hypertension, isolated, or in combination with obesity, which confirmed that hypertensive patients presented a proinflammatory and procoagulant status, which implies an increased risk of cardiovascular disease (15).

MetS is spread across the ill persons with chronic renal disorders, being reported that it might have a role in the progression and development of the renal lesions (16), favoring the instalment of the renal disease in its final stage (17). In the sample of the studied patients, it was obtained the improvement of the renal function after the 12 months of treatment and diet regime.

TABLE I

Evolution of the biological markers in patients with metabolic syndrome

Marker	Initial	Re-evaluation	p value for paired T test
Cholesterol	201.25 ± 53.06	186.35 ± 49.35	0.001
LDL	123.03 ± 44.12	112.21 ± 39.15	0.001
Serum urea	52.74 ± 17.20	51.78 ± 15.98	0.050
Creatinine	1.41 ± 0.54	1.35 ± 0.51	0.001
CRP	2.97 ± 3.59	2.61 ± 3.25	0.001
ESR	9.81 ± 7.07	8.54 ± 7.06	0.001
Uric acid	5.91 ± 1.51	5.70 ± 1.42	0.001
Fibrinogen	384.78 ± 114.10	358.22 ± 98.60	0.001
ALT	27.11 ± 22.61	21.57 ± 15.79	0.001
AST	22.92 ± 10.69	17.85 ± 8.07	0.001
GGT	42.45 ± 35.99	30.99 ± 23.84	0.001

The patients with present inflammatory treated with Rosuvastatin had the weakest response to the treatment, in the sense of this syndrome's improvement (fig. 1).

Taking into view the results of the various studies which have proved a direct

relation between the increase of the uric acid's values and of the arterial hypertension at the level of the studied sample, it is observed the fact that not only in men, but also in women, the increased serum value of the uric acid was met significantly more frequently in the hypertensive subjects (fig. 2).

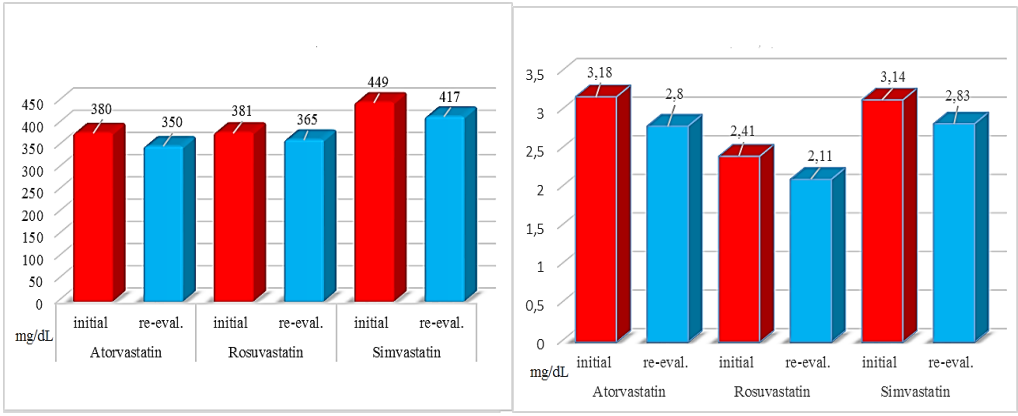

Fig. 1. Initial average distribution and the re-evaluation of the fibrinogen and C-reactive protein according to the type of administered statin

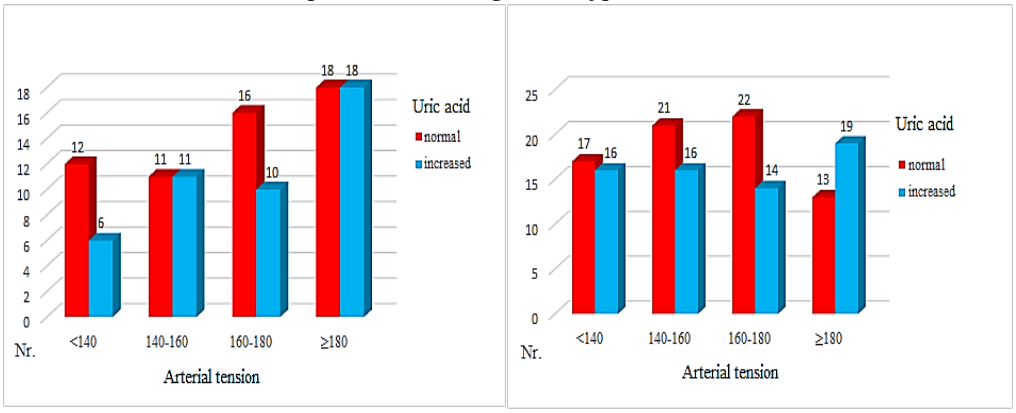

Fig. 2. Distribution of the initial values according to the AT and uric acid for men and women

At patients treated with Candesartan it was possible to observe the decrease of the uric acid's values by 0,36 mg/dl in comparison with Perindopril, where the decrease was not statistically significant (fig. 3).

Establishing the values of the C-reactive protein is a practical modality to evaluate the presence of the inflammatory syndrome. The increase of the CRP values (≥ 3 mg/L) is a risk factor for the later apparition of the CVD. The medicine used for the treatment of the metabolic risk factors were efficient also regarding the reduction of the CRP serum levels (statins, fibrates, ACE, nicotinic acid).

An intervention study which has evaluated the study with Rosuvastatin (*Justification for the Use of Statins in Primary Pre-*

vention: An Intervention Trial Evaluating Rosuvastatin - JUPITER) has emphasized the statins additional benefit for the patients with increased CRP value, even in the presence of an LDL within normal limits (18).

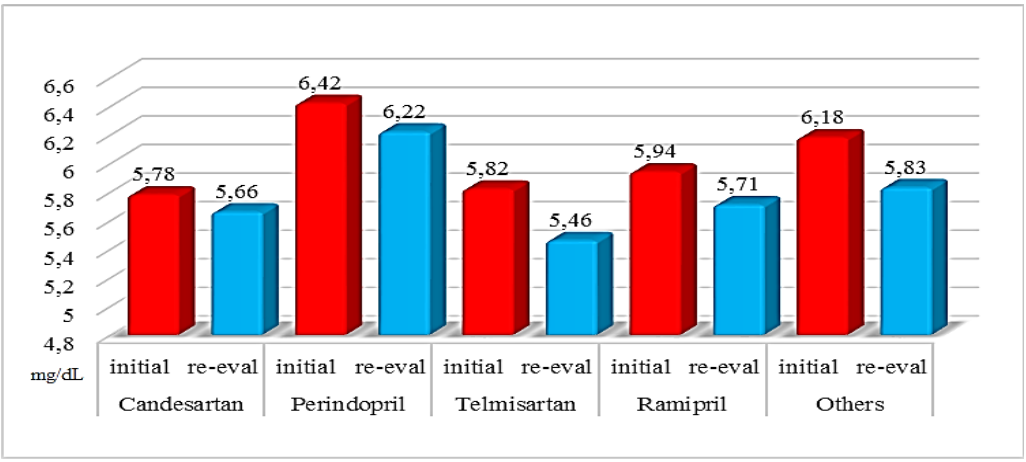

Fig. 3. The distribution of the initial and re-evaluation average values of the uric acid, according to the administered ACE / ARB type

In the studied casuistry, it can be observed a decrease of the CRP values compared to the initial moment, the most important improvement being observed at the patients which have received Perindopril (fig. 4).

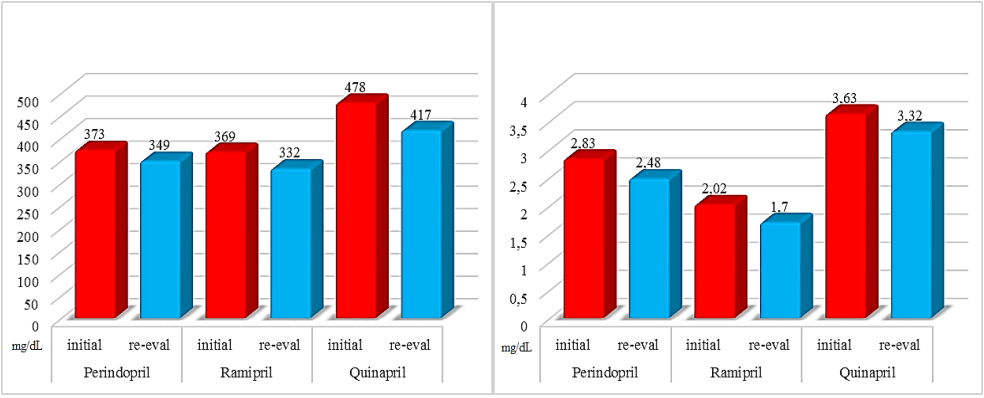

Fig. 4. Initial and re-evaluation average value distribution of the fibrinogen and C-reactive protein according to the administered ACE / ARB type

CONCLUSIONS

In the present study, we demonstrated that inflammation within the metabolic syndrome decreased differently depending on the type of statin administered.

Also, we demonstrated a direct relationship between the increased uric acid's concentrations and arterial hypertension, its values being significantly higher in hypertensive individuals.

Our study revealed that at patients which have received Perindopril was observed a significantly decrease of the CRP values.

PREVALENCE OF SELF-MEDICATION WITH ANTIMICROBIAL DRUGS IN THE SOUTHEAST REGION OF ROMANIA (Abstract): Self-medication represents a global health issue with an increasing negative impact on the society regarding health evolution and socio-economic progress. There are few studies regarding the self-medication practices with antimicrobial drugs in general population in Romania. **Aim:** to evaluate the prevalence of self-medication with antimicrobial drugs in general population in the counties of the south-east region of Romania. **Material and methods:** a questionnaire-based cross-sectional study which investigated the rate of self-medication with antimicrobial drugs in a population from the counties of the southeast region of Romania during 2016-2017. Data were analyzed using descriptive statistics and the chi-square test, when applicable. **Results** There were 355 persons included in the study, with a predominance of female sex (62.8%) and of persons with urban residence (57%). The most common antimicrobial drugs used for self-medication were amoxicillin (34%), followed by amoxicillin-clavulanate (32%), and the most frequently reported reasons for self-medication were respiratory infections (52%), and genitourinary infections (25%). **Conclusions:** This study reveals a medium prevalence of self-medication with antimicrobial drugs in the population from South-eastern Romania. **Keywords:** SELF-MEDICATION, ANTIMICROBIAL DRUGS, PREVALENCE.

Self-medication represents a global health issue with an increasing negative impact on the society regarding health evolution and socio-economic progress (1). According to World Health Organization (2), self-medication is defined as "the selection and use of medicine by individuals to treat self-recognized illness or symptoms". Self-medication practice involves procuring medicines without a prescription, reusing old prescriptions in order to buy medicines, recommending particular medicines to relatives and acquaintances, consuming leftover medicines kept at home, non-compliance with the professional prescription by interrupting or decreasing the doses (3). Several studies have established the main factors that influence self-medication practice: socio-demographic characteristics (gender, age), socio-cultural aspects (level of education, access to information, accessibility to health care facilities), economic and political factors (3, 4).

Self-medication behavior has a major impact on health promotion of the population. The health system is positively influenced by a responsible self-medication practice which helps in preserving the medical resources and reducing costs. An inappropriate self-medication practice has mul-

tiple negative effects such as a delay in managing the health problem by a doctor, a failure in identifying the contraindications of the drug and the interactions between the self-administrated drugs, the appearance of adverse effect leading to hospital admissions, risk of abuse and addiction, an inadequate period of treatment and an increasing resistance to pathogens (5, 6).

In Romania, antibiotics are released only with medical prescription, but leftover medicines stored at home are sources for self-medication in the case of antibiotics. Few studies (7) regarding self-medication practices with antimicrobial drugs in the general population in Romania were published. Therefore, a questionnaire-based cross-sectional study was conducted with the aim to evaluate the prevalence of self-medication with antimicrobial drugs in the general population in the counties of the south-east region of Romania.

MATERIAL AND METHODS

The present study represents a questionnaire-based cross-sectional study which investigated the rate of self-medication with antimicrobial drugs in a population from the counties of the southeast region of Romania during November-December 2016. The Ethics Committee of the University of Medicine and Pharmacy Grigore T. Popa approved the study. Verbal consent was obtained from all participants after a brief introduction by explaining the aim and the significance of the study. To collect data, we cooperated with pharmacies from Galati, Braila, Buzau and Vrancea, counties of the south-east region of Romania. In the study were included only adults (>18 years). Before filling the questionnaires, each potential participant was informed about the purposes of the study and the confidentiality of the information. We excluded from the study the individuals who presented at the pharmacy with a medical prescription for a disorder that required antimicrobial drug treatment or people buying cosmetics or medical equipment. A self-administrated questionnaire, organized in two parts, was prepared after reviewing the literature for similar studies and validated as previously described in the study of Damian et al., in 2014 (7). The first part of questionnaire contained information regarding demographic characteristics of the population (gender, age, employment status) and information related to general self-medication practiced during the last 6 months. The second part of the questionnaire was focused on the use of the antimicrobial drugs (name of antimicrobial drug, treatment period, person who recommended the treatment and the illness that required the use of antibiotic, in case of confirming the use of antibiotic in the last 6 months). Means ± standard deviation (SD) were used for quantitative variables like age, while frequencies and percentages were used for qualitative variables. Data were analyzed using SigmaPlot 11 descriptive statistics and the chi-square test was used to test the differences between proportions. A limit of p value less than 0.05 was considered significant.

RESULTS

There were 355 persons included in the study, with a predominance of female sex (62.8%) and of people with urban residence (57%). Participants' age in the study ranged from 18 to 90 years, with a mean of 42±9. The unemployed group included students and retired individuals (tab. I).

The results showed that the practice of self-medication is differently correlated to age. In the group of >60 years old, the rate of self-medication is the highest (51%) in comparison with the 51-60 years group, where the practice of self-medication was

the lowest (26%). The irrational use of the antimicrobial drugs among the respondents was applied based on self-recommended medicine, the pharmacist recommendation, the advice of a relative or a friend and a low percentage using internet information. The most common antimicrobial drugs used for self-medication were amoxicillin (43%), followed by amoxicillin-clavulanate (32%), and the most frequently reported reasons for self-medication were respiratory infections (52%), and genitourinary infections (25%).

TABLE I

Socio-demographic characteristics of the study population (n=355)

Characteristics	Age (years)						Total
	≤20 (n=37)	21-30 (n=123)	31-40 (n=56)	41-50 (n=69)	51-60 (n=38)	> 61 (n=32)	
Gender							
Male	16	43	19	25	12	17	132
Female	21	80	37	44	26	15	223
Place of residence							
Urban	13	23	53	61	32	20	202
Rural	24	100	3	8	6	12	153
Employment status							
Employed	2	60	49	61	26	2	200
Unemployed	35	63	7	8	12	30	155

DISCUSSION

The irrational use of antimicrobial drugs represents a much-explored area by the researchers. Many studies (8, 9, 10) focused on establishing the prevalence of antibiotic self-medication.

A study (8) conducted in Central Saudi Arabia in community pharmacies showed that a group of medicines with the highest rate of dispensing without a medical prescription is represented by antibiotics in a percentage of 22% (8). Another study (9) organized in Saudi Arabia after 3 years, in 2014, recorded a very high rate of irrational use of antibiotics. The 78.7% percentage showed that from a total of 681 responders to the study, 536 were antibiotic self-medicated. Another data showed by the study was the probability of the prevalence of self-administrated antibacterial drugs, which was higher among the older respondents compared to the younger participants from the age group 18 to 30 years.

In 2014, Banerjee et al. (10) evaluated the rate of irrational use of medication in a community of Nepal medical students. The results showed a self-medication rate of 81.35% with the antibiotics on the second place among the most common self-administrated drugs. The students' community, the young and informed section of the population, represents an important target of determining the self-medication practices and the prevalence of irrational use of drugs. A study designed to evaluate the self-medication behavior among medical and nonmedical students from the northeast region of Romania in 2014, showed that the irrational antibiotic self-medication had a percentage of 34%. The results clearly defined the difference among the medical group where the antibiotic self-administration rate was 38% and the non-medical group where was obtained a rate of 9% antibiotic self-administration (7).

The importance of demographic and socio-economic particularities is proven also by a study (11) conducted in 2013 in Guatemala City where self-medication behavior of peo-

ple from general population was compared the in suburban pharmacies versus city center pharmacies. The rate of self-medication was 79% in the suburban pharmacies and 77% in the city center pharmacies. Another study (12) that assessed the impact of demographic features was conducted in 2014 in the rural areas of Sindh, a province of Pakistan, where the prevalence of antibiotic self-administration was 81.25%.

A study (13) conducted in Lithuania in 2014 reported an antibiotic self-medication rate of 31% in the general population stated the significance of the demographic features in the evolution of antibiotic self-behavior (age, gender, residence, level of education, parenthood).

CONCLUSIONS

This study reveals a medium prevalence of self-medication with antimicrobial drugs in the population from South-eastern Romania. Self-medication with antimicrobial drugs is a relatively common practice, but the prevalence is reduced compared with other studies from previous years or other populations, maybe because of the effect of national education programs regarding the risks of irrational self-medication with antimicrobial drugs. Educating the population about the consequences of irrational use of antibiotics is urgently needed.

RARE TYPES OF HERNIA (Abstract): Depending on their origin hernias are classified into congenital and acquired, the latter occurring in people in which the respective hernia area is fully developed but is weak or weakens under the complex action of etiological factors. The development of hernia is the result of the imbalance between two constantly acting forces: positive intra-abdominal pressure and contraction of abdominal muscles which by their tonicity keep the viscera in place. The correct diagnosis and early treatment are keys to successful repair. **Material and methods**: This study analyses the clinical and laboratory findings and therapy response in 13 patients with hernia. The sample is representative for this condition, and the cases have been selected based on the acutization of inflammatory phenomena. **Results and discussion:** In the treatment and management of these rare hernias the fact that they are prevalent in the elderly with significant weight loss and associated chronic conditions has to be considered. **Conclusions:** These types of hernia have a precise anatomic identity; their onset is favored either by an inherited abdominal wall defect, or acquired by multiparity and physical strain. **Keywords**: STRANGULATION, PAIN, HERNIAL SUOCCLUSION, SURGICAL TREATMENT.

Hernias have been known since ancient times when simple methods were used for their repair (1, 2). Reducible hernias were supported with the help of a strap or bandage, whereas strangulated hernias were treated with palliative means (diet, rest, purgatives, astringent compresses/poultices, bleeding, massage) (1, 3).

A more rational treatment was used by Phoenicians, 900 years B.C. The first man to perform surgeries for hernia repair was Celsus (100 AD.); surgery consisted in the ligature and excision of the hernial sac without opening it. Heliodorus (second century A.D.) was the first to isolate the inguinal hernia sac from the cord, while Oribasius (fourth century) performed the ligature and excision of the freed sac followed by cautery of surrounding tissues. (1). In Middle Ages, the Arab surgeons Haly Abbas (930-994), and Avicenna (980-1037) frequently practiced surgery to treat hernias (1).

The 19th century marks the beginning of modern hernia surgery, famous monographs, such as those by Cooper and Scarpa, being published (1).

Despite the fact that people have started to lose confidence in surgery due to the abusive practice of castration, suppurations and relapses, in order to rehabilitate the surgical art, numerous authors strived to

find better treatment procedures (3).

The breakthrough in hernia therapy was the discovery of antiseptics, which resulted in less postoperative infections and thus encouraged more surgery.

MATERIAL AND METHODS

The study included 13 patients, study group representative for this condition. The cases were selected based on the acutization of inflammatory phenomena, and were admitted in the interval 2005-2010 to the General Surgery Department of the Iasi Railroad Hospital. The data collection process was followed by data processing and interpretation, using 95% confidence intervals; for differences χ^2 and t-Student tests were used. In the end, the data were centralized in the epidemiologic systems *Excel* and *SPSS* 13.0.

RESULTS

Rare hernias include Spigelian, obturator, lumbar, ischiatic, and perineal hernias.

Our study included: 5 (38.46%) cases of Spigelian hernia, 4 (3.76%) cases of obturator hernia, 3 (23.07%) cases of perineal hernia, 1 (7.69%) case of lumbar hernia, and no case of ischiatic hernia (fig.1).

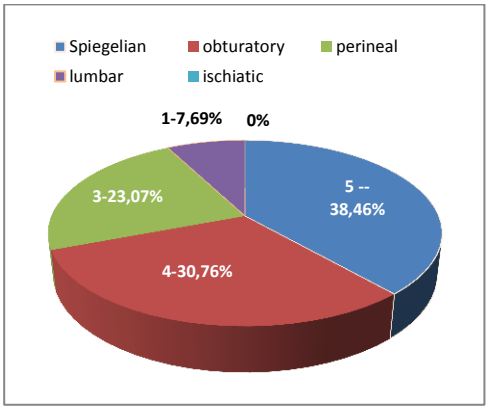

Fig.1. Case distribution by hernia type

Spigelian hernia (or lateral ventral hernia) is a rare abdominal hernia through a congenital or acquired defect in the aponeurosis of the transverse abdominal muscle limited by the semilunar line (or Spigelian line) laterally and the lateral edge of the rectus muscle medially. The semilunar line is in fact an aponeurotic line located between the muscle mass of transverse abdominal muscle and the flashy mass of the large abdominal muscles. In its upper part it is narrow and solid, but in the lower part it progressively widens, being visible (fig. 2).

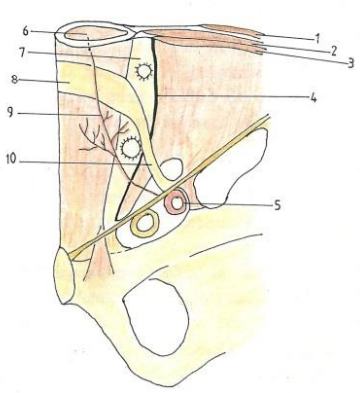

Fig. 2. Deep orifice of Spigelian hernia (collection of the clinic)
1. External oblique; 2. Internal oblique; 3. Transverse abdominis; 4. Spiegel's line; 5. External iliac artery; 6. Rectus capitis posterior major; 7. Lateral flank of the abdomen; 8. Douglas' line; 9. Epigastric artery; 10. Hesselbach's triangle.

The weak point of the aponeurotic fascia is located at the intersection of the spinal-umbilical line with the lateral margin of the rectus abdominis and it corresponds to the arcuate line of Douglas, where the peritoneum contacts the interstitial space of the aponeurosis of the transverse muscle, or even the space between the internal oblique

and the transverse muscle; here, the fibers of the two deep major muscles are parallel, they do not meet in order to strengthen the wall. There are high Spigelian hernias, near Douglas' arcuate line, and Spigelian hernias which can be mistaken for inguinal hernias. This type of hernia is acquired, usually unilateral, and may contain omentum, intestine or colon.

Clinical examination detects the parietal character of the formation presenting the features of a hernia: pain, irreducibility, expansion, impulsion on cough. The diagnosis is based on clinical and laboratory findings; once diagnosed, the surgical treatment is necessary; because strangulations are frequent, the removal of hernia sac and closure of the inguinal orifice are required. The surgical approach may be classical, direct, or laparoscopic.

Of the 13 studied cases 5 (38.46%) presented Spigelian hernia located at the lateral margin of the rectus abdominis muscle, underneath and outside the umbilicus on the line that unites the anterior superior iliac spine and the umbilicus. The deep orifice where the hernia sac is engaged is located in the anterolateral fascia of the abdomen under Hesselbach triangle and above the epigastric artery, which ascends obliquely inwards, behind the transverse fascia and then in front of Douglas' arcuate line. The content of hernia sac is a thin loop of sigmoid, colon, cecum, and vermiform appendix. Due to the fact that the hernia orifice was usually small and had fibrous wall in 4 (30.76%) out of 5 cases, occlusive phenomena occurred, with paroxysmal abdominal pain, vomiting, Koenig's sign, absence of bowel movements, and poor general health status.

Hernias were repaired in all 5 cases via indirect paraumbilical medial approach, repairing the abdominal wall (1 case - 7.69%); the classic, direct, hernial approach was used in 3 cases (23.07%); the medial and paraumbilical approach was used in 1 case (7.69%).

A special mention deserves the case of the patient admitted one year earlier for a mass in the left iliac fossa the size of an orange and increasing in size during physical exercise; the mass was more visible in orthostatism and smaller in supine position. Personal history included multiparity and a uterine fibroma, surgically removed when the patient was 34 years old.

During local examination in orthostatism, we noticed that the patient presented on the bispinal line an approximately 2/3 cm mass expanding during physical exercise. The clinical examination did not reveal anything special.

The intraoperative diagnosis was of left Spigelian hernia; we used the Bauthelemy technique; it revealed a hernia duct the size of an orange, containing a fragment of sigmoid colon attached to the bottom of the sac. The neck of the hernia sac crossed the muscle part of the transverse abdominis muscle. The hernia sac was resected together with the serrated sigma, then the wall was repaired with catgut. We closed the hernia gap by fastening the Douglas arcuate line at the external margin of the left rectus abdominis muscle. The anatomic plans were remade. Above, we fastened the aponeurosis of the oblique muscle in the vest. The patient was discharged from hospital clinically cured.

Obturator hernia occurs through the obturator groove situated between the obturator membrane and the horizontal branch of the pubis, a groove through which the obturator package passes from pelvis towards the thigh. The hernia sac is engaged

in this groove, and, depending on its progress, there are three anatomical-clinical forms: - interstitial hernia, in which the sac and the groove do not extend the obturator groove; recto-pectineal hernia, in which the cul-de-sac extended the groove and reached the thigh under the pectineus muscle; and the pre-pectineal hernia, in which the sac superficially reaches the cribriform fascia. The sac is thin and it may contain intestine, omentum, tube, or ovary. Obturator hernia is more frequent in frail elderly women with changes of the pelvis (figs.2,3).

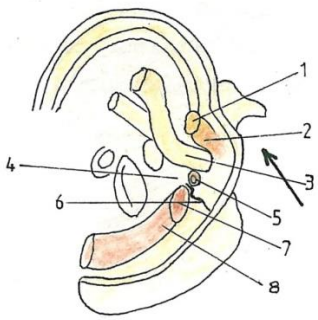

Fig. 2. Palpation of strangulated obturator hernia in vagina (apud Wakeley) (1).
1. Pubic symphysis; 2. Pectineus muscle; 3. Hernia sac; 4. Vagina; 5. External obturator muscle; 6. Obturator membrane; 7. Obturator muscle, 8. Levator ani.

Clinically, obturator hernia is characterized by pain at the inner side of the thigh and the knee due to the compression of the obturator nerve. When it exceeds the obturator groove, we can palpate a tumoral formation at the root of the thigh, which is irreducible, unpainful, located near the obturator groove. Most commonly the diagnosis is made intraoperatively, when the surgeon repairs a mechanical bowel occlusion of unknown causes. A strangulated obturator hernia is a surgical emergency. The approach can be transperitoneal in complicated forms of occlusion, femoral or pro-peritoneal inguinal. The repair of hernia consists in exposing the sac, opening it, reducing the viable contents or resection in case of occlusion with necrosis and closure of the defect, which can be done with mesh.

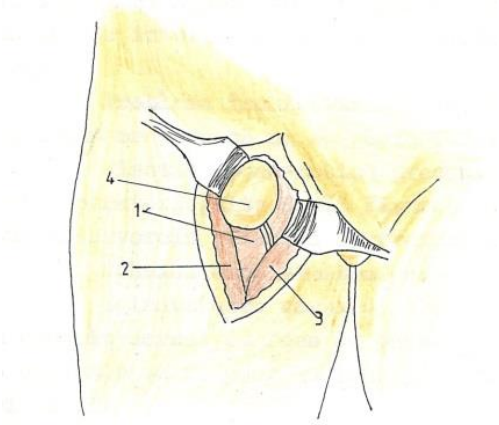

Fig. 3. Crural approach of obturator hernia (collection of the clinic).
1. external obturator; 2. pectineus; 3. middle adductor muscle; 4. sac.

Of the 13 study cases, 4 (30.76%) presented obturator hernia; the hernia sac passed through the obturator canal and established intimate relations with the vascular-nerve package, especially with the obturator artery and its anastomosis with epigastric artery. The sac was thin and small, containing small intestine. The tumor was not felt at palpation, but we noticed a painful spot while pressing the obturator area, under the genitofemoral groove, in the cranial medial part of the Scarpa triangle. During medial subumbilical exploratory laparotomy, we discovered a loop engaged in the deep orifice of the obturator groove. The orifice was removed from accessing the gullet, masked by dilated loop (fig.4).

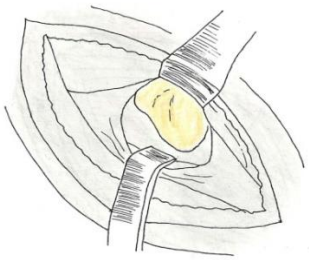

Fig.4. Revealing the strangulated loop, engaged in the obturator groove. Reduction. (Collection of the clinic).

Special Note related to patient S. S., 60 years old, hospitalized for abdominal cramps, nausea, repeated episodes of vomiting, absence of bowel movements and flatulence.

The patient presented several years earlier pain at the root of the right thigh, irradiating towards the knee, more intense in physical strain and which involved a certain degree of functional discomfort. Due to the fact that the pain exacerbated, also the general state of the patient worsened. We chose subumbilical medial laparotomy. Parts of the intestinal loops were dilated, and during exploration we noticed the fastening of a terminal loop on the right lateral wall of the pelvis. In Trendelenburg position, it is easy to reveal a "barrel gun" loop in the subpubic groove. It was possible to reduce it only after the digital enlargement of the abdominal orifice. Only few centimeters of the intestine were involved and it was not compromised. The orifice was closed using the peritoneal fold technique. The patient was discharged healed.

Perineal hernias are rare, being caused by parietal defects of the pelvic floor; they are more frequent in women, and can be medial and lateral. Medial hernias are muscular-aponeurotic in women, favoring the externalization of the pouch of Douglas through the posterior vaginal wall. The vaginal and rectal examinations reveal a soft, reducible mass, larger on cough. Bilateral perineal hernias are located in the anterior perineum in women, and in the posterior ones in both genders. Anterior lateral hernia crosses the pelvic floor in women and exists through labia, while the posterior lateral hernias cross the levator ani and reach beneath the gluteus like ischiatic hernias. The diagnosis is clinically suspected and confirmed by tomodensitometry. The treatment is surgical and it consists of identification and treatment of the sac, repair of the wall by transperitoneal approach for medial hernias, as well as perineal and mixed approaches (fig.5).

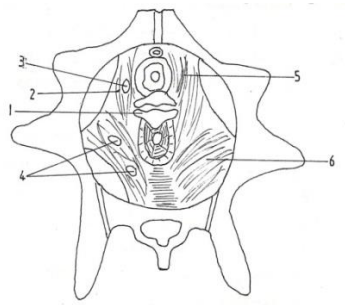

Fig. 5. Perineal hernias (collection of the clinic).
1. Medial perineal hernia - hydrocele;
2. Medial perineal hernia - elytrocele;
3. Lateral ventral pudental or labial perineal hernia; 4. Dorsal lateral perineal hernia.
5. Levator ani; 6.- Ischiococcygeus muscle.

Perineal hernia incorporates in its structure 3 cases (23.07%) out of the 13 cases included in this study. The hernia orifice is found in the soft parts of the pelvic floor.

Special note concerning patient P.S. 39-year-old, hospitalized for a mass the size of an apple, painful, with limited consistency, reducible, accompanied by intestinal gurgling, pulsating on cough. The patient complained of a feeling of intense perineal pressure, with discomfort during walking, sitting

or defecation, pain or cramps. The hernia contained vesical structures, with particular symptoms (dysuria, pollakyuria, miction) or frequent urination. The treatment is surgical, with perineal approach. The patients is cured and released from hospital.

Another mention refers to patient M. M., 34 years old, hospitalized for an ovoid, unpainful, irreducible mass located on the posterior vaginal wall. The patient was a multiparous woman, the last childbirth being laborious. After the last childbirth, the patients felt permanent pelvic pain. After a few months, she noticed the occurrence during exertion of a small, soft, and reducible mass at the level of the pudental cleft; in time, the mass increased in size.

During the local orthostatic examination, we noticed a prominence of the posterior wall of the vagina, forming a reducible tumor of the size of a pigeon's egg. In gynecologic position, we noticed that the vulvar orifice is half opened, with a posterior vaginal hernia on the posterior wall of her vagina, a smooth, stretched and shiny mucosa; at palpation, it felt soft and reducible; during vaginal examination we noticed a lax posterior vaginal wall and free vaginal cul de sac; during mixed examinations, we noticed that the fingers are separated by the thickness of the tumor. After reduction of the tumor, we noticed that the fingers are separated only by the rectovaginal septum, with deficient levator ani.

We applied a surgical perineal intervention; we split the posterior vaginal wall and we reached to a cystic formation, partially reducible, prolonging upwards to a diverticulum between the rectum and vagina. This pedicle is sectioned after the ligature. We performed a colpoperineorrhaphy. There was a good postoperative evolution.

The cystic formation contained a whitish fluid. The histologic examination showed that its internal facet presented a serous epithelium that looked like the peritoneal serous membrane, doubled by a lamellar coating of connective tissue.

Lumbar hernia can be congenital, post traumatic or due to lumbar, lumbosacral and iliac crest abscesses, areas in which there are two weak points of the inferior abdominal-lumbar wall.

One variety of hernia is produced by lumbar-abdominal denervation or relaxation, because of parietal paralysis of oblique muscles after urologic interventions affecting the last two intercostal nerves. The clinical examination in orthostatic position revealed a painful and reducible mass in the lumbar area, pulsating on cough. It naturally grows, with a high risk for strangulation. The differential diagnosis includes lipoma or other tumors of the area. The clinical diagnosis can be confirmed by imaging investigations, ultrasound, CT, etc. The treatment is surgical and consists in an incision over the mass site, detection and reduction of the sac, replacing its contents and repairing the abdominal wall (fig.6).

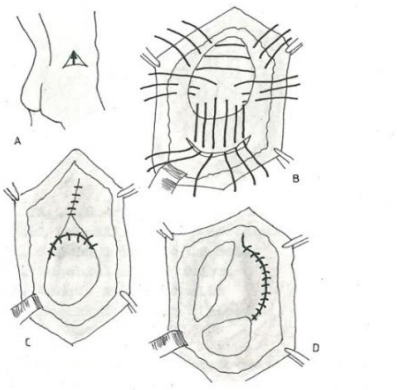

Fig. 6. Treatment of lumbar hernia. Dowd procedure: A. vertical incision; B. bringing the muscle fascicles closer; C. suture of margins; D. creating the second flap. (Collection of the clinic).

In small hernia, the plain muscular-aponeurotic suture can close the parietal defect. In large hernias, the preperitoneal placement of a prosthetic mesh is required.

In our study, only 1 (7.69%) of the 13 cases had lumbar hernia.

Ischiatic hernias are exceptionally rare and they are produced by parietal defects located at the level of the ischiatic notches, between the muscles and ligament formations. There are three anatomoclinical forms of ischiatic hernias: suprapyramidal, the most common, subpyramidal, both supraspinous and infraspinous, developing between the greater and lesser sacrosciatic ligament. The diagnosis is difficult, and it is usually made due to strangulation, when the patient experiences pain along the course of the sciatic nerve and signs of bowel obstruction. The treatment is surgical and the transperitoneal or gluteal approaches are used (4, 8).

DISCUSSION

Our study supports that the main cause of rare hernias is strain, rarely sudden and violent, usually less intense, but repeated, especially in a certain position of the body.

Under the influence of strain, the pressure in peritoneal cavity increases, with visible effects. The peritoneum forms initially a small diverticulum, in an area of the wall with a limited resistance and then, under the influence of repeated increases of pressure, the diverticulum widens the parietal orifice, like a "ram head" (5).

All the presented cases of the clinic point to the reduced incidence of these types of hernia. In all studied cases, hernia was highlighted only in middle-aged women (3 cases in women under 50 years), which made or make physical strain, with hypotonic abdominal wall, lax, altered by many pregnancies. These rare types of hernia may be accompanied by obvious weight loss or obesity. Cooper (6) reports a vascular hernia that shows that the hernia crosses over along a ram of the inferior epigastric artery, deep circumflex iliac artery or of greater or lesser abdominal-genital nerves. Mayer-Wildisen and Quervain (8) ascribe the spontaneous break of lateral abdominal wall to a muscular, neurogenic insufficiency and paralysis.

Related to **Spigelian hernias**, we could individualize two clinical pictures: a) spontaneous or provoked pain, intense or dull, accentuated by coughing while strain, sub- and paraumbilical, at the external margin of the straight muscle (2 cases); b) in three cases, the reason for hospitalization was a progressive tumor mass, of variable size, located in the right iliac fossa in 2 cases and in the left iliac fossa in 1 case, at the lateral margin of the rectus muscle, the masses being irreducible (13,15).

In all cases, the mass was unilateral and matte. In one case each, Spigelian hernia was interpreted as postoperative eventration after operated umbilical hernia and as inguinal hernia, and in three cases the correct diagnosis was made postoperatively.

In all our five cases, the clinical picture of Spigelian hernia was not accompanied by occlusive or subocclusive phenomena. Due to the fact that the hernia orifice was deep, at the external margin of the rectus muscle, in the proximity of the penetration point of the epigastric artery in the right abdominal muscle, we chose to use the direct hernial approach. We performed a McBurney incision and we dissociated the fibers of the greater oblique muscle. The hernia sac contained omentum in 2 cases, cecum in one case, sigmoid in one case, and a small sac without contents in another

case. The postoperative outcome was favorable in all cases, as mentioned by other authors as well (3, 8).

In cases of ***obturator hernias***, the diagnosis was made intraoperatively, the clinical picture being characterized by signs of occlusion or subocclusion. The intervention consisted in subumbilical midline laparotomy, during which we noticed an intestinal loop engaged in the obturator groove.

Due to the lesions that arose by strangulation of the intestinal loop in the obturator groove, in all 4 cases segmental enterectomy with termino-terminal suture was performed. In 2 cases the engaged intestinal loop was perforated. The serous citrine fluid was present in the abdomen in 2 cases, and mixed with feces in 2 cases. Fredet, Bonnet, Cottalorda, Lortat-Jacob et al. (11) studied the clinical and therapeutic aspects of obturator hernias.

Due to the complications and the fact that the obturator hernia was diagnosed late in strangulation phase the postoperative outcome was not favorable. Of the 4 cases, 2 patients died within the first 3 postoperative days due to cardiopulmonary arrest, and 2 had a good postoperative outcome. The deceased patients were 60 and 86 years old, respectively. The severity of these hernias was also due to their late detection (occlusion), as well as the complexity of the surgical intervention.

Perineal hernia is the only type of hernia that was diagnosed in our study in relatively younger women, 39 years old. One of the two multiparous women experienced a laborious delivery which affected her perineal muscles. The other woman underwent surgery for umbilical hernia 6 years before she developed perineal hernia. Obviously, this patient was prone to hernias.

In all the 3 cases of perineal hernia the diagnosis was made postoperatively, the outcome being favorable.

Lumbar hernia is the less common of the rare hernias. In Grance's statistics (quoted by 8), 22 hernias formed via Petit triangle, 8 via Grynfeltt quadrangle, 2 crossed the greater oblique muscle, and 3 were caused by congenital abnormalities in this area.

The presented case was a multiparous woman with intraoperative diagnosis and favorable postoperative outcome.

CONCLUSIONS

Our study highlighted the fact that rare hernias have a precise anatomic identity, while their onset is favored by the relationship between the intra-abdominal pressure and abdominal wall strength.

Rare hernias are an actual concern of emergency surgery, although due to their frequency they are not regarded as priorities.

Strangulated hernia, by the brutal, tight and permanent constriction of the contents inside the hernia sac makes the reduction maneuver impossible and very painful.

We pointed out the basics of clinical practice, crucial for making the diagnosis and an optimal surgical indication.

THE ROLE OF OMICS TECHNOLOGIES IN STAPHYLOCOCCAL INFECTION CONTROL

According to a study by Holtfreter *et al*, omics technologies (such as genomics, transcriptomics, proteomics, metabolomics and immunoproteomics) are powerful tools that can be used to draw a comprehensive picture of the pathophysiological processes that occur within tissues, organisms and populations and improve the control of some infectious diseases. Thus, omics technologies may contribute to the understanding of the interaction between *Staphylococcus aureus* and the human host and the adaptive immune response. *S. aureus* is an important cause of infection both in hospitals and in the community and many circulating strains have multiple resistance to antibiotics. The humoral immune response was described in detail using immunoproteomics, but T-cell mediated immunity was not yet fully analyzed by omics technologies. Increasing the knowledge of the protection mechanisms can prove useful for the development of new strategies for successful prevention or treatment of *S. aureus* infections and these technologies can speed up vaccine development by enabling reverse vaccinology approaches (Holtfreter S, Kolata J, Stentzel S, Bauerfeind S, Schmidt F, Sundaramoorthy N, et al. Omics approaches for the study of adaptive immunity to *Staphylococcus aureus* and the selection of vaccine candidates. *Proteomes* 2016: 4(1) pii: E11).

IMPORTANCE OF PSYCHOLOGICAL INTERVENTION IN THE MANAGEMENT OF A PATIENT WITH NON-HODGKIN LYMPHOMA AND STAGE C3 AIDS DISEASE (Abstract): Long-term evolution of HIV because of noncompliance and nonadherence to antiretroviral therapy favors the occurrence of difficult to treat HIV-related malignancies. We present the case of a female patient in "the pediatric cohort" registered at the Iaşi Regional HIV/AIDS Center since year 2000, now with stage C3 AIDS. In 2014, a Burkitt lymphoma was pathologically confirmed, and chemotherapy was initiated as recommended by the hematologist. The clinical course was characterized by multiple complications: hematologic and hepatic toxicities, opportunistic infections and depressive episodes. Highly active antiretroviral therapy associated with sustained psychological support resulted in stabilization of the patient's clinical course (lower HIV viral load and higher CD4 lymphocyte cell counts), anticancer therapy being better tolerated. Currently, patient's clinical-biological status is quasi-normal. The depressive episodes in this HIV-positive cancer patient undergoing chemotherapy contributed to her non-adherence and non-compliance to treatment, with serious consequences both on clinical and viroimmunological status. Therapeutic strategy in this patient with AIDS and Burkitt lymphoma raised management difficulties as both the drug interactions and cumulative adverse effects had to be considered. Multidisciplinary collaboration and especially psychological intervention are essential for creating a functional team, effective communication being key to achieving long-term adherence to treatment and diagnosis acceptance. **Keywords:** HIV/AIDS PSYCHOLOGICAL COUNSELING, NONCOMPLIANCE, NONADHERENCE, NEOPLASIA.

In Romania, the late 80s and early 90s marked the onset of a HIV epidemic characterized by perinatal transmission of the virus to many children (1). Changes over time in the guidelines for antiretroviral therapy in the patients included in the *"pediatric cohort"* were determinants of non-adherence and non-compliance. Maintaining low CD_4 cell counts for a long period in advanced stage HIV-positive patients predisposes to opportunistic infections, particularly tuberculosis, and HIV-related neoplasms (2, 3).

From a statistical point of view, there

was an increase in the number of non-Hodgkin lymphoma at the same time with the number of AIDS cases (4). For most lymphomas, a specific cause was not identified, however, some distinct non-Hodgkin lymphomas are associated with a viral infection (4, 5). According to some studies, patients infected with HIV are 59 to 104 times more likely to develop lymphomas, particularly the aggressive type (Burkitt or Burkitt-like lymphoma) with central nervous system damages (20-30%), and have a poor prognosis (6).

Non-Hodgkin lymphoma in patients with AIDS is often characterized by extra nodal involvement and severe course. Patients are treated with chemotherapy specific for non-Hodgkin lymphoma, though there are several potential risks: overgrowth of opportunistic pathogens and discontinuation of treatment in the context of the commonly associated depressive episodes (6, 7). The disease burden experienced by patients determines changes in self-perception with significant decline in self-esteem and motivation for a good adherence and compliance to antiretroviral and antineoplastic therapy, thus the role of the psychologist in the of HIV/AIDS department being essential (8).

CASE REPORT

We present the case of a 27-years-old woman registered to the Iaşi Regional HIV/AIDS Center since year 2000, currently with stage C3 AIDS. During patient monitoring a progressive decrease in CD4 count was found and the viral immunology tests showed moderate to severe immunosuppression (fig.1, fig.2) because of non-compliance and non-adhesion to treatment. In 2013 the patient was referred to the gynecology department for irregular periods and lower abdominal pain. Continuing the investigations, an abdominal-pelvic CT scan revealed an expansive tumor mass of 7/3/2.5 cm, located on the right ovary. A salpingo-oophorectomy was performed and pathological examination and immunohistochemical tests made the diagnosis of Burkitt lymphoma. Due to a depressive episode, the patient decided to delay the investigations for malignant non-Hodgkin lymphoma (NHL), during which time she received counseling and antiretroviral therapy consisting in combinations of Darunavir/Ritonavir, Etravirine and Raltegravir. Compliance and adherence to HAART were influenced by psychological support, the CD4 cell counts increasing from 33 cells/mm^3 (fig. 1), value recorded at the time of neoplasia diagnosis, to 165 cells/mm^3 (fig. 1) and the viral load decreasing to VL = 10,730 copies/ml (fig. 2). In January 2014, after repeated discussions with the infectious disease doctor, while benefiting of sustained psychological counseling, the patient was referred to the hematology department. Physical examination at the admission to the Regional Cancer Institute confirmed the presence of bilateral painless submandibular lymph nodes of about 2 cm in diameter. Bone marrow biopsy and CT scan of the thorax, abdomen and pelvis confirmed the diagnosis of stage III A Burkitt lymphoma, per ANN ARBOR staging. Hyper-CVAD (Cyclophosphamide, Adriamycin, Vincristine, and Dexamethasone) chemotherapy protocol was initiated, being subsequently associated with Rituximab. Secondary hematologic toxicity required granulocyte growth factor support and prophylactic antimicrobial therapy (acyclovir and cotrimoxazole). The patient received psychological support throughout the hospital stay, resulting in

improved adherence to antiretroviral and antineoplastic therapy. In November 2014, she had and emergency admission to our clinic for: vertigo, nystagmus, abnormal gait, with onset in the context of fever and marked anxiety. Biological exams revealed thrombocytopenia (Tr=84,000/mm^3), hepatic cytolysis syndrome (TGO=108 IU/L; ALT = 84 UI/L) and cholestasis syndrome (FA =134 IU/L; GGT =72 IU/L). Laboratory exams were supplemented by lumbar puncture, which ruled out lymphomatous meningitis and other causes, and cranio-cerebral MRI, which both invalidated the presence of tumor masses and brain infiltrates. Biological changes were considered secondary to oncologic therapy and to HIV infection. Following psychiatric and psychological evaluation the patient was diagnosed with generalized anxiety disorder for which antidepressant and anxiolytic therapy was initiated. Daily psychology sessions were resumed. In December, the same year, CD_4 cell count increased to 466 cells/mm^3 (fig. 1) and the viral load was undetectable (fig. 2).

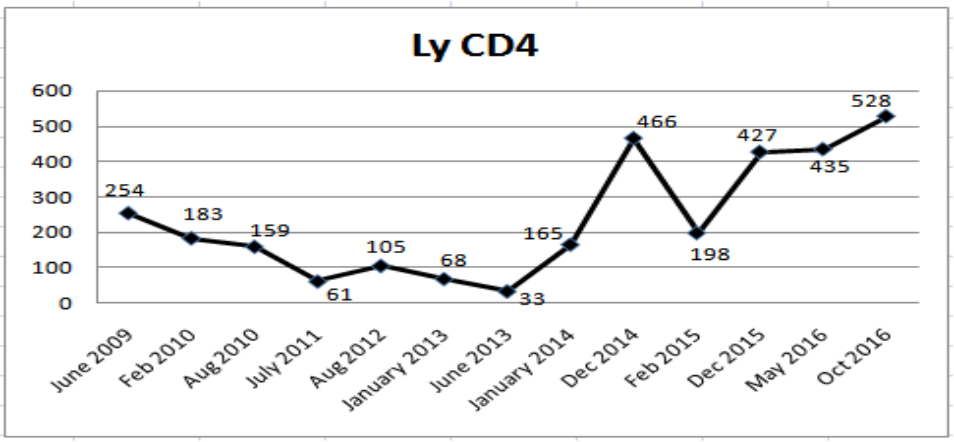

Fig.**1**. CD_4 cell count

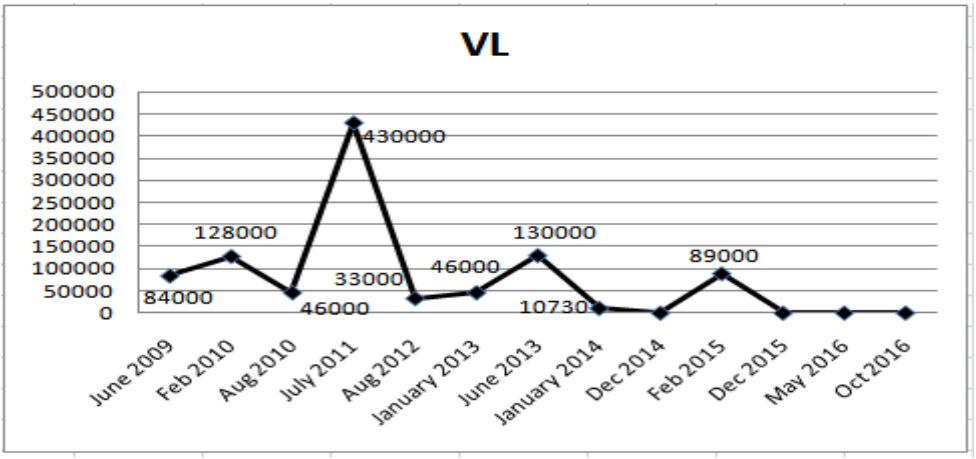

Fig. **2**. Viral load

Subsequently, in February 2015, the patient was reassessed for cough, chest pain and fever. Laboratory investigations have shown a decrease in CD_4 count to 198 cells/mm^3 (fig. 1) and a viral load of 89,000 copies/ml (fig.2). A chest X-ray was performed and it described a characteristic appearance of bronchopneumonia. But the etiology of infection could not be determined. Empirical antibiotic therapy was initiated with moxifloxacin and imipenem the clinical course being slowly favorable. Following discussions with the infectious disease doctor and psychologist the patient admitted that after her general status had improved she started missing doses of HAART, initially 3-4 days a week to complete discontinuation for one month. Remission of lung phenomena allowed patient's transfer to the hematology department. CT and PET-CT examination confirmed the recurrence of an abdominal lymphadenopathy and thus the relapse of the disease, and therefore antineoplastic therapy was reinitiated. In May 2016, the patient achieved partial remission of the disease, supported by imaging investigations, undetectable viral load (fig.2), and CD_4 count of 435 cells/mm^3. The viral immunology assessment in October 2016 showed that viral load remained undetectable, and CD_4 count increased to 528 cells/mm^3 (fig. 1).

DISCUSSION

Given the therapeutic advances in the management of HIV/AIDS the prognosis and the quality of life of patients with HIV have improved. However, the association between the diagnosis of HIV infection and a neoplastic disease has a strong psychological impact, causing recurrent depressive episodes that are a favorable factor of therapeutic abandonment. Under these circumstances the psychologist plays an important role in the multidisciplinary team, namely to guide the patient through acceptance of the diagnosis and adapting to challenges of everyday life. Counselling and psychological support, aimed at providing support in managing negative emotions was based on an honest and comfortable exchange of information (9).

Depression is a natural step in accepting the diseases with serious prognosis, characterized by apathy, insomnia, loss of appetite, constant anxiety, and fear of death (10). The recurrent depressive episodes were initially relieved and subsequently overcome by talks with the physician, psychological support, and antidepressant medication. However, the factors that contribute to the degree of patient adherence to therapy are myriad and include the socioeconomic status, level of education, family support, and finally motivation. In the here reported case the patient's high level of education and her desire to start a family were all decisive factors for accepting the psychological counseling.

CONCLUSIONS

Our case emphasizes the fact that the association of AIDS with a malignant disease predisposes to recurrent depressive episodes leading to nonadherence and noncompliance to antiretroviral therapy. We believe that the role of the psychologist tends to be minimized in favor of drug therapy, but the presented case highlights the important contribution of appropriate psychological support in the multidisciplinary management plan of the HIV-positive patient.

HYDROGEN PEROXIDE VASORELAXATION INVOLVES S-GLUTATHIONYLATION OF VOLTAGE-DEPENDENT K CHANNELS

H_2O_2 is an endothelium-derived hyperpolarizing factor (EDHF), but H_2O_2 effects vary with the vascular bed and experimental conditions. If H_2O_2 relaxes rat mesenteric artery, what is the mechanism? Methods: myography of isolated resistance arteries, patch clamp of mesenteric arterial smooth muscle cells (MASMCs), streptavidin pull-down assays with biotinylated glutathione ethyl ester. Relaxation of precontracted arteries by H_2O_2 was reversed by dithiothreitol, reduced by 4-aminopyridine (4-AP), blocker of voltage-dependent K channels (K_v) channels, but not by blockers of big-conductance Ca^{2+}-activated K^+ channels or of inward rectifier K^+ channels. H_2O_2 increased K_v currents; this was prevented by glutathione reductase; K_v incorporates glutathione (GSH) in the presence of H_2O_2. Thus, H_2O_2 activates Kv channels (maybe via S-glutathionylation) with artery relaxation, while the basal redox status of MASMCs determines K_v response to H_2O_2 (Park SW, Noh HJ, Sung DJ et al. Hydrogen peroxide induces vasorelaxation by enhancing 4-aminopyridine-sensitive Kv currents through S-glutathionylation. *Pflugers Arch* 2015; 467(2), 285-297).

SPONTANEOUS PREGNANCY IN SUBSEQUENT CYCLE AFTER LAPAROSCOPIC CYSTECTOMY. CASE REPORT (Abstract): Most women will experience a cyst on the ovaries at least once, and most are painless, cause no symptoms, and are discovered during a routine pelvic exam. Large cysts that can cause symptomatology or infertility problems occur in about 8% among women of reproductive age. The current case report comes to show that laparoscopic surgery is the key for persistent organic tumors of the ovary, after a complete diagnostic of the cyst; not the expectant management or hormonal therapy, but laparoscopic cystectomy after transvaginal punction and drainage of the fluid is minimal requiring as recovery timing, medical care period, low costs, and not the least, ovarian functionality, after suppressing ovulatory function. **Keywords**: CYSTECTOMY, PREGNANCY, OVARIAN CYST.

Abdominal cysts are sacs or lumps surrounded by a membrane, encapsulating fluid or semi-fluid material. While most cysts are benign, the presence of a mass may indicate an under-laying disease therefore, further investigation should be done. One of the most common abdominal cysts is the ovarian cyst which is formed on the ovarian follicles (1). In the last years, the number of diagnosed ovarian cysts has increased once the regular physical examination has been completed by more complex investigations such as imagistic technology and specific ovarian tumor markers. Nevertheless, the discovery of an ovarian mass may cause anxiety for the patient since future fertility is one of the major concerns in women of reproductive age.

CASE REPORT

A 28 years-old Romanian woman, normal conformation (65 kg body weight and 175 cm height), with no history of pregnancy or gynecological pathology, presented in our clinic with pelvic pain irradiated in the left inferior member accentuated during sexual intercourse and physical activity. The patient also experienced polakiuria, lumbar pain, low abdominal distension, bloating and perturbation of the intestinal transit and defecation, starting 6-8 months before but became acute in the last weeks. A non-investigated 2-year primary infertility was also declared by the patient.

According to the anamnesis, menarche commenced at the age of 15 years with subsequent irregular cycles and moderate dysmenorrhea. Deep abdominal palpation revealed sensitivity in the left flank, which was irradiating towards the hypo gastric region and sigmoid colon. The bimanual vaginal examination showed a mobile retroverted uterus, with normal dimensions. On the left adnexal topography, a voluminous mass, with imprecise limits was observed. The tumoral mass, whose appurtenance was established at the ovary, presented tenderness. The endovaginal echography showed a highly deviated uterus towards the right side, although the dimensions and aspect were normal. The left ovary was enlarged in volume, presenting a well-defined mass, 113 mm / 110 mm/100 mm, with thick membrane, clear content, without any proliferations or intracystic septae (fig.1, 2).

Fig. 1. Ultrasound image of anechoic cyst. No septations were observed; thin walls and a nodule without flow on Doppler was present on the posterior wall

Fig. 2. Normal ultrasound of right ovary**.** A part of left ovarian mass, compressing the right adnexa and the uterus

Doppler signal was reduced and the resistance index was normal. The adnexal torsion was excluded, additionally, no intracystic hemorrhage was observed. According to the biochemical exams, the ovarian tumor risk markers were in normal limits ranging: CA 125 15,59 U/ml (normal value < 35), CA 19-9: 4,8 U/ml (normal range < 27), CAE: 0,497 ng/ml (normal range < 4,3) results which are supported by (2).

The MRI evaluation revealed an extremely voluminous cystic formation (134 mm / 116 mm / 110 mm) (cranio-caudal/ transversal / AP) located in the pelvis and in the hypogastrium area. At MR imaging, the well-defined formation presented hyper-intensity in T2 and T2 iso-signal with moderate restriction, inhomogeneous diffusion and a discreet outlet contrast at the level of the thin wall (2 mm). The lesion, which originated in the left ovary, showed significant mass effect on the urinary bladder, uterus, right ovary, sigmoid colon and intestinal loops, as well as strong compression syndrome on the common and external iliac veins. In the upper pole of ovarian cyst formation, a wide oval area of 30/10 mm, hyper-signaling in T1, T2, with diffusion restriction and nonspecific appearance was observed plated on the right anterolateral wall. The uterus, which was shifted

posteriorly, presented normal size and structure. The dimensions of the right ovary were normal, although few small follicular cysts were present. Based on the ultrasound report, MRI evaluation and biochemical markers we decided to evacuate the cystic fluid throughout a minimal invasive procedure. Thereby, 1.3 liters of fluid were evacuated by transvaginal puncture and aspiration, using echo-guidance (fig. 3, 4).

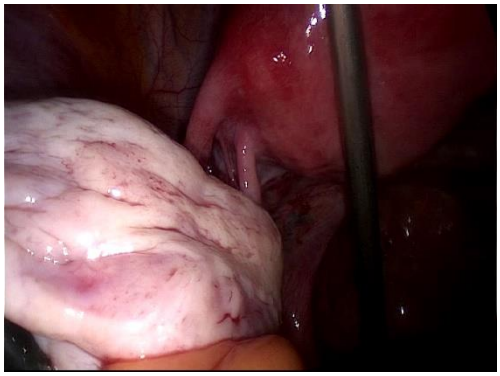

Fig. 1. Intraoperatory image of the tumor

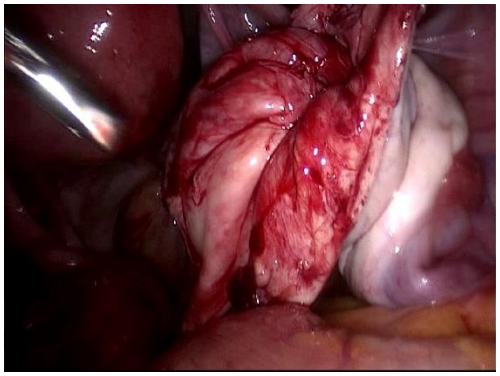

Fig. 4. Intraoperatory image of remaining ovary

The histological exam revealed smooth cystic walls, serous fluid and no vegetation inside. After the evacuation of the fluid, the cystic membrane was removed by laparoscopic excision. It was established that the tumor mass was a mature cystic teratoma, which presented epidermal cells and thyroid tissue. One-month post-operatory intervention, the patient presented with a positive pregnancy test, the single intrauterine gestational sac being confirmed by ultrasound scan. The luteal corpus was observed on the left ovary, which was previously affected by the tumor.

DISCUSSION

Mature cystic teratoma (MCT), also called dermoid cyst, is the most common ovarian benign germ cell tumor in women of reproductive age (from teens to forties) (3). Future fertility is one of the major concerns among these women therefore, the management of the tumor must focus on preserving ovarian tissue and minimizing adhesion formation. The particularity of this case resides in the fact that the left ovary, whose ovulatory and gametogenesis function has been inhibited by presence of the tumoral mass, regained its activity in the first month after the laparoscopic removal of the cyst. Conform to literature data regarding the surgical treatment of Stein-Leventhal syndrome, this mechanism is similar to the one observed in PCOS patients, which were submitted to cuneiform resection of the ovary.

Laparoscopic management offers many advantages for the patient: accurate diagnosis, minimal bleeding, reduced need for analgesia, less adhesion formation, fast recovery, better cosmetic results, shorter hospital stays (one-day surgery in selected cases), and reduced costs for the patient and hospital (4-7).

CONCLUSIONS

Laparoscopic cystectomy after transvaginal punction and drainage of the fluid

is minimal requiring as recovery timing, medical care period, low costs, and not the least, ovarian functionality, after suppressing ovulatory function.

CHRONIC ORAL MG LOWERS ARTERIAL PRESSURE INCREASED BY CHRONIC INHIBITION OF NITRIC OXIDE SYNTHASE (NOS)

Male rats received N-nitro-l-arginine methyl ester (l-NAME, 25 mg/kg/day in drinking water) for 6 weeks, alone or together with magnesium-oxide (0.8% in diet). Systolic arterial blood pressure (ABP) was measured weekly (tail-cuff). Constriction and relaxation was studied in rings isolated from thoracic aorta and third order mesenteric artery. Gradual hypertension induced by l-NAME was attenuated after five weeks of oral Mg. Chronic l-NAME increased phenylephrine induced constriction and decreased acetylcholine (ACh) induced dilation, both restored by Mg. Nitric oxide (NO) contribution to ACh relaxation of mesenteric arteries was suppressed by l-NAME, corrected by Mg. Flow-mediated dilation (FMD) of mesenteric arteries was blunted by chronic l-NAME; not corrected by chronic Mg. Vascular eNOS and Mg were not changed but plasma nitrite was reduced in hypertensive rats. Restoring arterial relaxation, chronic Mg decreases ABP increased by chronic l-NAME. (Basralı F, Koçer G, Ülker Karadamar P et al. Effect of magnesium supplementation on blood pressure and vascular reactivity in nitric oxide synthase inhibition-induced hypertension model. *Clin Exp Hypertens* 2016; 37(8): 633-642.)

COMBINED APPROACH FOR LARGE MALIGNANT TUMORS OF THE NOSE AND PARANASAL SINUSES – CASE REPORT (Abstract): Due to the insidious onset and common symptoms, the diagnostic of sinonasal tumors is late in the evolution. Usually, at that time, the preferred endoscopic approach alone is not recommended, therefore a mixed open-endoscopic approach appears to be the best choice in terms of exposure of the tumor and a clear margin resection. The purpose of this case report study is to demonstrate the necessity of careful preoperative assessment and the advantages of combined approach for a complete resection and favorable long-term results. **Keywords**: COMBINED APPROACH, NASAL ENDOSCOPY, AUTOLOGOUS GRAFT, SINONASAL TUMORS

Sinonasal malignancies are quite rare (5:1000000 rate in USA – 1% of all cancers) affecting women and men with equal rates, usually in the 6th decade of their life. The diagnostic is made late in the evolution due to the insidious onset and common symptoms (nasal obstruction, mucous rhinorrhea, sometimes recurrent minor nasal bleeding), therefore surgery – if still possible – needs open approaches to allow a wide exposure of the tumor. The endoscopic approach is rarely used alone, usually completing the open approach, allowing in the same time a better control of the excision margins.

We are reporting a case of a male patient diagnosed with a large tumor occupying the nose, paranasal sinuses and operated using a double approach (open and endoscopic) allowing a good control of the excision. The importance of preoperative assessment of the extent of the tumor and the best approach chosen are discussed.

CASE REPORT

D.D. a 53 years old male patient was admitted in ENT Department of the "Sf. Spiridon" Clinical Emergency Hospital Iasi, for bilateral nasal obstruction, mucous and purulent rhinorrhea, minor recurrent nasal bleeding on the left side, frontal headache, complete loss of smell, with an

onset 18 months before. 12 months before he was operated in a different ENT Department for nasal polyposis but no histopathological evidence was present at the time of actual admittance in the hospital.

The anterior rhinoscopy revealed a large purple, irregular, covered with puss, easily bleeding when touched mass, that could suggest some confluent polyps, and is blocking completely the left nasal fossa in its posterior 2/3 and almost completely in the anterior 1/3. The posterior rhinoscopy showed the complete blockage of the left choana and the protrusion of the mass to the nasopharynx.

The CT scanner revealed the presence of a large solid mass involving the left nasal fossa, ethmoid and frontal sinuses (fig. 1) with some small areas of bone erosion on the anterior skull base and the posterior wall of the left frontal sinus (fig. 2).

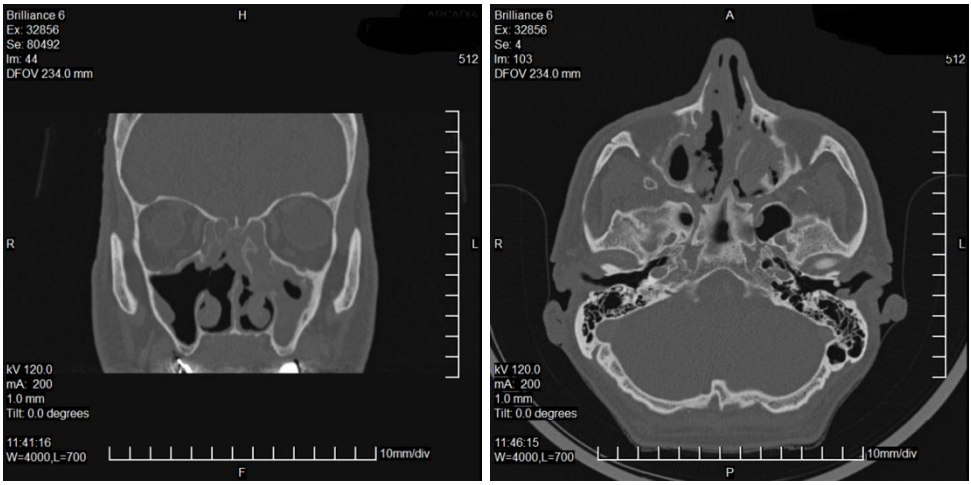

Fig. 1. CT scanner showing the tumor

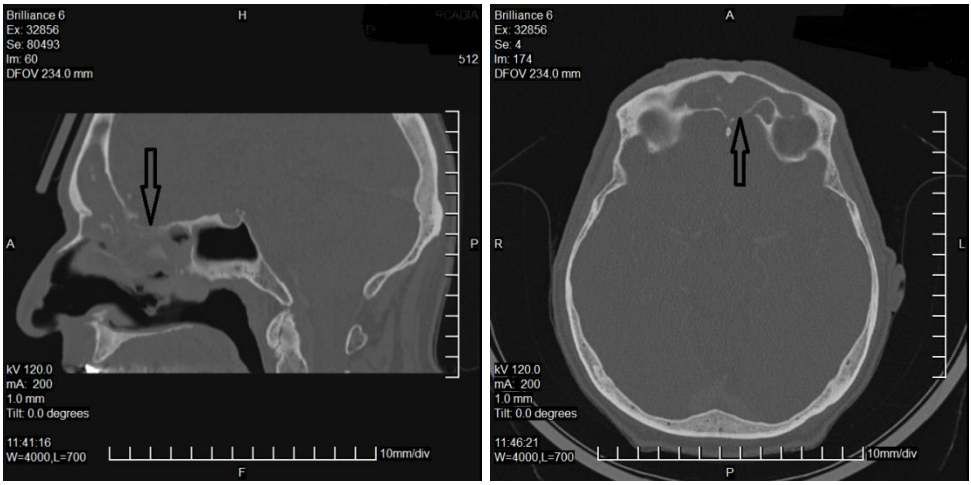

Fig. 2. CT scanner showing bone erosion areas

The complete removal of the tumor was performed using a combined approach – both open subcranial and endoscopic approach. The subcranial approach required the removal of a segment from the frontal bone (fig. 3) and due to the erosions of the posterior wall of the frontal sinus and the exposure of the duramater, the frontal sinus cavity was filled with an autologous abdominal fatty tissue graft (fig. 4).

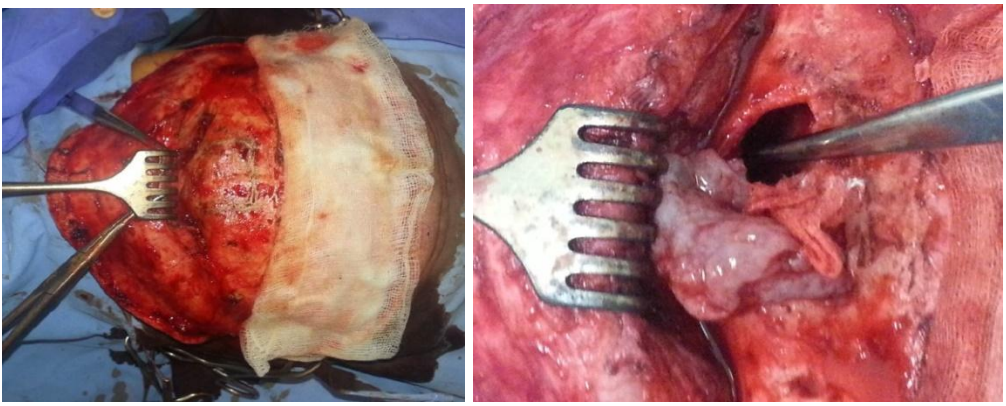

Fig. 3. External subcranial approach exposing the tumor; probe in the right frontal sinus

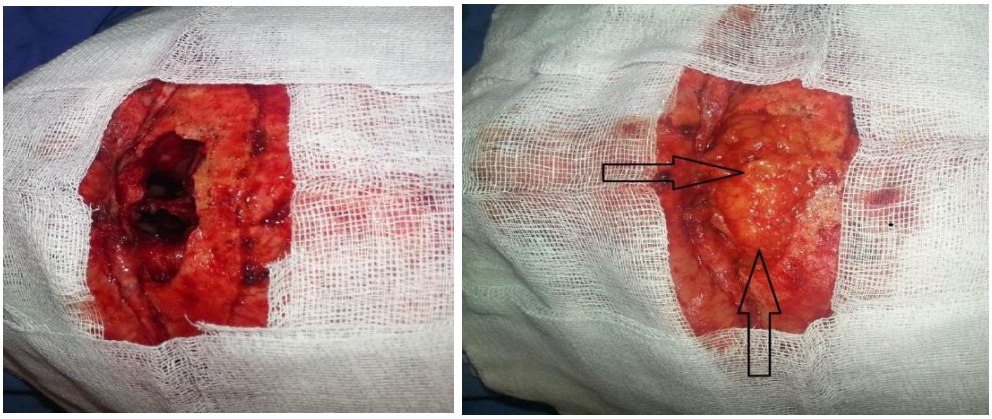

Fig. 4. The cavity left after resection; autologous abdominal fatty tissue graft

The histopathological examination revealed an inverted Schneiderian type papilloma. The postoperative evolution was good allowing the patient to be discharged after 4 days. The periodic follow-up showed no recurrence after 2 years.

DISCUSSION

The surgical approach of sinonasal tumours is not standardized and it has to be individualized for each patient, considering the extension. Due to the patient's late visit to the otolaryngologist and the large extensions of the disease, endoscopic surgery alone rarely solves the case. However, it can very often be a reliable resource in ensuring an accurate excision. This happens when the extensions are towards the orbit, sphenoidal sinus, pterygomaxillary

cavity, which is difficult to reach and control through external approach (1,3).

The frontal sinus in its inferior side as well as the frontal recess can be accessible through an endoscopic approach (using angular optics of 40 or 70) but in invasions superior to these areas, external approach is more favourable (2,4).

The invasion of the lamina papyraceea, the floor of the orbit, the anterior wall of the maxillary sinus and particularly of the covering skin ends with large excisions and important esthetical problems, especially if the resection is made for a malignancy, can be a relative contraindication to postoperative radiotherapy, due to lack of bone support of the pedicle flap harvested for reconstruction.

Sometimes the endoscopic approach is not satisfactory for a good exposure of the tumor and in the same time, the open approach alone can result in large cosmetic defects difficult to be accepted by the patient. In these cases, endoscopy due to the given magnification can complete and guide the excision of the tumoral tissue left in place, with lesser facial scars.

CONCLUSIONS

In the past, large tumours of the nose and paranasal sinuses were approached classically, using different facial incisions for a good exposure and leaving unesthetic scars. Lately, some authors are the advocates of endoscopic surgery that allows a good visualisation of the otherwise inaccessible areas. In our opinion, the approach must be individualized for every patient (considering general status, comorbidities), for every tumoral extension and for every histologic type.

The presented case demonstrated that, in this specific localization, the endoscopic approach alone would have been allowed the complete excision in the middle and lower part, but not in the frontal sinuses, while the external approach alone, in order to completely remove the tumour, would have been created some inesthetic facial scars. Combining these approaches gave us a complete control of the tumour and a very good esthetic result.

HEALTH CARE ECONOMICS IN ROMANIA – DYNAMICS AND EVOLUTION

B. I. Tamba, Doina Azoicăi, Daniela Druguş *
University of Medicine and Pharmacy "Grigore T. Popa" – Iasi

Department of Preventive Medicine and Interdisciplinarity
*Corresponding author. E-mail: ddrugus@dirgen.umfiasi.ro

HEALTH CARE ECONOMICS IN ROMANIA – DYNAMICS AND EVOLUTION (Abstract): Health economics refers to the analysis of medical institutions considering their economic and social efficacy, but also the regularity and the relationships that govern the phenomena and the processes from the field of health with the final purpose of achieving better results with the minimum of resources; it represents the study of health price in its complexity. The economics of the population's health needs and in particular the health needs in case of the poor groups of the population, consider health to be the main component of global human vulnerability. Health economics tries to change the simple interpretation of health price and disease cost into a wider consideration of a system administration similar to educational and social economics and the study of health in the context of the multiple specializations of the macro economy of the national group, as it is an instrument in the country's great economics symphony. **Keywords:** MANAGEMENT, HEALTH ECONOMICS, HOSPITAL SERVICES.

Health economics appeared as a result of the interest the economists showed in all social life's fields, starting with industry and agriculture and finishing with education and health.

In general, it is considered that the population's state of health deteriorates and the mortality increases when the macroeconomic situation gets worse. Nonetheless, nowadays, there are more and more data indicating the fact that physical health and not psychical health, actually improves in this type of periods (1).

In the middle of an age of interdisciplinarity, economists see health as an economic good. It is determined by biological factors (heredity, sex, and age), environmental factors and life style factors. But since prevention and early identification of diseases can be accomplished with huge financial investments and because health is quantified in terms of efficiency and efficacy, it becomes on abject of economic study.

This is only one of the arguments that place health in its position of segment of the national economy. Consequently, the economists wander to what extent it answers to the supply and demand relationship, what the society wants, what it is offered to it and what it gives in return. The answers are difficult and relative because health, just like education, provides long-term services. But precisely this type of

observations confirms the efficacy and social utility of the health care system. Naturally invaded by numerous and different diseases, in its need of preservation, the society formulates requests that cannot be postponed.

Medicine represents a dynamic field if we consider the technology it works with, but completely inert if we refer to its financial situation, as the reform of the health care system requires time and the answers to macroeconomic shocks take numerous years, even decades. Even if the population presents a better state of health which generates higher incomes and vice-versa, the improvement of life standards leads to a better state of health in people, the relationships between the state of health and economics remain difficult to quantify and even study (2).

As an answer, the health care system comes with a diverse offer of services. The national level and its economic fund generate the value a society invests in health. Human value health is a right of man protected by medical science but also by economic resources and means.

ETHICS AND HEALTH CARE

Decades ago the differences between health economic analyses and clinical practice were significant, with the physicians and patients who defended Hippocrates' Oath on one side and policy makers and health economists on the other side. It was the policy makers the first ones to have to solve the difficult allocation problem: the health care budget was growing faster than any other public spending. Later, the economists came in trying to make the optimal decisions in limited financial situations. Then, health policy makers decentralized their budget, which was an intelligent political move, as the responsibility for the healthcare budgetary allocations was now shared. However, clinical quality concerns started to appear: waiting lists and insufficient care, these rapidly becoming hot subjects in the public eye, with patients claiming their right for health care by law or by public indignation. It became clear that budget policy had to be justified by more arguments than just financial constraints.

In this context, the health's base results to be economic, and its management consist in obtaining maximum performances with the minimum (often limited) investments. This is how health economics was born, a science that can be mastered only by those with a dynamic, flexible thinking manner and endowed by the ethics of the health care system (5).

Ethical rationale for publicly financed health insurance rely on four logically related issues: (1) the ultimate purpose of a human life or human society; (2) the role of health and its distribution in society in advancing this ultimate purpose; (3) the role of access to or utilization of health care in maintaining or improving the desired level and distribution of health among members of society (4) the role of public financing in ensuring the ethically justified access to and utilization of health care by members of society.

It is true that economics must not prevail over the medical act, but it is equally true that the physician cannot ignore the efficacy of his actions (maximum results with minimum of resources) and their efficiency (health days, recoveries, years of life regained, lives saved). Deriving from political economics, health economics is part of a triad, along with education economics (medical education, in particular) and science economics (medical scientific research).

All the three entities work together un-

der the auspices of economics, according to the law based on maximum efficacy with the minimum of effort. The collaboration between physicians and economists results a necessity that can only be fulfilled through interdisciplinarity. Health economics contributes to economic health (6). C. Gastmans (cit. by 6) pleads for economists and ethicists to try and approach each other so that the tool of cost-effectiveness analysis is further developed to combine the two most important goals of health care systems: health maximization and the reduction of health inequalities.

In Romania, because the allocation of resources does not yet represent a purpose in itself, this necessity (for health economists) is less present. Nonetheless, there is hope for a rational perspective that might, at least support, if not impose, a decision and a smooth regulation of the decisional process.

HEALTH CARE ECONOMICS AND HTA

Romania spends approximately 6 percent of GDP (*gross domestic product*) on health (public and private) vs. the EU average (all EU countries) of 9.8 percent. Among current challenges are lagged health outcomes, patient dissatisfaction, lack of access to quality care by the poor and other vulnerable groups, and poor financial performance.

Romania had the highest infant mortality rate in the EU (3). Furthermore, the life expectancy gap between Romania and EU15 (EU countries on December 31, 2003) has increased 2 times since 1970, mainly due to the rising incidence of non-communicable diseases (NCDs).

Romania's health infrastructure and its service delivery system have not adjusted to modern technologies and do not meet the current needs of the population, which has suffered both a demographic and an epidemiological transition in last two decades. The hospital network in Romania is large and fragmented, with over 350 public hospitals that have been mostly been decentralized. Except for SMURD (*Mobile Emergency Service for Resuscitation and Extrication*) and several maternities, no other significant investments have been made in the last 20 years in medical infrastructure.

The rhythm of health care sector reform has been slow due to the lack of financial resources required to support the new policies.

Health technology assessment (HTA) is the 'systematic evaluation of medical technologies regarding their effectiveness, appropriateness, efficiency as well as social and ethical aspects and implications'(1). Its main purpose is to inform technology-related policymakers in health care and thus has a decision-support role in pricing and reimbursement. HTA provides the responsible bodies and organizations with timely, accurate, and sound information on new medical technologies (3, 4).

HTA focuses primarily on pharmaceuticals and medical devices (standardized technologies with clear ownership) as these constitute a high financial cost and their social impact and visibility are significant (7).

As pharmaceutical expenditures grew rapidly over the past decade and the 2008 crisis posed a major financial risk, the Romanian government, financed by the World Bank, contracted as consultants NICE International (*The National Institute for Health and Care Excellence*) (UK) to provide recommendations on how to reform the health care system. The legal framework for HTA in Romania was created

through Government Decision 351/2012. The responsibility of the HTA unit is broad: HTA can be applied to all existing medical technologies such as pharmaceuticals, medical devices, health policies and public health.

According to an HTA guideline, the assessment of innovative drugs is made using a 6-item scoring chart where the maximum number of points is 10, and for a positive reimbursement recommendation, the pharmaceutical product has to score at least 6.

The decision on reimbursement is reached by assessing two distinct types of evidence:

1. Reimbursement recommendations given by HAS (Haute Autorité de Santé) France, and 3 HTA bodies in the UK (NICE - *The National Institute for Health and Care Excellence* / SMC - *Scottish Medicines Consortium* / AWMSG - *All Wales Medicines Strategy Group*), and reimbursement status in other EU member states;

2. Clinical profile of the intervention: relative efficacy, relative safety and *patient reported outcome* (PRO).

The family physician, being well informed about the social and demographic dimensions of health care and on the extremes of medical consumption because he deals with patients of all ages, must be aware of the balance between promoting health and treating diseases, the amount of services provided, their cost and efficacy.

Applying the cost-advantage and cost-efficacy (benefit), he obtains the monetary value, the result of the relationship between the value of the resources invested and the value of the program made. Analysing the correlation advantage-unit and time unit, the physician observes that efficacy represents an economic manner of achieving a well-defined purpose.

The role of reason in using health resources eases the difficult action of keeping records of the cost-advantage. For example, the role of personal hygiene in preventing infectious-contagious diseases, especially digestive ones, represents a logical, cultural, scientific and concise resource used rationally as an investment for health. Its absence generates higher costs in treating the inherent diseases. The quantitative decrease of the number of these diseases reduces the number of the ones who get ill, as well as the financial results (costs) due to the logical and positive use of the resource in question.

Of course, if the group it is addressed to is well analysed from multiple points of view: the members' cultural level, receptivity period, logistical and support component of theoretical investment etc.

The high costs in health represent one of the biggest problems. High quality medical services, the production of medical science with sophisticated means, the consumers' request for more and more sophisticated devices and solutions that are mainly logistical, contribute fully to this phenomenon. The cost-efficacy relationship is always relative, depending of the results of other programs or of a general rule.

In order to make an informed choice about if and how much to pay for a medicine, it requires evidence beyond the classical safety and efficacy data from the clinical trials. Compiling huge amounts of economic data, *electronic health records* (EHRs), genomic data, labor statistics etc., business players can better illustrate the value of their products. Two studies showed that half of American consumers are willing to pay more for personalized medical products but at the same time, are divided about paying for the tests that enable these treatments (cit. by 6).

The analysis of the relationship between

cost and utility is measured in precise results: the effect of treatment on the patient's life quality; years of life won depending of the quality of life; number of days without getting ill; number of lives saved, early identification of cancer etc. Considering this multitude of advantages at human level, we understand that the moral aspect of the problem comes first (6, 8).

But providing an etiological treatment, apart from its efficacy, it also induces the advantage of diminishing the financial value of those treatments that are difficult to define, reducing the labour incapacity period, the hospitalization period etc. When referring to maximum efficacy with the minimum of resources, by minimum we must not understand "insufficient" or "cheap", but a scientific, rational, attentive use of resources.

Returning to preventive investment, it proves to be less financially demanding than curative investment, although none of the components can be pointed out in the detriment of the other as they create a logical balance. Prevention interventions are not necessarily more effective than the ones that focus on treating. The prevention and curation % worldwide are almost equal. The idea is that the damage once created brings along a lot of human suffering and medical effort, including material and financial effort.

Considering its efficacy, any treatment program must be subjected first to a keen examination: to what extent it is feasible; if it prevents complications effectively; if it justifies itself from a humanitarian (reduces pain, deaths) and economic (reduces the number of patients) point of view; to what extent it influences life quality. The decrease of the number of deaths, of irretrievable biological losses that are impossible to compare and label depends of preventing and counteracting the avoidable factors of post neonatal mortality with the aid of the managerial conception and intervention of health care services in correlation with social, economic, political and legal factors.

It results that any physician is invested with economic responsibilities even if he only writes down a recipe. Economic assessment is professionally necessary but also out of respect for the patient, as it represents a fundamental part of the decision making process. A good, useful, efficacious and effective use of resources depends of rational, scientific thinking that is the prime self-resource of total management. Resource management taken into custody must be credited with purpose, as an action, always compatible with similar activities.

HEALTH CARE AND INFORMATION TECHNOLOGY

While IT (*information technology*) has the potential to greatly improve the quality of health care, the evidence that IT improves important health related outcomes is limited. Some authors (9, 10) argument that while HIT (*health information technology*) has the potential to lead to a dramatic transformation in healthcare delivery, the empirical research showed limited results supporting HIT benefits. Their recommendations on a successful HIT implementation require a system that is intuitive to use and that requires little training for users; a system that can be modified and developed easily.

The authors also note that although there is an increasing number of a HIT solution designed to be used directly by the patient (for example, internet self-help sites), very little is known in terms of use and outcomes. Also, the main HIT implementation barriers are cost and overcoming misgivings from physicians due to per-

ceived adverse effects on their time.

The Integrated Health Information System of the Social Health Insurances goal is to ensure the computerized management of the economic and medical data necessary for an efficient Romanian health insurance system. Thus, it contributes to the development and improvement of the medical and pharmaceutical services.

System's coverage area: National Health Insurance House, all the County Health Insurance Houses, Physicians, Family Doctors, Medical assistants, Hospitals, Providers of ambulance services, Providers of homecare services, Out-patient recovery, Providers of medical devices, Providers of rehabilitation sanatoria services, Providers of pharmaceutical services.

IHIS (*Integrated Health Information System*) in Romania aims at improving the social health insurance system among others by collecting and managing the economic and medical information, ensuring the transparency regarding the control and management of the budgetary funds, creating and administering the National Registry of Insured Persons and the National Registry of Medical Services Suppliers. The main functionalities of IHIS include the management of the social health insurance funds, the management of the insurant, the management of the medical and pharmaceutical service providers, the evidence of taxpayers and control of the medical services.

However, the drive for more health data and integration comes also from the private sectors, as both consumers and physicians cheer the dramatic expansion of the personal medical kit, with wearable tech, smartphone-linked devices and mobile apps becoming increasingly valuable in health care delivery.

Personal medical kits could help diagnose illness, detect early signs of disease, and facilitate the recovery and rehabilitation closer to home. Clinicians seem more open to using these tools than consumers, according to HRI (*Health Research Institute*) survey findings. One-fifth of consumers said they would use a home urinalysis device. But nearly half of physicians said they would use data from such a device to prescribe medication or decide whether a patient should be seen. Nearly 90% of MDs said that patient devices and apps will be important to their practices in the next five years.

The app market – filled with 50,000 free and nearly-free products – is highly saturated. The Romanian market of smartphones had around 2.5 million units sold in 2014, and the tablets reached 700,000 units with at least as many potential users for health care apps.

PRIVACY AND SECURITY

All that may come to my knowledge in the exercise of my profession or outside of my profession or in daily commerce with men, which ought not to be spread abroad, I will keep secret and will never reveal. (The Hippocratic Oath, 4th Century BC) (11).

The number of websites and social networks providing health care related information and opportunities for patients to both share information and meet other patients is growing fast. For example, Yahoo health or WebMD, have around 20 million unique visits every month while in Romania, romedic.ro has over 1.5 million (1).

Several studies have showed the benefit of using Internet to share health-related information. Patients use the information to self-diagnose symptoms, understand the treatments and the medication devices (12) create or improve relationships (13), and deal with symptoms.

As the volume of personal information captured and digitized continues to grow at exponential rates, the concept of privacy has also been put on the top of the list of concerns for the public opinion. Recent research highlighted the significance of privacy concerns over the internet sharing of health or intimate data or how individuals deal with threats to their electronic privacy. Another author believes that privacy concerns could be the greatest threat to successful rollouts of EHRs.

At the same time with the increased shared and "in the cloud" patient and health data, the proliferation of medical devices in patients' homes, and apps on their phones points to an even more pressing need for strong information security systems.

In summer of 2014 alone, over five million US patients had their personal data compromised in health system privacy breaches. As for the mobile eco-system, the US Department of Homeland Security issued a warning to police officers, firefighters, emergency medical services and security personnel about the security issues in Android. The report says Android accounts for 79 percent of mobile malware, while Apple's iOS accounts for 0.7 percent. According to analysis company Stat Counter, Google's Android platform is the clear leader in Romania, reaching 62.73% market share in September 2014.

Still, the consumers want one-click access to their data and the challenge is to find the right balance between privacy, security and ease of use. Over 65% of respondents in a research said data security was more important to them than convenient access to imaging and test results, doctor's notes, diagnoses and prescriptions. For fitness data, the reverse was true. However, the consumers could agree to share health data if they would see social or increased care value in doing so.

Future cyber security safeguards will have to focus on what consumers look for – health data that is private, secure and one click away.

HEALTH CARE ECONOMICS – FUTURE DIRECTIONS AND CONDITION OF SUSTAINABLE HEALTH

The complete confidence with which a physician establishes the correct diagnosis determines the number of hospitalization days, the cost of the treatment, the number of recovering days, briefly, the efficacy of the medical act which is an important indicator for economic sciences.

Consequently, in spite of the fact that the economic factor is not the one guiding health, its decisive role cannot be ignored. From this point of view, Romania is facing severe problems. This situation will become even worse considering that the health care system confronts itself with three different pressure sources: the justified expectations of the population, which asks for a fundamental right of human beings; the progress of medical technology represented by equipment's, therapies and drugs, research studies in this field, which require important investments; population ageing (the costs with an older patient are 5-10 times higher than with a younger patient) (12, 14).

Seen from the economist's point of view, health, although it does not have a material meaning, is absolutely necessary for social and economic development, the economic activity being, by excellence, a support for protecting and conducting health care activities.

Health must be included in the political, economic, social, environmental and institutional context, the strategic frame being oriented toward accomplishing actions for

improving the state of health and assessing the impact of health care.

The economic principle applies to all the dimensions of the disease (apparition of pathogenic agents; their adjustment to the organism's defence mechanisms, to the artificial antimicrobial means; recombination of viruses; multi-causality and multi-diversity) and of health (preventing complications, premature death, disabilities, infirmities, diseases) (12).

Promoting health endows people with the best ways of ensuring and improving their own state of health. Health is not the purpose of life but one of its resources and it must be promoted through social responsibility, more investments and partnerships and the development of an appropriate infrastructure.

The promotion of health includes flexible models, adjusted to the present and future demographic situations, all of this in the general frame of the principles applicable to all people and all parameters that condition health care.

The health price and the disease cost are established based on an analysis that has at its base the medical and economic principles of efficacy and efficiency. The health price requires a longer period of time, even decades to be accomplishes. It is cheaper if moral investments are made, first of all, common sense in promoting health for the individual's physical, mental and social state of good. The disease cost refers to the disadvantages it brings at human level (13).

The priority for health economics in the process of providing health care services resides in the economy of human lives. Promoting health is an economic segment of the financial – material investment, and on the other hand, heath structure's relies on efficacy and efficiency.

Any attempt of restructuration of the health care system in Romania must begin from the analysis of the way in which the ones financially supporting the health system think and react; the health subsystem, as part of the global social system, relies on market economy, on the contributor's financial effort. The quality and the efficacy of the ones coordinating the professional destinies of the health care system must provide a convincing answer, based on the criteria and the methodology of an economic analysis at the level of health care services and individual practice. It is very important to be aware of the utility, the purpose of the activity, the patient's satisfaction and the contribution to the global health of the two essential factors: ethics and economic under-layer.

In Romania, decentralization and the reform of the financing system were made without a serious analysis of the consequences on the population in terms of territorial inequity and of the availability of the infrastructures and implicitly of the services. Pros and cons (*pro et contra*) for decentralization of the health care system:

- *Pros* (advantages):
  - Subsystems can be organized considering the local values, available infrastructure, diseases, preferences and services;
  - Increase the income in the community (local) level and the efficiency in resources allocation
  - Decentralized units can be used as "laboratories" for national policies.
- *Cons* (disadvantages):
  - Possible additional costs;
  - System fragmentation;
  - Decisional centralism vs. Administrative decentralization;
  - Misappropriation of national programs or institutions redundancy.

NSPHHSMPD (SNSPMS - *National School of Public Health and Management B ucharest*) contributes to improving the performance of health care services and improving the health of the population in Romania by consulting services and technical assistance to decision makers and providers of healthcare services, offered in order to optimize health policies and health services and developing health promotion programs with the purpose of responsibility and increasing health education among population

Main actions include providing scientific evidence to support health decisions and policies; evaluation, application and dissemination of research results to improve health practices; conducting studies and operational research in order to increase health system performance; educating and informing the population on attitudes and behaviors related to health, healthy lifestyle and public awareness about the importance of individual involvement in the maintenance and/or improvement of the health status.

Short and medium-term steps for health care system reform in Romania should focus, among others on:

a. Streamlining hospital services, implementation of regional hospitals networks, and reducing redundant capacity for inpatient services;

b. Enhancing primary health care services at the community level;

c. Implementing specialized secondary ambulatory care;

d. Increasing sector governance and stewardship to: strengthen the implementation of HTAs improve the management control mechanisms; implement health system continuous quality improvement and health system performance assessment; adjust the DRG (*diagnosis-related groups*) payment mechanism; streamline the National Health Programs; create the conditions for increasing the participation of private funds and private services; develop a Human Resource Strategy; strengthen the communications strategy

Examples of Public Health Schools with HTA dedicated departments or programs: University of Alberta, UMIT (University for Health Sciences, Medical Informatics and Technology, Tirol, Austria), Harvard School of Public Health, University of Birmingham, University of Adelaide, Aarhus University, and National University of Singapore.

NEWS

CLOSER AND CLOSER TO THE IDEAL BIOMARKER IN INFLAMMATORY BOWEL DISEASES

The role of the intestinal microbiota in the pathogenesis of inflammatory bowel disease (IBD) is more and more taken into consideration. Biomarkers obtained from alterations in the gut microbiome may be an alternative marker of disease presence and severity. A recent study showed that Trimethylamine-N-oxide (TMAO) production is dependent on the metabolism of GI tract microbiota. A case-control study carried out for 106 IBD patients and 373 non-IBD controls from southwestern Ontario found plasma TMAO levels to be significantly lower in patients with IBD. With further research, plasma TMAO levels may become a relevant, cheap, noninvasive means of diagnosing IBD (Wilson A, Teft WA, Morse BL, Choi YH, Woolsey S, DeGorter MK, Hegele RA, Tirona RG, Kim RB. Trimethylamine-N-oxide: A Novel Biomarker for the Identification of Inflammatory Bowel Disease. Dig Dis Sci. 2015 Dec;60(12):3620-30. doi: 10.1007/s10620-015-3797-3)

CONTRIBUTIONS TO RECOGNITION OF SOME PARTICULARITIES OF THE LINGUAL MUCOSA CONDITIONS **(Abstract)** Part of the oral cavity structure, the tongue plays an important role, both by its functions, and pathology, which sometimes can seriously damage the state of the entire body. As an important component of the dento-maxillary apparatus, the tongue has particular appreciative and perceptive abilities, also playing a role in articulation. The conditions of the mucosa and profound tissues of the tongue are generically named glossitis. Glossitis encompasses a wide range of conditions, from the common saburral deposits up to various forms of glossitis or the impressive tumoral lesions. **Material and method**: a clinical-statistical study has been conducted on a group of 24 patients, females and males, 55 - 70 years old, in order to monitor the detection of the lingual mucosa lesions. **Results:** the damage of the lingual mucosa of the examined patients was subject to statistical analysis, revealing 24 patients with lingual mucosa lesions. The analysis of the type of lesion highlighted the diversity of the presented forms of lesions. **Conclusions**: for a proper medical conduct, the dentist should know the degree of involvement of the aggravating factors in the onset of oral mucosa lesion, its particularities, and apply them in a customized manner; proper examination can be very important in detecting and treating these conditions. Keywords: PERIODONTAL MANIFESTATIONS, AGGRAVATING FACTORS, GLOSSITIS, CANDIDOSIS.

Tongue is a muscular – membranous organ, located in the proper oral cavity, which takes part to the formation of the floor of the oral cavity, essentially influencing the dynamics and morphology of the lower wall of the proper oral cavity (1).

During oral cavity examination, the dentist constantly meets this organ, therefore he/she must know the pathological states of the tongue. The proper tongue examination can offer very important data for detecting certain conditions, while the importance of knowing the tongue manifestations is also related to dentist's area of expertise (2).

Often, the appearance of the tongue is not only the expression of local manifestations, but can also indicate damage of important organs. This has been known and proved in Hippocrates's era, when the changes of the tongue mirrored the functionality of the digestive apparatus, liver, blood circulation, etc. This is why the patient's examination starts from checking

the appearance of the tongue.

The inflammatory forms of the tongue are called glossitis, which often shows as a symptom of certain diseases (3).

Superficial acute glossitis coexists most of the times with a general inflammation of the mucosa of the buccal cavity.

Lingual enanthema appear in eruptive fever or various forms of stomatitis. Glossitis is the early symptom of the diseases, in Biermer anemia, present in 80% of the cases as Hunter glossitis or as erythematous glossitis in hypochromic (4).

According to Klostermann, red or bluish tongue, with obvious atrophy of papillae and mucosa is frequently met in hepatic cirrhosis.

Glossitis frequently appears in combination with candidosis, especially after using antibiotics (5).

There are several classifications of lingual conditions, on etiologic, anatomic – chemical, evolutionary criteria, etc.

Not all lingual pathologic manifestations are under the competence of the dentist. That is why, in this paper, I will only write about the forms of illness mainly affecting the lingual mucosa, and less the lingual parenchyma. (3, 4).

The main goal of this paper is to identify the most frequent oral lesions of the tongue in elderly patients, and to present the information in an accessible manner, highlighting their variations during diagnosis. The importance is given by the fact that the changes are not only the expression of local disturbances, but they can also indicate severe general conditions.

MATERIAL AND METHODS

The study was conducted on 24 cases with various forms of glossitis. The study group consisted of 14 males (58.33%) and 10 females (41.67%), aged 45-60; 18 cases (75.00%) come from urban areas, while 6 cases (25.00%) live in rural areas.

TABLE I

Demographic parameters in studied cases

Parameter	Study group with glossitis (24)
Gender (n, %)	
F (female)	10 (41.67%)
M (male)	14 (58.33%)
Age (years)	53.07±7.27
Average age of the patient at the onset of disease (years)	52
Area (n, %)	
1 - Rural	6 (25.00%)
2 - Urban	18 (75.00%)

ANOVA test was used for descriptive statistical analysis. T-Student test, which takes into consideration the measurement of variability and the weight of observations, was used for quantitative significance.

The database was managed in Excel, Microsoft Office package, while the statistical analysis was made in statistical programmes MedCalc and Epi Info 2000.

RESULTS

We considered the possibility of the presence of general risk factors, since with advancement into age, the patients suffer from general conditions that, through their

evolution and medication (especially drugs that cause xerostomia), can be the causes of lingual mucosa conditions. Oral mucosa is the place of a great variety of lesions, including ulcerous, vesiculobullous, desquamative, lichenoid, infectious and malignant lesions (7, 8). Both the normal changes associated with old age, and the pathologic factors contribute to oral pathology. As we grow older, the mucosa atrophies, leading to a thinner and less elastic tissue. This change of the cell structure, in combination with the decline of the immunologic responses, facilitate the increased susceptibility to infections and traumas (10, 12). In adults, oral infections with ferments are more and more common as they grow older, especially in denture wearers (5). Other risk factors are: antibiotic therapy, xerostomia, uncontrolled diabetes mellitus, immunosuppressive drugs, corticosteroids (systemic and inhaled corticosteroids), and poor oral hygiene (8).

The analysis of the type of lesion revealed the diversity of the forms of lesions.

Diagnosis was set after ruling out all the possible etiologic factors, based on the patient's history, (6) physical evaluation and lab studies, by a thorough clinical examination, completed in some cases by a mycological examination (table II).

In the presentation of the clinical forms, it is obvious that *mycotic glossitis* prevailed (50%), to which the lab test confirmed the presence of yeast on the lingual mucosa.

Intraoral examination revealed the presence of a white-yellowish creamy deposit on the dorsal surface of the tongue, almost spread on the complete lingual surface. During palpation, the tongue is supple, unpainful. Scraping the deposit is not painful, removing the sticky mucosal deposits that leave behind a slightly bleeding lingual mucosa. This happened in white hairy tongue. In black hairy tongue, the colour of the deposit was brown-black, similar to coffee grounds (fig. 1)

TABLE II

Case distribution in relation with diagnosis

Forms of disease	No of cases	%
White hairy tongue	4	16,66
Black hairy tongue	2	8,33
Lingual candidiasis	2	8,33
Median rhomboid glossitis	2	8,33
Symmetric congenital plicated tongue	4	16,66
Marginal exfoliative glossitis	2	8,33
Erythematous glossitis	4	16,66
Saburral tongue	2	8,33
Glossodynia	2	8,33

Fig. 1. Black hairy tongue (clinical casuistry)

The lesion is mostly spread on the medial area of the tongue.

In another case, a female patient, 56 years old, wearer of upper and lower mobile dentures, showed small whitish deposits on the jugal mucosa and on the tongue, accompanied by an acute sensation of buccal dryness and motility disorders. The lab

examination confirms the presence of digestive and oral candidosis, as well as in cases of white hairy tongue (fig.2).

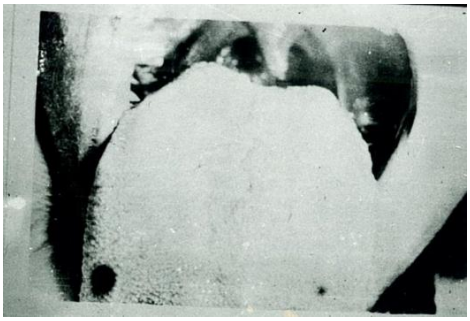

Fig. 2. White hairy tongue (clinical casuistry)

In all the 8 cases of candidosis (33.33%), patients were previously treated with various antibiotics for various infections.

There was one particular case, with *"median rhomboid glossitis"* diagnosis. During the clinical examination, we detected on the dorsum of the tongue, before the lingual V, a rhomboid area, depapillated, plane, neat, well demarcated, slightly recessed. The remaining tongue shows a white-creamy deposit, without any sensation of pain.

Median rhomboid glossitis (central papillary atrophy) is regarded as a congenital anomaly of the tongue, due to the persistence of the tuberculum impar, a depapillated area on the dorsum of the tongue, a rhomboid area, well demarcated in the midline of the tongue, immediately before the circumvallate papillae, with "kissing lesions" on the hard palate.

Recent studies have incriminated oral candidosis, an opportunistic infection, most of the times caused by the overspread of *Candida albicans*, as the etiopathology of the condition. Clinically, there are two forms: a plane form, red, neat, well demarcated, depapillated, slightly recessed comparing with the underlying normal mucosa; a mamelonated, hardened, reddish form, with depapillated, neat areas (fig.3).

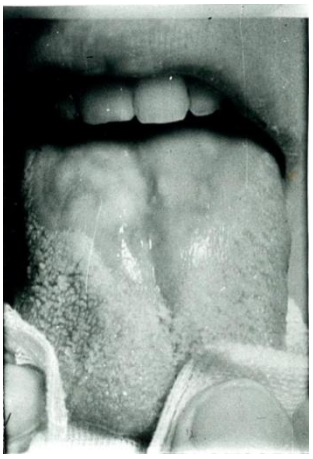

Fig. 3. Median rhomboid glossitis (clinical casuistry)

Median losangic glossitis is asymptomatic, but can be secondary colonized with *Candida Albicans*, provoking an inflammation with subjective signs. It is necessary to perform the differential diagnosis with: luethic glossitis, candidosis glossitis, geographic tongue (benignant migratory glossitis), lymphangioma, cancerous lesions. It is a chronic condition relatively frequent, usually asymptomatic.

The case which we diagnosed with this form of glossitis was a 49 years old woman, to whom the mycological examination showed the lack of levuric infection.

The 4 cases (16.66 %) of symmetric congenital plicated tongue were met in 49 and 60 years old men. In all 4 (16.66%) asymptomatic cases, the patients were not aware of this problem. Clinically, 2 (8.33%) had a scrotal character, while the other 2 (8.33%), a cerebriform character. The sur-

face of the tongue is crossed by numerous sulci, more or less profound, which imitate the appearance of a leaf, or of the brain (typical appearance). It usually appears in gastric conditions or other diseases. Informing the patients in this condition, an appropriate oral hygiene was recommended, avoiding local irritants of any type (fig.4).

Fig. 4. Scrotal tongue (plicated, symmetric congenital) (clinical casuistry)

In other situations, the patients who wore older removable acrylic dentures were diagnosed with erythematous glossitis, and erythematous stomatitis. They complained of burning and itching sensation on the buccal mucosa, and they had a poor oral hygiene. To limit the development of caries, it is important to improve the oral hygiene. (14).

They also complained about a metallic, sour or salty taste. In these kind of conditions, the burning sensation is continuous, but it doesn't affect the eating and sleeping. The Burning Mouth Syndrome is characterized by the constant burning sensation in the oral mucosa and/or the tongue, without other clinical and laboratory data (10). These sensations are caused by physiologic or psychic phenomena, related to menopause, accompanied by the redness or pallor of the skin, sweat, and palpitations.

During the clinical examination, the lingual mucosa was congested, with hypertrophied filiform papillae, appearance of a burned tongue.

Out of the 24 cases we studies, a retired woman had glossodynia. This patient was deeply affected by her suffering tongue.

The patient complained about lingual pain or itching during the contact with food, but also spontaneously, without any objective cause. The patient associated the lingual symptoms with the presence of a thicker, pathologic saliva. The clinical examination of the tongue did not reveal any change. The odontal examination also ruled out any lesion that might explain the lingual complaints.

The treatment consisted of sedative drugs, associated with antiseptic, alkaline therapy of the oral cavity, together with psychotherapy.

DISCUSSIONS

In general, there is no final remedy. To be able to determine the right diagnosis, one should do the biopsy of any lesion of the mucosa that does not fit the expectations on a certain period of time, or which persists despite all attempts to resolve the etiology, as Miriam R. Robbins recommends (Department Oral and Maxillofacial Pathology, New York University) (quoted 6,7).

We must assure patients that they do not suffer from an infectious or malignant condition, but they deal with chronic pain. After 6 – 7 years, approximately 50% of the patient experience an improvement of symptoms, as Sardella et al. states (9). Various topic and systemic treatments were suggested, with various evidence in their favour (10). There is some evidence in favour of cognitive behavioural therapy as adjuvant of pharmacologic therapies (9).

For a proper medical conduct, the den-

tist should know the degree of involvement of the aggravating factors in the onset of the oral mucosa lesion, their particularities and apply them in a customized manner.

CONCLUSIONS

24 cases have been studied, with various forms of damage to the lingual mucosa, with 4 (16.66) cases with erythematous glossitis (more severe symptoms) and 2 cases of glossodynia.

There was one distinct case, consisting of a form of median losangic glossitis (rhomboid glossitis), but this happens rarely.

INTERACTIONS BETWEEN ANGIOTENSIN II, HYPERTENSION AND INFLAMMATION IN RAT KIDNEY (Abstract): The renin-angiotensin system is one of the most important regulatory mechanisms of blood pressure homeostasis. Hypertension, a risk factor for chronic kidney disease, is able to induce renal injury by promoting inflammation. Inflammatory cytokines can induce fibrosis in various organs, including the kidney. **Aim:** The study verifies if angiotensin II is implicated in kidney T cells infiltration. **Material and Methods:** The experiment was performed on Wistar male rats, divided in two groups who received either a sham operation (control group, n=9) or continuous angiotensin II (Ang II) infusion (300ng/kgc/min)(Ang II group, n=9) subcutaneously, via minipumps. Blood pressure was measured noninvasively (tail cuff). After 14 days, the animals were sacrificed under anesthesia with xylazine/ketamine. The tissue obtained of each kidney was used for histopathological exam or flow cytometry. Renal inflammation was assessed using a flow cytometric analysis. The Histo Quest program quantified automatically the cellular elements and performed a statistical analysis on the obtained data. **Results**: Inflammation was observed in Ang II Wistar rats group, accompanied by an increase in renal CD45RC+, CD45RA+, CD19+. **Conclusions**: Our research underlines an undefined role for T cells in the genesis of high blood pressure up to that time and sustains the involvement of inflammation in the pathogenesis of this prevalent disease. Thus, T cells might correspond to a novel therapeutic target for the management of hypertension. **Keywords:** ANGIOTENSIN II, HYPERTENSION, KIDNEY, INFLAMMATION

Renin-angiotensin-aldosteron system (RAAS) is a hormonal system that contributes on regulation of arterial pressure (1, 2). The increase of RAAS, especially by Ang II levels, affects target organs and increases the risk of cardio-vascular disease by raising blood pressure and also by a direct effect that Ang II has on vascular endothelium of renal and cardiac tissue (3, 4), promoting inflammatory phenomena and arteriosclerosis. Ang II reduces the renal capacity of sodium excretion and initiates a range of events that leads to increased blood pressure (5, 6). Ang II also mediates key events related to inflammatory processes (7). Ang II leads to the accumulation of inflammatory cells in the tissues by stimulating the production of cytokines / chemokines. RAAS plays an essential role in morphopathologic changes that

produce progression of renal diseases. Renal inflammation represents the early stage of renal injury and is followed by tubulointerstitial fibrosis, tubular atrophy and glomerulosclerosis (8).

MATERIAL AND METHODS

Male Wistar rats weighing about 250g, were divided into two groups: the first group (control) made of animals who received continuously isoosmotic solution using osmotic minipumps Alzet, model 2001-1µl / h (9 rats) and the second group (9 rats) who received continuously Ang II infusion (300ng/kgc/min) (Bachem - 1008593) subcutaneously, via minipumps (Alzet), for 14 days. Systolic blood pressure was measured noninvasively using tail-cuff plethysmography (Biopac), every 3 days. After 14 days, the animals were sacrificed under anesthesia with xylazine/ketamine. Each kidney was divided into 2 equal pieces: a piece was immersed in 4% paraformaldehyde for tissue fixation in order to perform a histopathological exam (Hematoxylin-Eosin or Szekely trichromic methods) and the other was used to perform immunophenotyping (flow cytometry). The Histo Quest analysis program allowed the study of renal periglomerular and tubulointerstitial inflammatory reaction. Renal inflammation was assessed by quantifying CD45RC, CD45RA expression, using a flow cytometric analysis (6). Results were expressed as mean ± SEM. All protocols were approved by the Animal Care and Use Institutional Committee of the University of Medicine and Pharmacy "Gr. T. Popa".

RESULTS

Systolic blood pressure

The values of systolic blood pressure (BP) were similar among the two groups before the treatments. However, systolic BP progressively and significantly increased to 200±7 for Ang II vs. 120±5 mmHg for Sham at day 14 (fig.1).

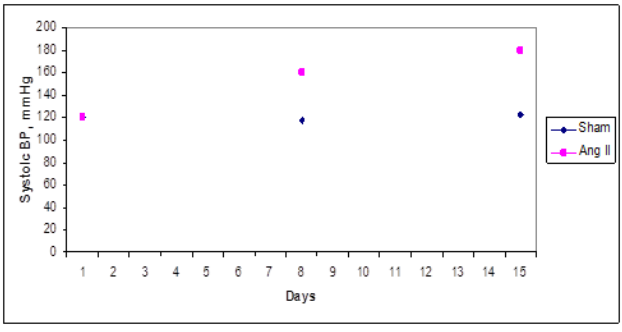

Fig. 1. Blood pressures at baseline and after angiotensin II infusion measured by tail cuff

Kidney inflammatory infiltration area

Histo Quest program allowed the mapping and the separation and quantification of all nuclei related to the periglomerular and tubulointerstitial infiltrate (fig. 3-14). We used as analysis criteria the following parameters: nuclear size and intensity of the nuclei in Hematoxylin-Eosin stain.

Flow cytometric analysis

CD45RA. As demonstrated in figure 16A, B, chronic Ang II infusion significantly ($p<0.005$) increased CD45RA (5.5±0.5% for Ang II vs. 2.7±0.8% for sham). Absolute numbers of T cells (CD45RA) in kidneys

from sham and angiotensin II infused rats were expressed as the means ±the SEM.

CD45RC. As shown in figure 17A, B, chronic Ang II infusion significantly decreased CD45RC ($p<0.05$). Data are expressed as the means ±the SEM.

DISCUSSION

The chronic kidney disease might be determined by varied conditions as hypertension, diabetes, nephritis, inflammatory and infiltrative diseases, etc. Into a varying number of cases, renal injury becomes chronic, progressive and irreversible and often requires substitution therapy (dialysis or renal transplantation) (9). Although renal impairment begins at the glomerular, tubular or renovascular level, the progression to chronic kidney disease is accompanied by common histological and functional changes, going to progressive glomerulo-sclerosis. Hypertensive nephropathy is initiated by an increased intraglomerular pressure that activates and destroys glomerular cells, including mesangial and epithelial cells, and also the podocytes. These cells produce proinflammatory and vasoactive mediators that contribute to the cell damage, the decrease of renal plasma flow and of the glomerular filtration rate (10, 11).

In a study carried out by Lombardi et al. (12), they showed that after chronic administration of 435ng/Kg/min Ang II for 2 weeks, to male Sprague-Dawley rats, renal histological changes including focal vascular damage (damage of peritubular capillaries) and tubulointerstitial injury occured (tubular atrophy and mononuclear cell infiltration). These changes are found both in the juxtaglomerular area and in the superficial cortex (13).

In the present study we intended to demonstrate that Ang II-induced hypertension leads to lymphocytic infiltrate in the kidney. In our experiment, we observed that in the control group, consisting of animals that received isoosmotic solution through minipumps and were subjected to the same laboratory conditions, histological examination revealed a normal appearance of the juxtaglomerular apparatus and a normal appearance of the renal glomerulus, afferent and efferent arteriole and renal tubules. The histological examination of kidney sections from rats chronically treated with Ang II for 14 days revealed presence of inflammatory infiltrate with lymphocytes.

CONCLUSIONS

In our study angiotensin II increased the activation of T cell markers in kidney tissue. T cells have an important role in the genesis of high blood pressure, pointing the inflammatory infiltrate involvement in the pathogenesis of this disease. Thereby, T cells might represent a novel therapeutic

target for the treatment of hypertension.

THE CORRELATION BETWEEN MARKERS OF SYSTEMIC INFLAMMATION AND ANGIOGENIC MARKERS IN PRE-ECLAMPSIA (Abstract): Pre-eclampsia is a severe multisystemic syndrome that represents a major cause of maternal, foetal and neonatal mortality and morbidity. In the study we conducted it stood out the significant modifications of angiogenic markers in pregnant women suffering from pre-eclampsia and the existence of a correlation between C-reactive protein (CRP) and SBP, DBP and average BP. **Material and method:** The group included in the study consisted of 138 pregnant women hospitalized at the "Cuza-Voda" Clinical Hospital of Obstetrics and Gynaecology of Iasi, between 2012-2014, with over 20 weeks gestational age and which gave their free consent to take part in the study. **Results:** It is confirmed the importance of determining the markers for diagnosing and monitoring hypertensive pregnant women and at the same time it was pointed out that the sFlt-1/PlGF ratio represents a good pre-eclampsia predictor. **Conclusions:** The results of our study confirm the importance of determining sFlt-1 and PlGF as markers for diagnosing and monitoring pregnant women with HBP as well as the sFlt-1/ PlGF ratio which represents a good pre-eclampsia predictor. **Keywords:** MOLECULAR MARKERS, PRE-ECLAMPSIA, PLACENTAL DYSFUNCTIONS, ENDOTHELIAL DYSFUNCTION, HELP SYNDROME.

Preeclampsia represents a pathologic condition specific to the pregnancy period, with an incidence of 3-5%, characterized by *de novo* hypertension and significant proteinuria (>300mg/24h), that frequently begins after the 20th gestational week. It is a systemic vascular disease that can affect numerous organs leading to severe complications for both the mother and the fetus. Although the exact causes that determine the apparition of pre-eclampsia are not known, it was noticed that placental dysfunctions play a key role in its apparition, being correlated with the subsequent maternal endothelial dysfunction (1-5).

The low vascularization of the uterus leads to the deficitary development of the fetus, with consequences on its further development (6, 7, 8). The clinical manifestations can vary from mild to severe forms, reaching its peak with the HELLP syndrome (haemolysis, growth of hepatic enzymes and

thrombocytopenia) and eclampsia (apparition of convulsive crises) (6, 9).

In Romania, the annual incidence of preeclampsia cases is between 6-14%, varying between 10 and 14% at primiparas and 5.7-7.3% at multiparas with a significantly increased incidence of preeclampsia cases in women with gemelar / multiple pregnancy, in the one with pre-eclampsia at previous pregnancies, in primiparas under 20 and over 35 years (20).

Considering the prevalence of this disorder, especially in developed countries, the existence of a validated biological marker allows a more careful supervision of asymptomatic patients so to anticipate complications with lethal risk. An ideal biological marker should have: high sensitivity and specificity level, predictive capacity for the prognostic and the evolution of the disorder as well as for the response to treatment, low accessibility and invasive level for collecting; its testing should be simple, effective and cheap.

C-reactive protein (CRP) is considered a sensitive marker of endothelial dysfunction and inflammation (10), but there are divergent opinions when referring to the value of CRP as a pre-eclampsia marker (11).

This study focused on assessing the clinical and progressive aspects of pre-eclampsia, by checking the correlation between inflammatory parameters, represented by C-reactive protein and blood pressure, on a group of pregnant women with pre-eclampsia and pregnancy induced hypertension (PIH) compared to a group of normal pregnant women. At the same time, it was intended to create a mathematic model to associate a predictor factor as PlGF, sFLT-1 or the PlGF/sFLT-1 ratio with the clinical parameters assessed in pregnant women with pre-eclampsia.

MATERIAL AND METHODS

This was a retrospective, case-control type of study and focused on studying the clinical-progressive aspects of PE, by checking the correlation between the inflammatory parameters, represented by CRP and blood pressure, in a group of pregnant women with pre-eclampsia and PIH compared to a group of normal pregnant women. 138 pregnant women hospitalized at the "Cuza-Vodă" Clinical Hospital of Obstetrics and Gynecology of Iasi were selected, between 2012-2014, with over 20 of weeks gestational age, which requested a specialized consultation and gave their free consent to take part in the study. At the same time, the study received the approval from the hospital's ethics commission. These patients were collected biological samples to determine their CRP not being the case of an infectious situation or spontaneous premature rupture of membranes. At the same time, there have also been determined the PlGF and sFlt-1 biomarkers and it was calculated the sFlt-1/ PlGF ratio, as a prognosis instrument for the patient with pre-eclampsia, depending of the influence of the cumulative risk factors.

The criteria for including them into the study group were: gestational age > 20 weeks; high blood pressure and proteinuria; the exclusion criteria were: gestational age < 20 weeks; high blood pressure pre-existent to pregnancy; spontaneous rupture of membranes; associated infectious pathology (chorioamnionitis, urinary infections, respiratory infections), seropositivity to HIV.

RESULTS AND DISCUSSION

Lab analyses. Hematological and biological investigations were conducted in the laboratory of medical analyses from the

"Cuza Voda" Maternity of Iasi, while the immunological ones were conducted within the Immunology laboratory from the "Sf. Spiridon" University Hospital of Iasi. For the hematological investigations total blood was used, collected on K_3EDTA type anticoagulant using an automatic hematology analyzer (Celltac MEK - 6318K). The biochemical investigations used serum obtained after collecting the blood into "clot activator" type test tubes and spinning it at 4000 rpm, for 10 minutes. In determining the biochemical parameters it was used an automatic analyzer of Clinical chemistry, RX Imola model, along with calibrators and control serums. The immunological investigations were made for the C reactive protein using the chemiluminescence technique and a IMMULITE 2000 type automat, while for the PlGF and sFlt-1 markers, it was used the chemiluminescence technique with the COBAS E411 ROCHE analyser. The detection limits for PlGF-1 were between 1-1.500 pg/ml, and for sFlt-1 were between 100-30.000 pg/ml. Proteinuria was determined from the urine samples collected upon hospitalization, using the VITROS 950 dry chemistry automatic analyzer and diluting the samples accordingly.

A clinical picture was made for each woman. It was recorded the height of the pregnant woman and the evolution of the weight during the pregnancy period. The dates and the hours of the results of the collected proteinuria were recorded in 24 hours, where appropriate. The markers of the inflammatory process were determined (CRP). At the same time, there were registered the dates and the hours when the highest blood pressure values were recorded during the pregnancy. By monitoring the blood pressure value, in the previous chapter, there were pointed out the correlations between the markers of systemic inflammation and cardiovascular risk.

Laboratory tests were conducted on all pregnant women, the blood tests being focused on the parameters of the hepatic function (TGO, TGP, bilirubin, LDH) and renal function (urea, creatinine, uric acid), hematological parameters (thrombocytes, white globules), coagulation indexes (INR, Quick time, and APTT), of the inflammatory process (CRP, fibrinogen) and determining the serum concentrations of angiogenic markers (sFLT-1 and P1GF), by calculating their ratio (sFlt-1/P1GF) and establishing the appropriate statistical correlations.

The data were processed and assessed using the statistic functions from SPSS 19, at the significance threshold of 95% ($p<0.05$). The statistical analysis used the F (ANOVA) test, χ^2 test, the Spearman correlation coefficient, the coefficient of determination (R^2) and the sFlt-1/PlGF factor.

Considering the clinical picture: HBP associated to proteinuria and/or edemas 3 study groups were created: PE group - 54 pregnant women (39.13%) with pre-eclampsia (PE), aged between 19 - 41 years; pregnancy induced hypertension group (PIH) - 34 pregnant women (24.63%) with high blood pressure values and/or insignificant proteinuria (<300 mg/24h) and/or edemas, aged between 22 and 44 years; normal pregnant women group (NG) - 50 pregnant women (36.24%) aged between 16 and 41 years.

From the 138 pregnant women included in the study, most of them were in the age group of 25-34 years (51.45%), the frequency peak being somewhere around the age of 29 years old. Depending of their gestational age, in the PE group the patients were generally in 33-36 weeks (37.5%), the patients in the PIH group had

a homogenous distribution for the gestational age intervals of 33-36 weeks and 37-40 weeks (29.4%), compared to the witness group (NG) where the patients were mostly over 37 weeks (76%).

Edemas were present in 50% of the pregnant women with PE and in 29.4% of the ones with PIH, the difference in percent being significantly higher compared to the witness group (p=0.001). Proteinuria was found in almost 87.5% of the patients in the PE group and 64.7% in the one with PIH. Pathological urinalysis was observed in 57.1% of the pregnant women with severe pre-eclampsia and in 44.7% of the pregnant women with milder types of pre-eclampsia, frequency distributions that were not statistically significant (p=0.833).

HBP and proteinuria are not invariably present; HBP may appear late in the evolution of PE and proteinuria can be absent in case of milder types of pre-eclampsia (12). On the other hand, there have also been cases of HBP during pregnancy that did not necessarily lead to pre-eclampsia, as it is the case of gestational hypertension and chronic hypertension. For the groups studied, the Systolic blood pressure (SBP) was significantly higher in the case of pregnant women with PE (p<0.001), with variations from 120 to 180 mmHg, the group mean being of 153.44±18.95 mmHg. Most pregnant women in the group with PE recorded values of systolic blood pressure between 143-164 mmHg (37%), but 24% of the pregnant women with PE recorded values higher than 160 mmHg. The pregnant women in the PIH group recorded values of SBP between 120-200 mmHg, with a group mean of 148.65±21.03 mmHg. In normal pregnant women, the systolic blood pressure varied between 100-165 mmHg, the mean value of the group being of 120.40±11.99 mmHg. The diastolic blood pressure (DBP) was significantly higher in the pregnant women from the group with PE (p<0.001), with variations from 70 to 150 mmHg, the group mean being of 92.50±14.83mmHg. Most pregnant women from the PE group recorded values of DBP between 85-100 mmHg (35%), but 26% of the pregnant women with PE recorded values of higher than 120mmHg. The pregnant women from the PIH group recorded values of DBP between 60 and 120 mmHg, with a group mean of 88.80±14.17 mmHg. In normal pregnant women, the DBP varied between 55 and 115 mmHg, the mean value of the group being of 72.56±11.09 mmHg. Depending of the growth of DBP, PE was grouped in two distinct clinical categories: mild (<110 mmHg) and severe (>110 mmHg). In the cases studies, it resulted 13% of pregnant women with severe pre-eclampsia and 87% pregnant women with mild pre-eclampsia. The severe types of PE were identified in the patients around the age of 37 years, while the mild types of pre-eclampsia were associated to the ages of 28-29 years (p=0.020).

The mean values obtained for the body mass index (BMI) indicated significant over weight (BMI=30.52 kg/m^2) in the patients from the PE group (p=0.001) and morbid obesity in 11.8% of the patients in PIH group compared to the witness group (NG). Depending of the BMI variation during pregnancy it was noticed that pregnant women with PE recorded body weight growth by more than 32%, while the pregnant women with PIH, the BMI growth was of almost 18%. Gestation and parity did not point out significant differences between the monitored groups (p>0.05)

In our study it was noticed that the women at their first pregnancy, teenagers and the women who remained pregnant after the age of 40 years presented a higher

risk of being affected by pre-eclampsia. The values of the biological markers indicated significantly higher differences for the PE group compared to the normal group (NG) for CRP (p=0.001), TGO (p=0.001), uric acid (p=0.001), serum urea (p=0.005) and proteinuria (p=0.001). In the cases when the pregnant women developed PE, the mean value of PlGF was significantly lower (p=0.003) and sFlt-1 was significantly higher (p=0.001) compared to the NG group. At the same time, the angiogenic factors were statistically significantly correlated with the mean values of BP. Thus, PlGF was significantly correlated with the age of the pregnant woman and with high mean BP (r=0.831; p=0.01). The sFlt-1 factor was significantly correlated with age, the mean BP and the high levels of LDH and TGO (r=0.784; p=0.046), being a better pre-eclampsia predictor than PlGF. The sFlt-1/ PlGF ratio was significantly higher at the group of pregnant women with PE (p=0.001) compared to the NG. The plurality of risk factors: age, mean blood pressure, LDH, TGO, INR, TQ and CRP were significantly correlated with the sFlt-1/ PlGF ratio.

CRP varied from values under 6 up to 192 mg/l recording a mean value significantly higher in the group of pregnant women with pre-eclampsia compared to the group of pregnant women with PIH (35.89 *vs* 6.72 mg/l) (p=0.001)

The individual values of CRP in the group of pregnant women with PE varied from 6 to 192 mg/l, most pregnant women recording values in the reliability interval (RI 95%):26.18-45.60 mg/l (42.6%), but 14.9% of the pregnant women with PE recorded values significantly higher of this parameter. In the case of pregnant women with PIH, CRP presented some values over the reference limit (=6 mg/l), but most of them presented values < 6 mg/l (82.1) (tab.1).

TABLE I

The values of some statistical indicators depending of the severity of pre-eclampsia

STUDY GROUP	N	Mean	Std. deviation	Std. error	Reliability interval		Min	Max	p

Total	54	35.89	35.57	4.84	26.18	45.60	6	192	

In the group of pregnant women with PE the work hypothesis was confirmed, the plasmatic level of CRP is in direct, statistically significant correlation with the blood

pressure. The values of CRP were directly correlated, having statistical significance, with both SBP (r=0.460; p=0.001) and DBP (r=0.614; p=0.001) as well as with the mean calculated pressure (r=0.612; p=0.001)

The mean values of CRP were significantly higher in the case of pregnant women with severe PE (89.14±51.31mg/L) while the pregnant women with mild PE the mean value was of 22.86±21.35 mg/L. In the cases studied, the mean values of Hb indicated a mild anemia in the group of pregnant women with PE (p=0.138) without a significant correlation with its severity (p=0.451). The hematocrit varied from 32.7 to 43.5% in the group of pregnant women with PE, recording a mean value of 37.25%±2.63 that is not significantly higher if compared to the values of the hematocrit recorded in the group of pregnant women with PIH 36.88% ±3.49 (p=0.102). In the cases of severe PE, the mean values of the haematocrit were slightly lower (33.93%±2.92) compared to the ones recorded in mild cases (34.87%±6.11) (p=0.847).

It was also observed that the plasmatic level of CRP was directly correlated also with the individual values of hemoglobin or hematocrit, but without any statistical significance (13).

In the group of pregnant women with PE the individual values of PlGF recorded a variation between 16.37-942 pg/mL with a mean value (119.3 pg/mL) significantly lower if compared to the mean value recorded in the witness group (327.57 pg/mL) or the PIH group (129.13 pg/mL) (p=0.003).

It was observed that the patients under 20 years of age had the PlGF median of 200 pg/mL, and at the patients aged between 20 and 34 years the median slightly surpassed the value of 100 pg/mL; in the pregnant women aged over 35 years the median of PlGF values was below 100 pg/mL. Depending of the gestational age the mean value of PlGF was significantly higher in the gestational weeks 33-36 (245 pg/mL) and 37-40 (254.4 pg/mL) (p=0.049). The correlations between the individual values of PlGF and the maximum values of blood pressure recorded were indirect, of moderate intensity. The higher values of PlGF were accompanied by lower values of systolic blood pressure (r= -0.359; R^2=0.1771, p=0.001) or diastolic (r= -0.320; R^2=0.1331, p=0.003). The correlation between the individual values of PlGF with BMI was not statistically significant (r= -0.126; R^2=0.016. p=0.255).

The values obtained for the sFlt-1 factor varied from 1152 to 32708 pg/mL with a variation of more than 92%, recording in the PE group the highest mean value (14365±6464), significantly higher if compared to the other study groups (p=0.001). Correlated to the age group, the mean values of sFlt-1 did not indicate statistically significant differences (p=0.342); nonetheless there have been noticed higher mean values at the age group of over 35 years. Depending of the gestational age, the mean value of sFlt-1 was significantly higher in the gestational weeks 25-28 (13867 pg/mL) and 29-32 (13033 pg/mL) (p=0.001). The correlations between the individual values of sFlt-1 and the maximum values of blood pressure recorded were direct, of moderate intensity, and statistically significant. The higher values of sFlt-1 were accompanied by high values of systolic blood pressure (r= +0.397; R^2=0.3445, p=0.001) or diastolic (r= +0.430; R^2=0.2755, p=0.001). There were not any significant correlations between the individual values of sFlt-1 and BMI (r= -0.136; R^2=0.0184, p=0.222) (Fig.1).

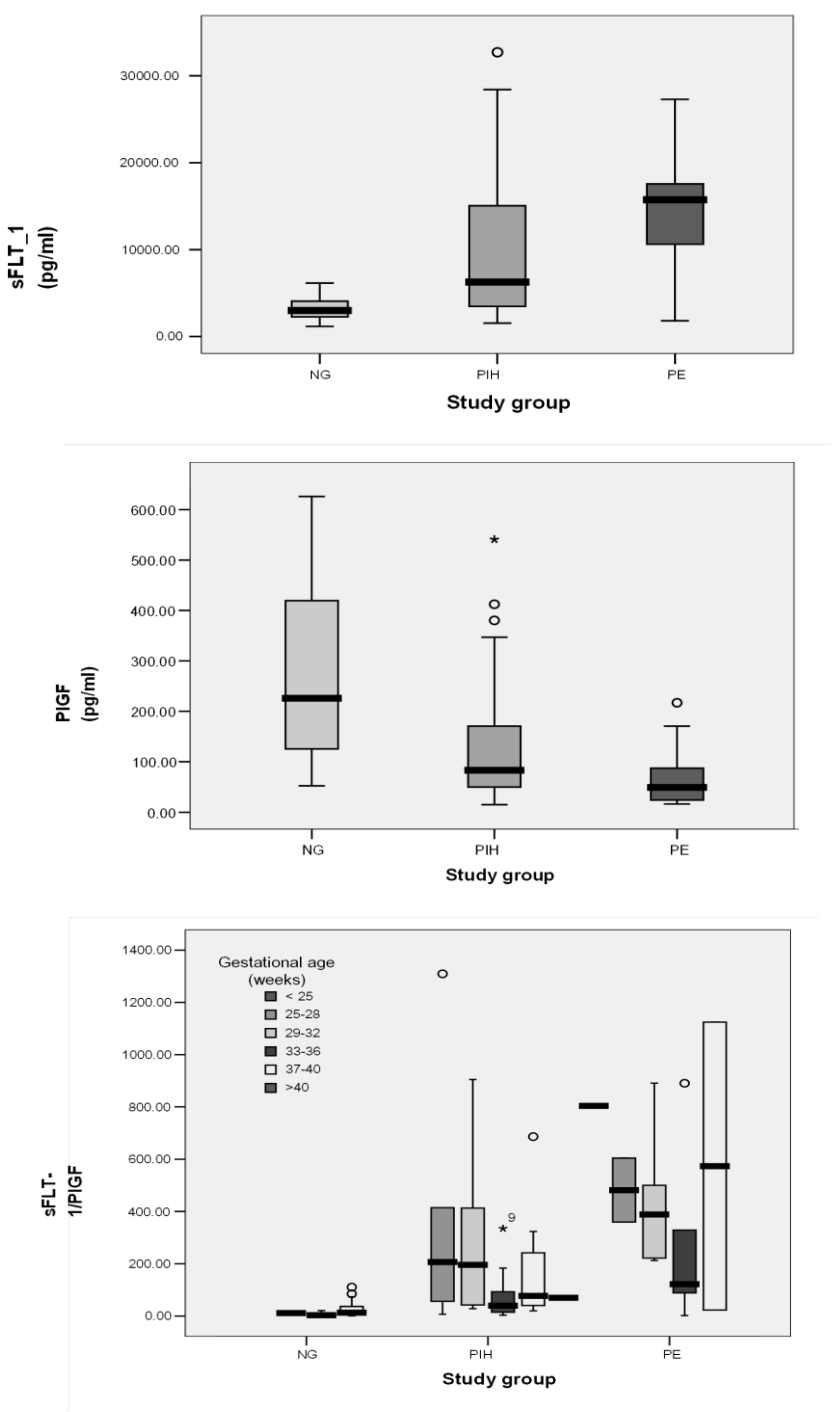

Fig 1. Mean values of PlGF, sFlt-1 and the sFlt-1/ PlGF ratio on study groups

The values of the sFlt-1/PlGF ratio indicated significant growth for the PE group compared to the witness group NG or PIH (p=0.001). In the patients with preeclampsia, it was observed a direct correlation, of moderate intensity, between the systolic blood pressure (SBP) and sFlt-1/PlGF (r= +0.555; p=0.026), but the high values of diastolic blood pressure (DBP) are associated with high values of sFlt-1/PlGF only in 18.5% of the patients (r=+0.185; p=0.493). At the patients from the PIH group, the correlation between SBP (r=+0.014; p=0.937) and DBP (r=+0.105; p=0.555) and the sFlt-1/PlGF ratio were not statistically significant.

The high values of CRP were accompanied by high values of sFlt-1/PlGF ratio only in 13.8% of the patients with PE (r= +0.138; p=0.724) and in 48% of the patients with PIH (r=+0.480; p=0.015). Correlating the values of PlGF with the preeclampsia risk factors it was noticed that the logistic model indicated an important cumulative risk depending of the age of the pregnant woman and the presence of high mean blood pressure (p=0.01 - Model 2) (fig. 2).

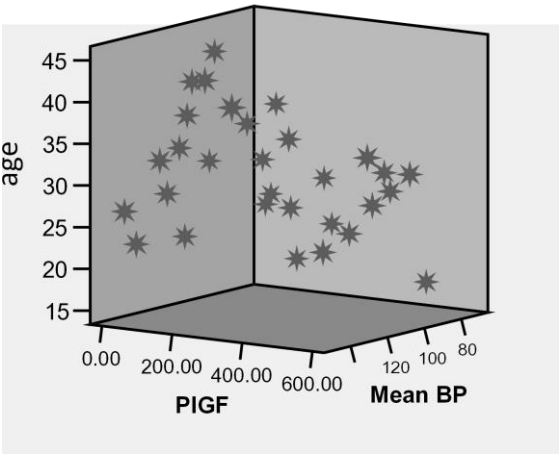

Fig. 2. PlGF correlation with age and mean blood pressure

It was noticed that PE was characterized by high levels of sFlt-1 associated with HBP, proteinuria and high values of CRP (p=0.049 - Model 8).

Correlating the values of sFlt-1 with the risk factors for PE it was noticed that the logistic model indicated an important cumulative risk depending of the age of the pregnant woman, the presence of high mean blood pressure and high LDH values (p=0.047 - Model 3) and the pregnant woman's age, the presence of high mean blood pressure and high LDH and TGO values (p=0.046 - Model 4) (fig. 3).

The logistic model indicated that a group of risk factors as age, blood pressure, LDH, TGO, INR, TQ and CRP were significantly correlated with the sFlt-1/PlGF ratio (R=0.663; p=0.04).

Nowadays there isn't any single objective test to identify PE or to quantifying the risk of certain severe complications, the diagnosis relying only on the clinical lab parameters evaluated in dynamics. Experience shows that early identification and the monitoring of the mother and fetus are use-

ful and hence the prediction of PE becomes very important. Early identification of PE, not only based on the inventory of risk factors, but also with the use of some markers might indicate better the moment suitable for beginning the treatment, its action and the moment to remove the child. Because of the fact that these modifications appear a long time before the apparition of the clinical signs of the disease, recent research focus on the endothelial dysfunction as a physiopathological mechanism of PE.

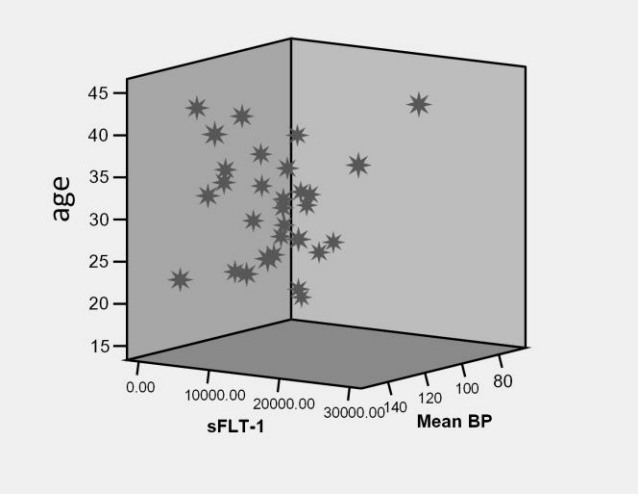

Fig. 3. sFlt-1 correlation with age and mean blood pressure

Many researchers (14, 15) noticed that the inflammatory maternal answer in PE and especially in severe PE, being known that there is an exaggerated systemic maternal inflammatory answer (16). In this context, it is considered that PE, at a given moment in its evolution, borrows a link of the systemic inflammatory answer that combines with the endothelial dysfunction. The increase of CRP indicates the presence of an inflammatory, destructive, infectious or non-infectious process but not specific. In this study we have demonstrated that the plasmatic level of CRP is significantly and directly correlated with SBP and DBP.

Thus, Can (17) use the mean arterial pressure as a severity indicator and he demonstrated the direct association with the inflammatory reaction. This result joins the studies that support the affirmation that CRP is an effective marker for the apparition of PE and it correlates significantly with the severity of the disorder.

Carl et al. (18) demonstrated that a value of more than 3 mg/L is a good predictor for cardiovascular and inflammatory risk in women with pre-eclampsia / eclampsia antecedents. At the same time, Mihu D et al. (10), state that CRP is a marker for PE's severity and for the new-born's birth weight. A prospective study, initiated by Behboudi et al. (20) on a group of 778 pregnant women, established a reference value of 4.5 mg/dL for CRP in the first trimester of pregnancy as a predictive factor for PE, and Bita (12) with a study on 400 pregnant women established the threshold over which PE can be predicted,

in the first trimester of pregnancy of more than 5 mg/L. In order to establish reference values for CRP in normal pregnant women and pregnant women with PE, Hwang et al. (19) demonstrated also the possibility of using CRP as a severity marker in PE.

Other authors pointed out the relationship between CRP and the clinical and biochemical parameters from PE; the high levels of hemoglobin, creatinine, TGO, TGP, LDH, blood urea and proteinuria were associated with high levels of CRP.

Nowadays, more and more studies confirm the fact that the CRP (10) marker can help in differentiating the pregnancy associated HBP whose etiology is not PE. Other studies, on the other hand, could not establish a real relationship between CRP and PE (13). In recent studies, Stefanovic (21) focused on the endothelial dysfunction as an anomaly in PE and concluded that CRP as a marker of the inflammation does not have high values and it is not associated with the severity of PE.

The high CRP values are a useful parameter in assessing the severity risk of PE in pregnant women with high body mass index in the third trimester of pregnancy (13). In our case it was noticed a risk of 6.71 times higher of severe PE in obese patients.

Considering the importance of carefully monitoring the mother and the fetus and the therapeutic intervention at the best moment in the process of PE, to avoid fontal and maternal complications, in this study it was assessed the sensitivity and the specificity of some laboratory tests, including the usual ones, that focus on assessing various angiogenesis markers in pre-eclampsia diagnosis and management. PlGF and sFlt-1/PlGF ratio were correlated with the clinical and laboratory signs of the cases included in the study. The higher the sFlt-1/PlGF ratio the better can it assess the risk of premature birth and it represents a potential prognosis parameter in PE monitoring.

It was noticed that PlGF and sFlt-1 levels are simultaneously affected in PE (especially in early pre-eclampsia); thus, the sFlt-1/PlGF ratio represents now a predictor element superior to the individual analysis of these markers. Another approach in assessing these markers might consist in the sequential determination of serum levels, an approach that has provided better predictive results than the punctual assessment in of the pregnancy a certain moment. The sensitivity of sequential determinations of the sFlt-1/PlGF ratio is of 100% and its specificity is of 98-99% (3, 5).

It was noticed that sFlt-1 levels and sFlt-1/PlGF ratio increase while PlGF levels decrease significantly in patients who develop PE, all this compared to the levels measured in normal pregnancies or in patients with chronic kidney disease (CKD). sFlt-1 levels increase and PlGF levels decrease even more in women who simultaneously associate CKD or chronic hypertension during pregnancy.

CONCLUSIONS

In our study it resulted that the mean value for the CRP marker correlated with SBP, DBP and mean BP, but it did not correlate with hemoglobin and hematocrit.

It was pointed out that CRP is an inflammation marker but in PE it was not proved that it can be used in the clinical practice on a daily basis.

The results of our study confirm the importance of establishing sFlt-1 and PlGF as markers for the diagnosis and the monitoring of pregnant women with HBP as well as the sFlt-1/ PlGF ratio which represents a good PE predictor.

LIFE-THREATENING COMPLICATIONS OF IMPACTED COMMON BILE DUCT LITHIASIS. A CASE REPORT (Abstract). Impacted common bile duct (CBD) lithiasis poses therapeutical challenges and repeated attempts of removal may result in life-threatening complications. **Case report**. A 45 year-old female patient was admitted in emergency for right upper quadrant abdominal pain and jaundice. Clinical, lab data, abdominal ultrasound (US) and cholangio-MRI established the diagnosis of acute cholecystitis and obstructive jaundice due to distal CBD lithiasis. Endoscopic retrograde colangiopancreatography (ERCP) confirmed the presence of a distal CBD stone but extraction failed. The patient was operated on and surgical procedure consisted of cholecistectomy, intraoperative cholangiography and a side-to-side choledocho-duodenal anastomosis was performed because all attempts to extract the stone through choledocotomy or duodenotomy and enlargement of endoscopic shincterotomy failed. The postoperative course was endangered by a severe pancreatitis, a massive upper digestive bleeding and portal vein thrombosis that responded to conservative management in the intensive care unit. The patient was discharged after 34 days in good clinical condition and approximately 9 months later was readmitted electively for an incisional hernia. Apart from this, physical examination, lab tests and imagistic studies were normal; the patient was operated and rapidly discharged in good condition. In **conclusion**, the management of CBD lithiasis may be a serious challenge both for interventional endoscopists and surgeons and require a concerted team effort. **Keywords**: LITHIASIS, COMMON BILE DUCT, ENDOSCOPY, SURGERY, PANCREATITIS.

Impacted common bile duct (CBD) lithiasis poses therapeutical challenges and repeated attempts of removal may result in life-threatening complications. We report a case in which endoscopical and surgical attempts of stone removal from the distal CBD resulted in serious complications such as cholangitis, acute necrotizing pancreatitis, upper digestive bleeding and portal veins thrombosis.

CASE REPORT

A 45 year-old female patient was admitted in the IIIrd Surgical Unit on emergency basis for right upper quadrant abdominal pain and jaundice. As past medical history she was diagnosed and treated with steroids for sarcoidosis with joint and pulmonary involvement but for the last years she was symptoms free without any medication. Obstructive jaundice due to biliary (gallbladder and CBD) lithiasis was sus-

pected due to clinical, lab data and abdominal ultrasound (US). Further on, cholangio-MRI showed dilated intrahepatic bile ducts and a CBD of 12 mm due to distal biliary lithiasis (fig. 1).

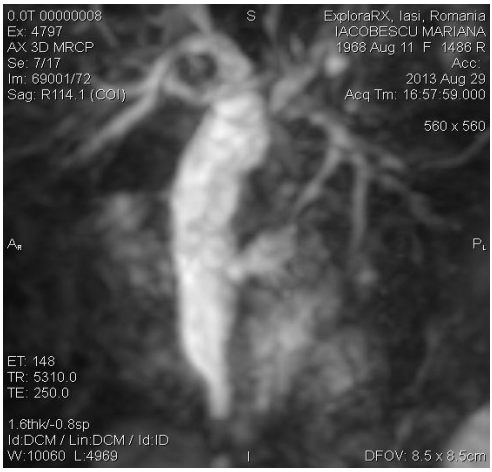

Fig. 1. Cholangio-MRI revealed a dilated CBD with high suspicion of distal biliary lithiasis

The patient was referred for endoscopic retrograde colangiopancreatography (ERCP) that confirmed the presence of a distal CBD stone; a large shincterotomy was performed but stone extraction failed due to the size of the stone and repeated rupture of balloon catheters. As the patient refused another ERCP she was planned a few days later for surgical removal. Surgical procedure started with a classical cholecistectomy and intraoperative cholangiography showed a 15 mm stone fixed in the distal CBD (fig.2).

Further on, a standard choledocotomy was performed but attempts to remove the stone through choledochotomy failed. Duodenotomy and enlargement of endoscopic shincterotomy followed but the calculus could not be extracted due to its size and adherence to the CBD. Moreover, a persistent bleeding from the margins of sphincterotomy required haemostatic sutures and cauterization. Under these circumstances, in order to restore the biliary flow, a side to side choledocho-duodenal anastomosis was performed, abandoning the impacted stone.

Fig. 2. Intraoperative cholangiography showed a large stone impacted in the distal CBD with difficult duodenal passage.

The first 48 hours postoperatively the patient was alert, hemodinamically stable, on spontaneous respiration, without fever but she complained of upper abdominal pain and nausea with a naso-gastric output of 900 ml. The level of pancreatic enzymes rose significantly (amylase- 2709 U/L and lipase-3835U/L). US of the abdomen revealed a peripancreatic, perisplenic and left retrocolic fluid collection and partial thrombosis of the portal vein. Abdominal computer-tomography (CT) confirmed the diagnosis of postoperative acute pancreatitis and established a Balthasar score of 8 and partial thrombosis of the portal vein. Under anticoagulation in prophylactic doses, in the third postoperative day the patient presented an abundant hematemesis allegedly from the margins of sphincterotomy, with Hb of 6 mg/dl, Ht- 20%, platelets-95000, INR-1.77, APTT-36, PT-20.

A conservative treatment was decided, consisting of transfusions, fresh frozen plasma and hemostatics and finally, after administration of recombinant factor VII, hemostasis was achieved. Following standard conservative treatment, the clinical, biological and CT status of pancreatitis improved significantly although pseudomembranous colitis was diagnosed and subsequently successfully managed. After 34 days of hospital stay she was discharged in good clinical condition. A follow-up admission after 2 months revealed a symptom free patient, with hematology and biochemistry tests within normal limits while abdominal CT showed a homogenous pancreas, a small interhepatogastric collection and partial thrombosis of the left portal vein. More recently, approximately 9 months postoperatively, the patient was readmitted electively for a small incisional hernia. Apart from the incisional hernia, physical examination, lab tests and imagistic studies were normal; the patient was operated and rapidly discharged in good condition.

DISCUSSION

It is stated that the first-line treatment for CBD lithiasis is endoscopic retrieval but dealing with a stone larger than 1.5 cm and impacted in the terminal CBD becomes quite a challenge both for interventional endoscopy and surgeons. Several endoscopical procedures are currently available - basket mechanical lithotripsy, mother and baby choledochoscopy and intraductal lithotripsy, electrohydraulic lithotripsy, intraductal laser lithotripsy or extracorporeal shock-wave lithotripsy - with a rate of success of 90% -95% and no greater frequency of pancreatitis and hemorrhage than with the standard techniques (1-4). When bile duct stones cannot be removed through endoscopic procedures, stent placement allows biliary decompression and prevent cholangitis. Biliary stents may also fragment large stones, making them easier to extract later (5-7). Pancreatic stent placement seems to reduce the incidence of post ERCP pancreatitis in high risk patients (8, 9). The incidence of choledocholithyasis has been noted as 10-15% of patients at the moment of cholecystectomy, increasing with age (10, 11). In a prospective study of common bile duct calculi in patients undergoing laparoscopic cholecystectomy, Collins et al. showed that choledocholithiasis occurs in 3.4% of patients undergoing laparoscopic cholecystectomy but more than one third of these pass the calculi spontaneously within 6 weeks of operation (12).

In the reported case, the endoscopical management failed and aggravation of cholestasis imposed surgery. However, local circumstances did not allow the removal of the calculus and the only option was a biliary bypass procedure. The postoperative course was endangered by massive upper digestive bleeding and severe acute pancreatitis, that responded to conservative treatment.

AESTHETIC CONSIDERATIONS IN THE RECONSTRUCTION OF ORBITO-ZYGOMATIC FRACTURES

AESTHETIC CONSIDERATIONS IN THE RECONSTRUCTION OF ORBITO-ZYGOMATIC FRACTURES (Abstract) **Aim:** The purpose of this study is to present our experience regarding the aesthetic and functional reconstruction of zygomatic bone fractures. **Material and methods:** We retrospectively reviewed the medical charts of 19 patients diagnosed with orbito-zygomatic fractures needing surgical reduction and fixation, in between January 2016 and January 2018. Two of the patients presented late with cosmetic and functional sequelae of fracture malunion. A two-point fixation was performed in most cases. Titanium mesh was used in four comminuted fractures at the level of the zygomato-alveolar crest and for the reconstruction of orbito-zygomatic fracture sequelae. Reconstruction of the orbital floor was performed in five cases. **Results:** No significant complications were recorded. Good aesthetic outcomes were obtained in all cases regarding the reconstruction of the orbital walls and the restoration of facial symmetry. Because of the accurate anatomic reconstruction, functionality was resumed postoperatively, with diplopia resolving immediately after surgery and in only one case during the three weeks following the procedure. **Conclusions:** The most important aspect regarding the immediate restoration of facial symmetry in fractures of the zygomatic complex is the repositioning of the zygomatic prominence by ensuring adequate fixation and support at the level of the zygomato-alveolar crest. The restoration of the contour and volume of the orbital area is also important regarding facial aesthetics and with repercussions regarding functionality. The three-dimensional reconstruction of CT (computed tomography) images in complex cases helps understanding the fracture pattern, reduction pathway and selecting the most accurate fixation method. **Key words:** ZYGOMATIC, ORBIT, FRACTURE, RECONSTRUCTION, AESTHETIC.

The role of the zygomatic bone in establishing the uniqueness of facial features is without doubt. The prominence of the cheek region stands for youth and beauty. Due to the projection of the zygomatic body, it is one of the first points of reference when determining facial symmetry. Beauty implies symmetry and therefore, any change in the position of this prominent facial feature will cause obvious asymmetry and will influence the judgement of facial attractiveness. Another important issue is the contribution of the zygomatic bone to the formation of the orbit. The orbital volume and the position of the orbital contents are greatly impacted by the

position and characteristics of the zygomatic bone. An altered position of the eye will be extremely noticeable since maintaining eye contact is one of the most important aspects of human social interactions.

The functional aspect of zygoma malposition is not to be neglected since double vision related to misalignment of the eyes can be extremely bothersome in performing everyday activities. The limitation of mouth opening due to blockage of the coronoid process determined by an inwardly displaced zygoma can also cause functional impairment related to mastication. For all these reasons, sequelae related to zygoma fracture mal-positioning should be avoided whenever possible, since the immediate repair of orbito-zygomatic fractures is always easier to perform and with better results than sequelae surgery.

Being a prominent facial feature, the zygomatic bone is affected in many facial traumatisms, ranking first in some studies (1) and second to mandibular fractures in other studies (2). We present our experience around orbital and zygomatic trauma surgery to aid maxillofacial surgeons in deciding the best treatment method for this common traumatic occurrence. We also provide tips on obtaining the optimum reduction and fixation of orbito-zygomatic fractures for best cosmetic and functional results.

MATERIAL AND METHODS

We retrospectively reviewed the medical charts of patients diagnosed with orbital floor and zygomatic bone fractures in between January 2016 and January 2018. We included only patients who had indication for osteosynthesis due to displaced fractures causing aesthetic and functional deficit.

A total of 19 patients were included, of which 17 men (89.47%), aged between 18 and 71. The etiology involved 10 human aggression cases (52.63%), six traffic accidents (31.58%) and three accidental falls (15.79%). There were three (15.79%) isolated fractures of the orbital floor (blow-out fractures) and 16 (84.21%) orbito-zygomatic fractures. Zygoma fractures comprised of 14 (87.50%) tripod fractures and two (12.50%) comminuted fractures. Two patients (10.53%) presented late with malunion and consequent sequelae. Associated lesions were zygomatic arch fractures in four cases (21.05%), nasal bone fractures in three patients (15.79%), occlusal-facial fractures in three cases (15.79%) and mandibular fractures in two patients (10.53%). Signs that indicated the need for surgery consisted of facial asymmetry and sinking of the zygomatic region in 14 patients (73.68%), diplopia in five patients (26.32%), enophthalmia and hypoglobus in three cases (15.79%), restricted eye movements in four patients (21.05%) and restricted opening of the mouth in five cases (26.32%). There was one patient (5.26%) with preoperative posttraumatic cicatricial ectropion. All patients presented with hypoesthesia of the infraorbital nerve.

RESULTS

The reconstruction of the orbital floor was performed using PDS (polydioxanone) mesh in two (10.53%) cases and titanium mesh in three (15.79%) cases of orbital floor fractures. Zygoma fixation was achieved by a two-point fixation in 12 (63.16%) cases - at the level of the zygomato-alveolar crest and inferior orbital rim. In four (21.05%) cases a three-point fixation was used by placing titanium plates at the level of the zygomato-alveolar crest (fig. 1, 2), inferior orbital rim and frontal-zygomatic suture. In four (21.05%) patients

Fig. 1. Intraoperative view of the displaced fracture line at the zygomato-alveolar crest in a patient with a zygomatic bone fracture.

Fig. 2. Intraoperative view of the reduced zygomatic bone fracture and fixation using a titanium plate at the level of the zygomato-alveolar crest.

a titanium mesh fixation at the zygomato-alveolar crest was needed due to comminution. The sequelae following fracture malunion were addressed by reconstructing the orbital floor and zygomatic region with titanium mesh. The approaches used for reduction and fixation were the trans-conjunctival incision for the orbital floor and inferior orbital rim, the external brow incision for the frontal-zygomatic suture and the intraoral horizontal incision located in the superior oral vestibule for the zygomato-alveolar crest. For the simultaneous access to the orbital floor, the zygoma body and the anterior maxillary sinus wall necessary in wider reconstructions and sequelae cases, a single cutaneous inferior palpebral incision extended to the nasolabial fold was used. In two (10.53%) cases of open fractures, the approach was achieved via the posttraumatic wounds from the cheek area and brow area.

Postoperative periorbital and genian edema and ecchymosis were the most common occurrences. No infections or extrusion of the osteosynthesis material were noted. The facial asymmetry improved following surgery in all cases. The outline of the zygomatic bone was regained, as well as the contour of the orbit (fig. 3-6). In four patients (21.05%) diplopia completely resolved, while one patient (5.26%) had transient diplopia that disappeared after three weeks. Eye movements were in normal ranges following surgery. The amplitude of mouth opening returned to normal after reduction and fixation of the fracture. No cases of orbital hematomas were encountered postoperatively. There were no cases of ectropion related to the trans-conjunctival incision. In one (5.26%) sequelae case the cicatricial ectropion present preoperatively improved because of reconstructive surgery. A second surgery for soft tissue repositioning using suspension sutures was needed for improving aesthetic and functional results.

DISCUSSION

The zygomatic bone is a defining element of individual facial aesthetics since it provides the projection of the cheek region, it contributes to establishing the width of the face and it also provides support for the inferior eyelid. Changes in the position or three-dimensional shape of the zygomatic bone can cause a completely different appearance of the face - a concept used in aesthetic surgery when performing zygomatic bone osteotomies for achieving a more appealing facial contour (3). Trauma can cause unaesthetic changes affecting both the cheek region and the orbital area, since there is also an orbital component to any zygomatic bone fracture that can be clinically apparent considering the fracture fragmentation. The resulting facial asymmetry depends on the type of zygomatic displacement. In most cases a flat appearance of the cheek area will be caused by the interior displacement of the zygoma towards the maxillary sinus. This is usually accompanied by a widening of the face when the zygomatic bone is rotated medially and inferiorly, while a lateral and inward rotation might cause a decreased facial width on the affected side (4). Orbital floor fractures with displacement of the orbital content towards the maxillary sinus can lead to enophthalmos, hypoglobus and related functional disturbances- diplopia, restricted eye movements (5). An inward displacement of the lateral orbital wall could cause diminution of orbital volume, pressure on the orbital content, exophthalmia and restricted eye movements.

Optimal functional and aesthetic results can only be obtained by a proper fracture reduction and fixation. The basis for obtaining the most favorable reduction is set by understanding the fracture pattern and path of displacement. Intraoperatively, the reverse pathway of fracture displacement will be applied to obtain a simple correct

reduction. Although there are several different closed reduction treatment options, they are controversial as they do not allow direct visualization of the zygomatic bone and its articulations (5) sometimes leading to unacceptable or failed reduction. Intraoperative imaging advancement may lead to a more reliable outcome after closed reduction (6).

Information on the degree and direction of displacement, as well as the number of fragments and associated lesions are crucial on deciding the treatment plan and the approaches used. This can be achieved by adequate imaging that allows direct visualization of the fractured bone fragment displacement as a spatial image (6, 7). In our study the three-dimensional reconstruction of Computed Tomography (CT) or Cone Beam Computed Tomography (CBCT) images offered the best understanding of the fracture pattern and translated in positive outcomes regarding facial symmetry restoration. CT examination can also provide information on the presence of soft tissue entrapment or foreign bodies (8) which can impede proper reduction of the fracture if not properly diagnosed and removed. Imaging can also help diagnosing preexisting conditions that could decrease bone strength and lead to pathological fractures of the zygomatic bone in the context of minimal trauma. Mucocele formation in the maxillary sinus is a frequent encounter. In rare cases, they can grow to erode through the walls of the maxillary sinus, including the inferior orbital floor, leading to functional consequences (9) but also decreased bone strength. Such occurrences can complicate the treatment of zygomatic bone fractures by decreasing the available fixation points in quality bone. Titanium mesh reconstruction could be needed for an increased surface coverage and strength.

In the first days after the trauma, radiologic investigations helped decide the indication for surgery, since it is a well-known fact that local posttraumatic edema can mask facial asymmetry. Additionally, diplopia can manifest after the initial three days after trauma, when orbital edema resolved, the volume of the orbital content returns to normal, and any inferior displacement will manifest as double vision. All zygomatic fractures were resolved in the first week or within two weeks after trauma. It is the surgeon's preference to wait for the resolution of local edema to better estimate the result of the reduction intraoperatively, unless there is indication for emergency surgery, such as orbital apex syndrome. Edema diminution usually happens after the first three days following the traumatism. If more than two weeks passed from the fracture onset due to contraindication or late presentation, surgery was scheduled later for addressing the sequelae of the fracture healed in malposition. Most authors agree on performing the surgery for zygomatic bone reduction and fixation within the first two weeks posttraumatic (4).

The goal of surgery is to achieve proper positioning of the zygomatic prominence and to adequately reconstruct the orbital contour and volume. If the proper reduction is not achieved, the resulting facial asymmetry will be easily seen with a lower position of the zygoma prominence (10). All associated lesions must be addressed, both extraoral and intraoral (11) - the bone contours as support structures as well as the soft tissues as covering structures, but also the integrity, height and contour of the dental arches (12) that contribute to the outcome. The reconstruction must address

the anatomical repositioning of both hard and soft tissues. The soft tissue rearrangement can be achieved by using intraoperative suspension sutures to the periosteum and performing the layered closure of the postoperative wound (13). Secondary corrections can be performed by lifting the tissues with the help of barbed threads that offer increased support with the advantage of an incisionless procedure (14). Residual volume deficit can be addressed by autologous fat transfer for filling of the involved area (15). Lipofilling can offer additional benefits related to scar softening and decreasing residual postoperative pain (16).

There are differences among surgeons regarding the number of fixation points necessary for zygomatic fractures, choosing between one and four fixation points located at the level of the zygomato-alveolar crest, the inferior orbital rim, the frontal-zygomatic suture and rarely the zygomatic arch, with or without orbital reconstruction. Kim et al. (17) state that one-point fixation offers satisfactory results when using the zygomato-alveolar crest for fixation. Ellstrom and Evans (5) conclude that for a simple fracture, fixation at the level of the zygomato-alveolar buttress is sufficient, while for more complex patterns, two or three points of fixation are needed for ensuring the proper positioning of the zygomatic bone. We consider that a two-point fixation (including the zygomato-alveolar buttress and inferior orbital rim) is suitable for most displaced zygomatic bone fractures, while a three-point fixation (with an additional plate at the zygomato-frontal buttress) can improve results for multi-fragmentary fractures. For improved stability and support, fixation at the level of the zygomato-maxillary crest is crucial. Fixation with this location is also important to best reposition the zygomatic prominence, an important issue in reestablishing facial symmetry. Because it is an inferior point, it will impede tipping of the zygomatic bone towards the maxillary sinus and support the forces applied on the body of the zygoma. Another important fixation point in our view is the inferior orbital rim. Fixation at this level can be subject to errors if there is an undiagnosed displaced fracture of the frontal process of the maxillary bone. In such an occurrence, the medial fixation landmark would be wrong, and fixation would occur in a medially displaced position, leading to improper positioning of the zygomatic prominence and medially widened orbital contour. When an additional fracture of the frontal process of the maxillary bone is identified with the help of preoperative imaging, the zygomato-frontal suture could be used as a more accurate level of reduction assessment and fixation, together with long plates at the inferior orbital rim, reaching the nasal bones.

We consider that one of the key aspects for the functional reconstruction of comminuted orbito-zygomatic fractures is the adequate restoration of the orbital volume. This objective can only be achieved by the proper restoration of the integrity and contours of the orbital walls. Respecting the medial landmark represented by the intra-orbital buttress located at the intersection of the medial orbital wall and the orbital floor, is crucial for ensuring support and a fit containment for the orbital structures (18). Its importance was also noted in performing orbital decompression surgery for Basedow disease (19, 20) when the preservation of this medial orbital buttress decreases the incidence of postoperative diplopia (21). Another anatomical landmark

that must be respected in orbital reconstruction is the posterior orbital ledge, a bone shelf representing the orbital surface of the palatine bone. It behaves as a posterior landmark and support point for the reconstructive material impeding the inferior placement of the reconstructive material and improper restoration of the orbital volume. It also announces the proximity of the orbital apex and optic nerve and the need for increased care during insertion and positioning maneuvers (18).

CONCLUSIONS

As demonstrated in our study, achieving the most favorable outcome in orbito-zygomatic fracture surgery depends on the accurate repositioning of the zygomatic prominence. Just as important is to reestablish the dimensions, contour and volume of the orbit, for a symmetric appearance of the eyes. A three-dimensional understanding of the fracture pattern helps decide the most suitable approach, reduction and fixation method. We consider that a minimum of two fixation points ensures stable reduction and fixation, especially when involving the inferior supporting buttress- the zygomato-alveolar crest. Titanium mesh is a useful tool for comminuted fracture repair allowing the simultaneous spatial reconstruction of bone contours as well as the surface of the orbital floor. The role of the overlying soft tissues is not to be underestimated, especially when wider soft tissue undermining is performed for access, such as in posttraumatic sequelae surgery. From our experience, repositioning the soft tissues at the end of the procedure ensures sufficient volume of the regions overlying the reconstructed skeletal frame for an aesthetic, symmetric aspect.

The aesthetic disturbances determined by zygomatic-maxillary fractures are best outlined in cases of late presentation with fracture malunion. They should be avoided whenever possible by performing immediate fracture reconstruction with proper spatial positioning of both bone structures and overlying soft tissues.

THE INFLUENCE OF DELTALYCYN AND TRANSCRANIAL CEREBELLAR STIMULATION UPON RECOVERY OF RETINA AFTER PHOTO STRESS IN PATIENTS WITH DIABETIC RETINOPATHY

Nataliya Valentinivna Kresyun
Odessa National Medical University, Odessa, Ukraine
Department of Ophthalmology

THE INFLUENCE OF DELTALYCYN AND TRANSCRANIAL CEREBELLAR STIMULATION UPON RECOVERY OF RETINA AFTER PHOTO STRESS IN PATIENTS WITH DIABETIC RETINOPATHY (Abstract) **Aim:** The characteristics of visual evoked potentials (VEP) have been studied in diabetic patients with and without diabetic retinopathy. **Material and methods:** Magnetic impulses (2.0 Tl at the height of impulse) have been delivered to the cerebellar surface transcranially using the "Neuro-MS/D", (Russia Federation). Delta-sleep inducing peptide ("Deltalycyn", "Biopharma", Russia Federation) was intranasally delivered in 30 min before photostress. Afterwards VEP have been registered every 20 s from the moment of photo stress during one minute. **Results:** An increase of the latency period and a reduction of the VEP amplitude have been recorded in the period following photo stress exposure of the macular part of the retina. The VEP characteristics restored to the initial level in 73.5± 3.3 s from the photo stress moment in the control group; while in diabetic patients with retinopathy this index was 137.2±11.3 s. In the presence of cerebellar transcranial magnetic stimulations (2.0 Tl, 20 impulses) the VEP amplitude depression was less pronounced, and the restoration period of the VEP characteristics shortened to 110.3± 12.7 s, while in deltalycyn treated patients restoration was observed in 95.1± 6.8 s. Under condition of combined usage of deltalycyn and TMS period of restoration of VEP was shortened up to 82.5± 6.5 s. **Conclusions:** Retinopathy development is linked to prolonged VEP latency period (P100), lowering of the N75-P100 amplitude, as well as to enlargement of the recovery period of the retina's functional capacity in patients suffering from the diabetes mellitus in the presence of photo stress. Superlatively administered deltalycyn and cerebellar transcranial magnetic stimulation facilitates a faster recovery of the retina's functional capacity in response to photo stress in diabetic patients with retinopathy. 3. Combined usage of deltalycyn and cerebellar transcranial stimulation caused the potentiated shortening of post-photo stress recovering of VEP in patients with diabetic retinopathy. **Keywords**: DIABETIC RETINOPATHY, VISUALLY EVOKED POTENTIAL, DELTA-SLEEP INDUCING PEPTIDE, CEREBELLAR TRANSCRANIAL MAGNETIC STIMULATION

Diabetic retinopathy is one of the causes of development of the acquired blindness at the heart of which are the microcirculatory bloodstream impairment, increased vascular walls permeability, and vascularisation development that lead to the retinal detachment (1, 6). It has been established lately that retinopathy pathogenesis is linked to the activation of lipid peroxidation and to the increased concen-

tration of proinflammatory cytokines in the retinal structures (6). Hence, the methods based on usage of drugs with antioxidant mode of action are justified for the usage in patients suffered from diabetic retinopathy (2, 6). On the other hand, raising the neuronal brain tissues activity by means of transcranial stimulation in cerebellar zone is resulted in the retinal improvement in diabetic patients (4), and such an effect might be justified by activation of antioxidant potential of brain tissue (1).

Till the last time there were not investigations on effects of delta sleep-inducing peptide (DSIP) upon functional state of retina in patients suffered from diabetes retinopathy. Meanwhile DSIP is regarded as a compound with pronounced antioxidant and neuroprotective properties (5).

Therefore the objective of this research was studying of the recovery process of the retina's functional activity in patients suffering from the diabetes retinopathy following a photo stimulation (photo stress) test (7) performed under conditions of DSIP – based drug – deltaycyn administration along with of cerebellar transcranial stimulation (4, 8).

MATERIAL AND METHODS

15 practically healthy individuals (the mean age 32.1± 3.6 years old) and 30 insulin-dependent diabetics (the mean age 30.9± 3.7 years old) were observed in this research.

All subjects provided written consent to research conduction. All investigations have been performed in accordance to ethics demands of commission on ethics at Odessa National Medical University (ONMedU Animal Care and Ethics Committee, 2008/84).

By selecting the control group the following criteria were adhered to: the intraocular pressure less than 21 millimeters of mercury, preserved acuity of vision, unaltered visual field, and absence of eye diseases and neurological disorders. For the diabetics the criteria were as follows: the intraocular pressure less than 21 millimeters of mercury, correctable acuity of vision (more than 7/10), as well as absence of signs of the proliferative retinopathy, which was established by means of fluorangiography (4, 7). This method allowed us to compose the group of 30 patients with mild and severe proliferative retinopathy formed the third to fifth level groups in accordance to classification after (7).

While conducting the research the patients were observed in a dark and soundproof room. Before recording the visually evoked potential (VEP) each subject has been adapting to the light intensity for 10 minutes till the moment, when the pupil diameter became equal to 3 mm. The level of the background screen glow was 5cd/m^2.

VEP was recorded using the adopted technology (9). The visual stimuli – chess pattern – had the contrast degree 70% and the mean luminescence degree 110 cd/m^2, while the contrast reversion was carried out with a frequency two times per second. A subject was placed at a distance 114 cm from the screen center, what allowed a 15-seconds acceptance angle of separate pattern elements, and a 25 acceptance angle of the screen height. Only the right eye of all patients was tested, while the left one remained closed (4, 9).

The electrodes were placed at points Oz (the active electrode) and Fpz – the reference (recording) electrode; the grounding was fixed on the left arm.

The interelectrode resistance was set at 3 kOhm. The bioelectric signals were amplified (by 20,000 times); the signal transmission band comprised 1-100 Hz,

after which the signals were averaged, and the artifacts were eliminated for the stimulation period (9). The experiment was organized in form of no less than two sessions of stimuli exposure; during each one the 100 answers were averaged after the artifacts elimination. The VEP analysis period was 500 ms. The visual VEP in this case included several waves, among which three peaks always could be distinguished that normally appeared in 75-100 ms and 145 ms. These peaks had negative (N75), positive (P100), and negative (N145) polarities.

After the preliminary testing the control VEP were recorded, while 40 stimuli responses were averaged. Connected details of procedure have been described earlier (4).

Deltalycynum («Biopharma», Russia) was administered intranasal with 2 drops in the middle part of each nasal *meatus* after dissolving of vial portion of delta-lycyn with 10 drops of distilled water. It should be noted that one vial contains 0.0003 g of delta-sleep inducing peptide. That peptide represents by itself nano-peptide with molecular weight of 850 D and structured as: Trp-Ala-Gly-Gly-Asp-Ala-Ser-Gly-Glu.

The device "Neuro-MS/D", ("Neurosoft" Russia Federation) was used for transcranial magnetic stimulation along with the appropriate colis and 2.0 Tl inductions at the height of the magnetic-influence impulse. The coil was positioned on the middle line of the occipital zone in the plane tangential to the cranium surface according to the adopted cerebellum stimulation technique (3, 4). In the control group false stimulation was carried out positioning the coil perpendicularly to the same occipital zone (4).

Research results were statistically processed applying the ANOVA method and the Newman-Keuls test.

RESULTS AND DISCUSSION

Dynamics of the development latency period (LP) P100 revealed that before the exposure onset in the group of patients with diabetic retinopathy this index exceeded that in the control group by 30.0% ($p<0.05$) (tab. I). In the first 20 s following the stress period LP in the group of patients with diabetic retinopathy exceeded that in the control group by 33.7% ($p<0.05$) and was higher than that before the photo stress exposure by 17.2% ($p>0.05$). Significant difference from the control group persisted till the end of the observation. The amplitude N75-P100 was by 42.0% ($p<0.05$) lower in patients with retinopathy than in practically healthy patients ($p<0.05$).

In the first 20 s of post-stress exposure a 53.0% ($p<0.05$) lowering of the amplitude N75-P100 was observed in comparison to the initial background in the group of patients with retinopathy ($p<0.05$). Significant differences in comparison with the control group have persisted for 60 s of the post-stress observation. LP and amplitude recovery to the basic value was recorded in the control group after 73.5$\pm$ 3.3 s, and in the group of patients with retinopathy that period was longer by 86.7% ($p<0.05$) (tab. II).

Under conditions of deltalycyn treatment the LP of P100 at the end of 40th s of post stress period exceeded initial value by 6.5% ($p>0.05$) (tab. I). The absence of differences maintained till the end of observation. The P100 amplitude during first 40 s of post stress period was significantly less when compared with the initial value by 20.3% ($p<0.05$), but at the end of observation (60th s) the difference was 10.5% ($p>0.05$). The total time of recovering of LP and amplitude of P100 was reduced by 30.7% when compared with patients who were not treated ($p<0.05$) (tab. II).

TABLE I

Dynamics of photo stress – provoked worsening of visual evoked potential precipitation in patients with diabetic retinopathy under conditions of deltalycyn and TMS usage (M± SEM)

Groups of patients	Investigated index	Before photo stress	Time from the moment of cessation of photo stress (seconds)		
			20	40	60
Control (n=15)	Latency	92.1± 2.2	105.0±3.2#	100.2± 3.0	96.4± 2.8
	Amplitude	9.17± 1.05	6.75±0.80#	7.63± 0.86	8.2± 0.91
Diabetes retinopathy (n=15)	Latency	119.8± 3.2*	140.4±4.8 *#	135.8± 4.1*#	134.2± 3.9*#
	Amplitude	5.32± 0.42*	2.50± 0.23*#	2.90± 0.27*#	3.40± 0.31*#
Diabetes retinopathy + deltalycynum (n=15)	Latency	119.8± 3.2*	127.6± 4.5 *	125.8± 5.0 *	124.3± 4.6*
	Amplitude	5.32± 0.42*	3.12± 0.30*#	4.23± 0.32*#	4.76± 0.42 *
Diabetes retinopathy+ TMS (n=13)	Latency	118.7± 3.4*	130.5± 3.3*#	128.4± 4.1*	126.3± 3.8*
	Amplitude	5.21±0.35*	3.21±0.27 *#	3.48±0.30*#	3.91±0.32*#
Diabetes retinopathy+ eltalycynum+ TMS (n=15)	Latency	119.8± 3.2*	124.3± 3.2*	122.8± 3,5*	117.6± 3.7*
	Amplitude	5.32± 0.42*	3.93±0.24*#	4.53± 0.33*	5.13± 0.40*

Notes: *-p<0.05 compared with the control group; #-p<0.05- compared with the initial data in the same group (ANOVA + Newman-Keuls test).

Exposure to photo stress under the conditions of the preceding TMS application (20 impulses) was accompanied with a tendency of the faster recovering of the P100 LP: in the first 40 s of the post stress exposure the latency exceeded initial value by 8.2% and in 60 s - by 6.4% (p>0.05) (tab. I). The total time of investigated indices recovering was reduced by 19.6% when compared with that one registered in patients without treatment (p<0.05), but it still continued to be 1.5 times longer when compared with the control group (p<0.05) (tab. II).

TABLE II

Time of recovery from the photo stress (M± SEM)

	Control (n=15)	Diabetes retinopathy (n=15)	Diabetes retinopathy + deltalycynum (n=15)	Diabetes retinopathy+ TMS (n=13)	Diabetes retinopathy+ deltalycynum+ TMS (n=15)
Investigated index (seconds)	73.5± 3.3	137.2± 11.3*	95.1± 6.8#	110.3±12.7*#	82.5± 6.5#

Notes: *-p<0.05 compared with the control group; #-p<0.05- compared with the initial data in the same group (ANOVA + Newman-Keuls test).

The LP of P100 in patients treated simultaneously with deltalycyn and TMS exceeded the initial value by 3.8% ($p>0.05$) at the end of first 20 s of observation (tab. I). Contrary to effects of separate usage of deltalycyn and TMS, combined application of both revealed significant differences of LP when compared to those ones registered in patients with retinopathy without treatment. Thus, at first 20 s such difference was confined to 11.5%, while at next 20 s – 9.6% and at the end of observation – 12.2% ($p<0.05$). The amplitude of P100 at the end of 40-th s was less by 14.8% when compared with the initial value ($p>0.05$). At this moment amplitude exceeded similar index in patients treated only with deltalycyn by 26% ($p<0.05$). At 40th and 60th seconds of post stressor period amplitude of P100 also exceeded similar index in patients with retinopathy who were given only TMS – by 30,2% ($p<0.05$) and 31,2% ($p<0.05$) correspondently. The total time of recovery of LP and amplitude in this group was reduced by 39.9% when compared with the same index registered in patients with retinopathy without treatment ($p<0.05$) (tab. II).

Thus, the obtained results showed that in patients suffering from the diabetes mellitus with diagnosed retinopathy the following impairments of the VEP characteristics observed: lengthening of the latency period P100 and lowering of the amplitude N75-P100 in comparison to these indices in the control group. Besides, more time (by 86.7% pertained to control group) it was of need to recover functionally from photo stress.

It may be assumed that the described disorders are the result of a decreased velocity of the nerve impulse conductance along the optic nerve (8). Also quite possible that observed results have been contributed with a selective damage to the ganglion cells and their axons in the central part of the retina as a result of metabolic stress and continuous hyperglycemia. Also it may be assumed that photo stress impairs the ability of the macular photoreceptors to produce the action potential after such stimulation. Meanwhile, a prominent role in the VEP recovery seemingly belongs to the photopigment resynthesis that can be supplied by a sufficient bloodstream volume (4, 7). Hence, the improvement in microcirculation along with the affecting functional state of retinal neurons antidromically from stimulated cerebellar structures might be suspected as main targets for the precipitation of observed positive therapeutic effects. Also it should be noted that both – deltalycyn and cerebellar TMS are able to affect number of neuromodulator effects including heightening of antioxidative mechanisms (1, 5). The last ones are known as critical for the prevention of diabetic retinopathy (5).

CONCLUSIONS

Retinopathy development is linked to prolonged VEP latency period (P100), lowering of the N75-P100 amplitude, as well as to prolongation of the recovery period of the retina's functional capacity in patients suffering from the diabetes mellitus in the presence of photo stress.

Superlatively administered deltalycyn and cerebellar transcranial magnetic stimulation facilitates a faster recovery of the retina's functional capacity in response to photo stress in diabetic patients with retinopathy.

Combined usage of deltalycyn and cerebellar transcranial stimulation caused the potentiated shortening of post photo stress recovering of VEP in patients with diabetic retinopathy.

PREMATURE BIRTH LINKED WITH INFLUENZA COMPLICATIONS IN YOUNG CHILDREN

A group of researchers leaded by Kay Wang, from the University of Oxford in the UK, shows that children younger than two years who were born prematurely are at increased risk of being hospitalized if they develop influenza. One in four children who develop influenza or influenza-like illness will have complications, such as otitis media or pneumonia. The systematic review and meta-analysis, published in Lancet Respiratory Medicine on December 4, analysed 27 studies including more than 14,000 children. In this study, factors that increased the likelihood of hospitalization included neurological disorders (univariable odds ratio, 4.62), prematurity (OR, 4.33), sickle cell disease (OR, 3.46), immunosuppression (OR, 2.39), diabetes (OR, 2.34), and being younger than two years of age (OR, 2.51). When age younger than two was included as a risk factor in a multivariate analysis, children with more than one risk factor had a 74% chance of being admitted to the hospital, while the risk for children with one risk factor was 52% ($p<0.0001$). These findings provide an evidence-based definition of which children are most at risk of developing complications from influenza. Dr. Wang concluded that interventions aiming to prevent these complications, including vaccination and antiviral medications, should therefore be prioritised in these groups, particularly during seasonal influenza epidemics and influenza pandemics (Anne Harding. Premature Birth Linked With Influenza Complications in Young Children. *Medscape*. December 14, 2014).

2. Ph.D. student

INTERDISCIPLINARY CORRELATIONS REGARDING THE CLINICAL AND PARACLINICAL EVALUATIONS IN HIV-PREGNANT WOMEN (Abstract): HIV infection in pregnancy has an increasing prevalence due to the effectiveness of antiretroviral therapy. The risk of HIV vertical transmission varies between 15-20 % in European women who do not breastfeed and 25-40 % in African mothers who breastfeed. The most important predictive factor of the vertical transmission is maternal plasma HIV viral load. Vertical transmission can be largely prevented by prenatal screening, perigestational ART, an adapted obstetrical attitude and exclusively artificial feeding of the infant. **Material and method**: the study included 36 HIV-positive pregnant women, between 2012-2014, at age of 25-32 years. **Results and discussions**: It has been found that the birth weight was less than 2,700 grams in all newborns of HIV-positive pregnant women or those with advanced disease (AIDS) and, also, they received an APGAR score less than 7. The primordial desideratum is to decrease the rate of mother-fetus vertical transmission, thus the caesarian section has been established as the birth method in all HIV-positive pregnant women after 38 weeks of amenorrhea, on intact membranes, outside labor, resulting in halving the percentage of HIV-positive children. A very important role belongs to the interdisciplinary collaboration between the obstetrician and the infectious diseases specialist during the pregnancy, but also during the postpartum period. The role of the obstetrician is present in all the moments of pregnancy evolution. The HIV-positive pregnant woman is included in the group of high risk pregnancies. **Keywords**: HIV-POSITIVE PREGNANT WOMAN, VERTICAL TRANSMISSION, INTERDISCIPLINARY COLLABORATION

HIV infection in pregnancy- reflected through the number of HIV-positive pregnant women- has an increasing prevalence due to the effectiveness of antiretroviral therapy (ATR), especially of the highly active antiretroviral therapy (HAART)- with consequent prolongation of the life of HIV-positive patients, due to the increasing incidence of heterosexual transmission and of the increasing significant number of infected people who are not aware of their condition (1, 2, 3).

The risk of HIV vertical transmission varies between 15-20% in European women who do not breastfeed and 25-40% in African mothers who breastfeed. Without treatment, it is estimated that over 80% of the transmission cases takes place after 36 weeks of amenorrhea, during labor or birth and only 2% of the transmissions occur

during the first two pregnancy trimesters (2, 4). The most important predictive factor of the vertical transmission is maternal plasma HIV viral load (4). Other perigestational risk factors are the advanced maternal disease (AIDS) and the low maternal plasmatic level of CD4 T lymphocytes (4, 5). The main obstetrical risk factors are the vaginal birth, the increased duration of the period of ruptured membrane and premature birth. Breastfeeding increases the risk of vertical transmission by 14-28% in patients without HAART (5, 6).

Vertical transmission can be largely prevented by prenatal screening, perigestational ART, an adapted obstetrical attitude and exclusively artificial feeding of the infant (1).

MATERIAL AND METHODS

The study included 36 HIV-positive pregnant women within "Sfânta Parascheva" Clinical Hospital of Infectious Diseases of Iasi during 2012-2014, who subsequently gave birth at "Cuza-Vodă" maternity of Iasi.

The information was collected by collaboration with the medical statistics services of the two clinics and by studying the birth registers within the maternity.

The cases included in the studio were analyzed in relation to: the stage of the maternal disease (advanced or not), the type of birth (natural or caesarian), birth weight (>2,700 grams, <2,700 grams), gestational age (>37 weeks of amenorrhea, < 37 weeks of amenorrhea) and APGAR score (>7, <7).

The processing and the interpretation of the results were carried out by clinical, mathematical and computerized methods.

RESULTS AND DISCUSSION

1. Staging of disease in HIV-positive pregnant women.

In the two years taken into consideration for the study, 36 cases of HIV-positive pregnant women were reported, of which 16 cases (44%) with advanced disease (AIDS). In all of the 36 cases the birth was carried out through caesarian. A birth weight of <2,700 grams had been found in all the newborns of the HIV-positive pregnant women with advanced disease (AIDS) and in only 5 newborns of HIV-positive pregnant women without advanced disease. Also, the APGAR score was <7 in 12 newborns of the HIV-positive pregnant women with advanced disease, as compared to the newborns of the HIV-positive pregnant women without advanced disease, who received APGAR > 7.

2. Viro-immunological evaluation of pregnant women.

Pregnant women with advanced HIV disease (AIDS) presented a low plasmatic level of CD4 T lymphocytes, level which proved to negatively influence the rate of vertical transmission to the newborn and its morbidity(1,2). Newborns of pregnant women with advanced HIV disease had a lower birth weight as compared to the newborns of the mothers without advanced disease and they also received a lower APGAR score and they had a more increased morbidity, represented by neonatal infections.

3. Psychological evaluation of the HIV-positive pregnant woman.

Counseling for HIV testing represents the "key" service, both for initiating certain efficient programs for preventing/restricting the epidemic, and for initiating care and support measures for the people affected by HIV/AIDS. HIV testing has to be voluntary, carried out according to the informed consent of the pregnant woman and, thus, in all situations, accompanied

by pre- and post-testing counseling, by complying with confidentiality. Women have to benefit from access to quality counseling and testing services before getting pregnant, for the evaluation of their personal HIV status, but also for their partner's HIV status. Also, the information will help her protect against and prevent HIV infection, both for herself and for her partner, as well as for the future child.

4. Study of the patients from the obstetrical point of view.

The primordial desideratum is to decrease the rate of mother-fetus vertical transmission, thus the caesarian section has been established as the birth method in all HIV-positive pregnant women after 38 weeks of amenorrhea, on intact membranes, outside labor, resulting in halving the percentage of HIV-positive children.

A caesarian section was performed in all of the 36 HIV-positive pregnant women, as the recommended method of birth.

The gold standard is that the caesarian section should be performed, in HIV-positive pregnant women, in the absence of labor, on intact membranes.

Pregnancy hospitalization is carried out as follows: months 1-7, 1 check-up per month, month 8, 2 check-ups per month and month 9, 1 check-up per week.

The intrapartum conduct is represented by the limitation of the time during which the child comes in contact with the blood or other maternal fluids with high viral load.

The postpartum conduct is represented by the prophylaxis of the puerperal infections with antibiotics, prophylaxis of postpartum thrombosis (collaboration with anesthesia and intensive care specialist), and check-up after 6 weeks and after 3 months, establishing a contraceptive method.

The HIV-positive pregnant woman is included in the group of high risk pregnancies. The planned caesarian section is preferred, in pregnant women who are known and monitored, in order to significantly decrease the rate of vertical transmission. ART is administered ante, intra and postpartum, as well as for the newborn.

CONCLUSIONS

In this study a very important role belong to the interdisciplinary collaboration between the obstetrician and the infectious diseases specialist during the pregnancy, but also during the postpartum period.

In our study, a caesarian section was performed in all of the 36 HIV-positive pregnant women, but 5 of them came late to the maternity and their membranes had been ruptured for over six hours. The 5 newborns were prematurely born after 35-36 weeks of amenorrhea, they had a birth weight of < 2,700 grams and they received an APGAR score <7.

HIV infection represents a current major health problem in most of the countries and, for this reason; it represents a increasingly higher interest. The primordial desideratum is represented by the decrease of the rate of mother-fetus vertical transmission.

The mandatory condition is the existence of a multidisciplinary team, obstetrician-neonatologist-infectious diseases specialist-family physician.

NUCLEOTIDE SEQUENCE ANALYSIS OF BETA TUBULIN PROTEIN-CODING GENE

Rezaei-Matehkolaei et al. studied the beta tubulin protein-coding gene (BT2) in 26 species belonging to *Trichophyton*, *Microsporum*, and *Epidermophyton* genera. A number of 144 strains were identified using internal transcribe spacer (ITS) sequencing and BT2 gene was partially amplified in all strains. After construction of a BT2 database, sequence analysis was performed, showing length that ranged from 723 nucleotides (*T. ajelloi*) to 808 nucleotides (*M. persicolor*). In some species, the study found intraspecific sequence variation, while other species were invariant (*T. tonsurans, T. equinum, T. concentricum, T. verrucosum, T. rubrum, T. violaceum, T. eriotrephon, E. floccosum, M. canis, M. ferrugineum,* and *M. audouinii*). In different strains of the same species the sequences were relatively conserved. The dendrogram obtained using BT2 was almost compatible with the species concept based on ITS sequencing, and similar species were distinguished. After characterization of BT2 in a wide range of dermatophytes, the researchers concluded that beta tubulin protein-coding gene is a taxonomically valuable gene.(Rezaei-Matehkolaei A, Mirhendi H, Makimura K et al. Nucleotide sequence analysis of beta tubulin gene in a wide range of dermatophytes. *Med Mycol*. 2014. pii: myu033).

4. National Institute of Public Health – Regional Center of Public Health, Iaşi

EPIDEMIOLOGICAL AND PATHOLOGICAL ASPECTS OF SKIN CANCER IN NORTH EAST OF ROMANIA (Abstract): In the last years skin cancer has become the most frequent cancer in humans, with the majority made up of two tumors: malignant melanoma (MM) and non-melanoma skin cancer (NMSC). **Aim**: To provide for the first time in the North East region of Romania, descriptive epidemiological data of melanoma and non-melanoma skin cancers. **Material and methods**: We undertook a retrospective study over a five year period on the most frequent forms of skin cancer, basal cell carcinoma (BCC), squamous cell carcinoma (SCC) and MM, which included a total number of 1231 patients, hospitalized and treated in the Plastic Surgery Department of "St. Spiridon" Emergency Clinical Hospital, Iaşi from 2008 until 2012. Results: BCC was diagnosed in a total of 675 patients, representing 54.9%. SCC was found in 217 patients, representing 17.6% and melanoma was diagnosed in 119 cases, a percent of 9,7% of the total number. The predominance of cutaneous malignancies waried with age, major site distribution was face and neck for BCC and SCC and the trunk for MM. **Results**: This article describes the most common forms of skin cancer in our region, BCC (almost 55%), SCC (17.6%), and less in number MM (near to 10%); these results are similar to those published abroad in the last years. **Conclusions:** Future more elaborate interventional studies are necessary to identify the main risk factors in order to design the best preventive methods and, according to the skin cancer trend to specify the needs for dermatology network in our country. **Keywords:** SKIN CANCER, BASAL CELL CARCINOMA, SQUAMOUS CELL CARCINOMA, MELANOMA.

In the last decades skin cancer has become the most frequent cancer in humans, with the majority made up of two tumors: malignant melanoma (MM) and non-melanoma skin cancer (NMSC) (1). These two are the most common types of cancer encountered in white population, with an increasing incidence rate worldwide, but the epidemiological data regarding this type of cancer are incomplete because of the absence of some cancer registers or simply the lack of information (2).

In the battle against cancer we must know all the aspects about the disease with the special features for every country and every region. In the North – East region of Romania, the Cancer registry was recently introduced, and the data were collected and

statistical processing only until 2009, thus the prevalence and the histological forms of this type of neoplasm are not very well known, and there is no national database for this epidemiological surveillance.

In this retrospective study we have examined the epidemiological and pathological features of 1231 skin cancer cases, made by the Plastic Surgery Department of"St. Spiridon" Emergency Clinical Hospital, Iaşi from 2008-2012 with the purpose of documenting the pattern of skin neoplasia in Iaşi, the largest city of Moldavia.

Non-melanoma skin cancer is the most common human skin cancer, enclosing basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), both derived from epidermal keratinocytes, and it rarely metastasizes (3). NMSC is the neoplasm of elderly people, with a predilection for sun exposed areas, and, in contrast with melanoma, rarely metastasize (4). BCC, also known as "basalioma" was described for the first time in the 1824, by Arthur Jacob, as *ulcus rodens*, and, since then its incidence is continuously rising worldwide. BCC represents about 65% of the epithelial skin tumors, it has a maximum incidence in the 6-th decade of live and a slightly male predominance. It is a slow-growing, locally invasive epidermal tumor with a metastatic rate of <0.1% (4). The majority is found on the cephalic extremity (head and neck), almost 80% of the cases respectively; the distribution but these can vary according to the histological pattern: superficial BCC is more often found on the truck (5). Fibroepithelioma's Pinkus is a rare type of BCC that is usually located above the natal cleft or on the lower trunk with a pink colored nodule that may look like seborrheic keratosis. The incidence of NMSC is increasing, while the mortality is decreasing, a fact that is explained by earliest diagnosis with efficient therapeutical intervention all over the world (6). Keratoacanthoma is relatively common, especially in middle-aged white people, uncommon in dark-skinned ones; moreover it is a benign epidermal tumor with a tendency to regression after a few months that can develop areas of CSC in approximately 25% of cases (7). Merkel cell carcinoma is a rare neuroendocrine carcinoma of the skin, 40 times less common than melanoma, but with a higher mortality (33%) than melanoma (15%) (8). MM is the most aggressive form of all skin neoplasms with a reduce survival rate. It can start either from the existing moles or from the normal-looking skin. Many studies have reported at least two important data about the survival rate: that women have a longer survival score than men, and that the anatomic location varies with this rate. For example, melanomas located on the trunk were correlated with worse prognostic (8).

MATERIAL AND METHODS

In this 5 years (2008-2012) retrospective and descriptive study a total of 1,231 cases registrated in the Plastic Surgery Department of „St. Spiridon" Emergency Clinical Hospital, Iaşi were investigated. Detailed description of clinical appearance of the excision area is previously described in patients' clinical records. Surgical excisions and histopathology examinations were performed in all cases. The biopsy specimens were processed using paraffin embedding and hematoxylin-eosin staining method. Statistical analysis were performed as case-control analyses, without adjustment for multiple testing, with nominal significance defined as $p<0.05$. Intergrupal

qualitative differences were established using the Chi-squared Kruskal-Wallis Test. In this study we included only patients with clinical diagnosis of BCC, SCC and MM. The variables introduced in the current study were: gender, inhabitant population of place of residency (urban/rural), anatomical location of the cancer (face/scalp/neck/ trunk/anogenital region/upper limb/lower limb), clinical presentation, histological diagnosis, presence of residual malignant cell in the safety margins (oncologic excision), and risk factors (smoker/non smoker for MM).

RESULTS

Of the total number of patients (1231), 1319 biopsy pieces has been histological analyzed, because of the existing multiple lesions on the same patient. BCC was diagnosed in a total of 675 patients, representing 54,9% of the cases taken to the study, with the nodular form as the most common histological type (40.4%), followed by BCC with adnexal differentiation (21.1%), keratotic (14.8%), superficial (6.8%) and pigmented (6.1%). 81.6% of BCC had a facial localization, 11.4% a trunk localization and 11.1% had the tumor on the scalp. We did not find a male predominance in these forms of carcinoma, but maximum incidence of it was found in the sixth decade of live (4). SCC was found in 217 patients, representing 17.6% with the major histopathological pattern being the keratotic form (81.9%), and MM was 9.7% of the total number with a preponderant level of invasion as Clark III (33.6%). The frequency of BCC, SCC was higher in the rural district *versus* the urban district (82% *vs.* 68%) as described in tab. I and on the age group, the variation of skin cancer was significantly statistical: in the group aged 20-29 the MM was the most frequent form, between 50-59 years BCC was the prevalent one and over 90, SCC.

TABLE I

Skin cancer distribution according to gender and place of residency

Skin cancer	**Total**		**Male**		**Female**		**Urban**		**Rural**	
	N	%	N	%	N	%	N	%	N	%
BCC	675	54.9	335	53.9	340	55.9	322	53.7	353	56.8
SCC	217	17.6	123	19.8	94	15.5	77	12.8	140	22.5
MIXT	26	2.1	12	1.9	14	2.3	9	1.5	17	2.7
MM	119	9.7	64	10.3	55	9.0	74	12.3	37	5.9
Other	193	15.7	88	14.1	105	17.3	118	19.7	75	12.1
Kruskal Wallis Test			Chi-square=6.081; df=4; p=0.193				Chi-square=43.672; df=4; p=0.001			

In SCC 76% of the cases had a facial localization and 11, 1% were found on the upper limbs. In MM, the main localization was the trunk (44.5%), followed by the upper limbs with a 28.6% percent as described in table II.

All patients with mixt carcinoma had a facial localization and 26.9% of them were associated with another mixt carcinoma on the scalp or upper limbs.

TABLE II
Site distribution of skin cancer

Skin cancer	Face		Scalp		Neck		Trunk		Anogenital region		Upper limb		Lower limb	
	N	%	N	%	N	%	N	%	N	%	N	%	N	%
BCC (N=675)	551	81.6	75	11.1	14	2.1	77	11.4	-	-	9	1.3	9	1.3

Other (N=193)	86	44.6	25	13.0	4	2.1	34	17.6	3	1.6	13	6.7	35	18.1
Total (N=1230)	**837**	**68.0**	**122**	**9.9**	**22**	**1.8**	**176**	**14.3**	**6**	**0.5**	**64**	**4.2**	**92**	**7.5**

The histopalogical pattern of SCC revealed aproximatively 82% of them as SCC with keratinisation and 3,7% *in situ* SCC. Precancerous keratinocytic lesions found in our study were: actinic Keratosis (AK), Bowen's disease, Bowenoid papulosis and Erythoplasia of Qeuyrat (9). Regarding the safety margins of the excision of the tumor, there were differences between the three types of cancer: 87.6% for the BCC, 85.3 % for SCC and only 72.3% for the MM.

DISCUSSION

Although skin tumors registries have been established for several European countries, in Romania only since 2007 regional registries were created in order to collect and to analyze data regarding all cancers that were diagnosed in our oncology clinical units. Specific data regarding evolution and tendency of skin cancer will be available probably in the next years. Although non -invasive therapeutic ways of screening a skin lesion are increased, such as demartoscopy, the most frequent way of treating such lesion remains the surgery. Unlike BCC, SCC has some premalignant lesions, such as actinic keratoses or Bowen disease, lesions that may benefit from a non-invasive treatment, first-rate for the patient and less expensive for the health insurance companies. In the studied period the major forms of skin cancer was homogenous (p=0.927) (fig. 1).

Related to the histopatholgical forms of skin cancer, we found some statistically semnificative differences between BCC, SCC and MM. The majority of NMSC lesions were encountered on the head and neck area, a visible site that affects the quality of live score on these patients (10). 81.6% of BCC had a facial localization and 76% our cases of SCC were in this site. The major histopathological form of BCC was the nodular one, in accordance with other data (11). According with another international data, the BCC and SCC localization was predominantly in the same area- head and neck (limit: 74 - 84% - Plesko et all. 2009, Jung G.W et all. 2010, Dacosta Byfield et all. 2013). The clinical presentation of BCC is quite variable: nodular lesion, ulcerated lesion, erythematous plaque or nodule like lesion and tends to occur in elderly people (12). Due to the good prognosis and high inci-

dence of this type of NMSC, BCC is not considered an aggressive cancer, but the local destruction potential may bring some intricate methods of treatment (13). Related to the histo-patholgical forms of skin cancer, we found some statistically significantly differences between BCC, SCC and MM. Our findings are similar to one of the largest systematic review of worldwide incidence of nonmelanoma skin cancer, made by Bath-Hextall et all (2012): the most frequent skin cancer was BCC (54.9%) while a smaller percentage is represented by SCC (17.6%) and melanoma (9.7%) (6,14). The frequency of BCC, SCC was higher in the rural district *versus* the urban district (82% *vs.* 68%), but the frequency of MM was significantly higher in the urban area (12.3% *vs.* 5.9%) (p=0.001). On the age group, the variation of skin cancer was significantly statistical: in the group aged 20-29, the MM was the most frequent form, between 50-59 years BCC was the most prevalent one and**,** over 90, SCC. MM was predominant in men and, in comparison with other adult cancers, more common in young people. We did not find the increasing incidence of MM in this period of study, probably due to the short duration of it. More than 25% of MM occurs in persons less than 45 years old with an incidence that has increased significantly worldwide, especially in lightly pigmented Caucasians (7). In our study the majority of MM cases were in 20-29 group of age. In order to improve the chance of an early diagnosis, the histopathological exam remains the golden standard in the all forms of skin cancer and the way to a proper staging (15).

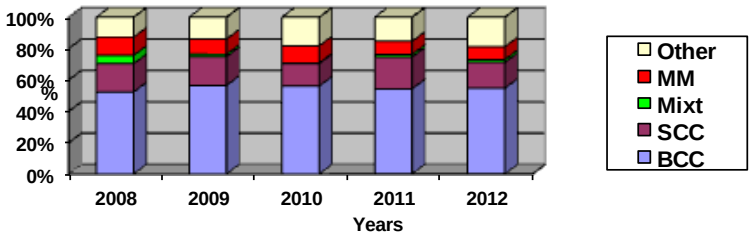

Fig 1. Years distribution of major forms of skin cancer by year of study.
Other: trichoepithelioma, leiomyosarcoma, hemangioma, papilloma.

CONCLUSIONS

This study has investigated the prevalence of skin cancer and the histopathological pattern of BCC, SCC, MM in North-East Romania, with the aiming at bringing an overview to the exact incidence of skin cancer in our country. To our knowledge these data are provided for the first time in this region and our findings are similar to other international data. In a five years retrospective study, the most frequent skin cancer was BCC (54.9%) and less in number SCC (17.6%) and melanoma (9.7%). Future more elaborate interventional studies are necessary to identify the main risk factors in order to design the best preventive methods and, according to the skin cancer trend to specify the needs for dermatology network in our country.

THE IMPLICATIONS OF HAZARDOUS WASTE NEUTRALIZATION ON EMPLOYEES HEALTH: A CASE STUDY (Abstract): Chronic obstructive pulmonary disease is a lung disorder characterized by chronic inflammation of the respiratory tract after exposure to pollutants, causing the obstruction of small respiratory tracts and the destruction of lung parenchyma. These changes ultimately lead to a limitation of air flux. We investigate the association between professional exposure and the risk of developing chronic obstructive pulmonary disease. This study presents the case of a non-smoker patient, aged 61, a mechanic locksmith by profession at a hospital in Mures County. He has been working with neutralization of medical waste for 13 years with exposure to pneumotropic and biological contaminants and to the overuse of osteoarticular apparatus, recently having been diagnosed with COPD after exposure to mixed powders and hospitalized at the occupational health clinic. Interruption of occupational exposure and establishment of treatment with topical corticotherapy has shown a significant improvement. Measurements of inhalable powder content in the work environment revealed that they exceed the allowed limit in case of neutralization of medical waste and there is an association between occupational exposure and increased risk of chronic obstructive pulmonary disease. Preventive methods should aim to reduce exposure at workplace. **Keywords**: COPD, POLLUTANTS, SPIROMETRY

Medical wastes are hazardous both for people and for the environment, exposing people to the risks of toxic infections. These types of waste result from all the medical activities in the national health system (1). Persistent Organic Pollutants (POPs) are chemicals which are particularly harmful to human health and the environment. They have been the subject of several environmental policies, and the subject of an International Convention (7). The Stockholm Convention on POPs has taken into consideration 12 categories of pollutants and has noted the obligation of each part to elaborate a National Plan for the Implementation of the provisions of the above mentioned Convention (9). These 12 priority POPs are aldrin, chlordan, dichloro-diphenyl-trichlorethan (DDT), dieldrin, heptachlor, myrex, endrin, toxaphen, poly-

chlorinated biphenyls (PCBs), dioxins and furans, hexa-chloro-benzene (2).

The Stockholm Convention, adopted in 2001, is the one which regulates the scrapping of POPs on a worldwide scale (3,4). In addition to tobacco smoking the exposure to pollutants at the workplace (dusts, fumes, and irritating gases) is a major risk factor for chronic obstructive bronchical pneumopathy (5,6).

CASE REPORT

In this paper we present the case of MF, a 61-year-old non-smoker, a professional locksmith mechanic, with approximately 40 years of professional service. From his professional route we would like to highlight the past 13 years, when the patient worked as a mechanical locksmith in a hospital in Mures County, in the last 3 years carrying out his activity in the department of medical waste neutralization. The patient participated in all the stages of neutralizing waste, involving: loading the autoclave with the medical waste collected from different wards of the hospital, automatic and manual ventilation, extraction of sterilized medical waste transported on conveyors up to grinding, ripping with a shovel, loading and storage of waste in the form of powders in crates and then loading them into bags as well as the transport towards the container. The patient therefore has currently been exposed professionally to the biological contamination, infections in hospitals that come from the neutralization of materials disposable sanitary remains, pneumotropic fumes arising from the ventilation of the autoclave, metal powders, plastics and textiles from the process of chopping, overuse of the osteo articular apparatus by removal of weights and repetitive harmful movements and positions as well as an unfavorable microclimate.

The patient complains of shortness of breath at the moment of hospitalization, in especially upon exertion, predominantly dry cough. The symptoms first appeared 2 years ago, the period coinciding with the professional activity in the neutralization station. He complains of pain in coxofemoral joints, lumbar spine pain, and persistent bilateral pain in the lower limbs. The patient had accidental exposure to HIV (Human Immunodeficiency Virus) and hepatic viruses, for which he sought treatment with antiretroviral drugs in 2010 as a means of prevention; for the osteoarticular problems he was admitted to the clinic of Rheumatology in 2013, and for pulmonary disease to the clinic of Pneumology. He was diagnosed with chronic obstructive bronchial pneumonitis stage I/II, interstitial reticulonodular pulmonary fibrosis, for these conditions treatment with slight improvement in symptomatology was followed. Occupational health surveillance is recommended and hospitalization for occupational diagnosis is needed. The patient is hospitalized in May 2013 at the Occupational Health Clinic of Târgu-Mureş. The general clinical examination revealed osteoarticular affections and a pulmonary disease. The thoracic radiography describes a chronic bronchitis with pulmonary emphysema.

The spirometry (tab. I) carried out two years ago in a periodical medical control at work shows a mixed average ventilation dysfunction FEV1 (Forced Expiratory Volume in 1st second) at 60%. FEV1 at the moment of hospitalization shows an increase of 72 percent. Therefore, the patient is being treated in conformity with treatment recommended by the Clinic of Pneumology, and 3 months after the suspension of the activity, the value of FEV1 increased

to 84%.

The bronhodilation test was also performed (tab. II) for differential diagnosis between fixed obstruction, namely chronic obstructive pulmonary disease and the reversible obstruction of the respiratory tract, namely bronchial asthma. The test is negative, meaning that the obstruction is fixed.

The body-plethysmography (tab. III) shows an increased resistance of the respiratory tract.

In conformity with the anamnesis, clinical and paraclinical examinations the following diagnoses were established: (i) chronic obstructive bronchopneumopathy, stage I/II due to exposure to mixed powders (metal, plastics, textile) and vapors; (ii) mild mixed ventilation dysfunction with the dominance of restriction; (iii) lumbar polydiscopathy of professional etiology; (iv) cervical spondylosis and vertebrobasilar insufficiency.

During hospitalization the patient followed treatment for the above mentioned diagnosis with a favorable evolution of his general state. It is recommended to avoid overloading the osteoarticular apparatus and harmful positions, wearing protective masks in the workplace, ensuring natural ventilation.

Determinations were performed from the work environment (tab. IV) measuring the total dust in suspension in the medical waste neutralization area, in the waste removal hydroclave and their placement in the chopper. Here the powder is in normal range, below 1 mg/m^3 on 8 hours and at the loading of powder in bags it is 1.39 mg/m^3, above the maximum concentration, i.e. more than 1 mg/m^3.

TABLE I

Spyrometry

Spyrometry	FVC (%)	FEV1 (%)	Tiffeneau index (%)	Conclusion
Periodical medical control	50	60	85	Medium mixed ventilation dysfunction
Occupational Health Clinic	66	72	80	Mild mixed ventilation dysfunction
3 months after the suspension of activity	71	84	92	Mild restrictive ventilation dysfunction

FVC-forced vital capacity
FEV1-forced expiratory volume in 1 second
Tiffneau index –FEV1/FVC ratio

TABLE II

Test of bronchial dilatation

Test of bronchial dilatation	FEV1 (%)	FVC (%)	Tiffeneau index (%)	PEF (%)	MEF50%
Initial	72	66	80	79	96
After the administration of Ventolin	76	61	91	93	116

PEF- Peak Expiratory Flow
MEF50%- Maximal Expiratory Flow at 50%

TABLE III

Body-Pletismography

Body-Pletismography	Raw	Gaw	TLC	VR	TLCO	DLCO
%	155	175	73	59	119	119

Raw- specific airway resistance; Gaw- reciprocal of airway resistance; TLC- total lung capacity
VR-residual volume; TLCO-transfer factor; DLCO- diffusing capacity for carbon monoxide

TABLE IV

Determinations of the work environment

Medical waste neutralization department	Chemical agent	Result (mg/m^3)	Maximal admissible concentration on 8 hours (mg/m^3)
Removal of sterilized waste from the hydroclave and loading it into the grinder	Powder- inhalable fraction	0.465	1
Loading the powder in waste bags	Powder- inhalable fraction	1.39	1

CONCLUSIONS

Dust concentration measured at the work site exceeds maximal admissible concentration with 0.39 mg/m^3. These values do not greatly exceed the maximal admissible concentration. However they have a significant impact on the health status of employees engaged in the process of medical waste neutralization. The medical waste neutralization procedure reduces the risk of environmental pollution, but does not eliminate the risk of diseases among employees.

METFORMIN INDUCED LACTIC ACIDOSIS – PARTICULARITIES AND COURSE (Abstract): Diabetes mellitus is a widespread disease with many serious chronic complications. An improvement in the oral antidiabetic medication in respect to its mechanism of action and toxicology was needed in order to have effective therapies with high compliance and minimum side effects. In this context, metformin is a widely used oral antidiabetic drug, which, through its mechanism of action, has no risk of hypoglycemia. However, a rare but serious side effect of biguanides is lactic acidosis. This paper presents a number of 13 cases of metformin-associated lactic acidosis, which outline the circumstances triggering the adverse event and the clinical therapeutic measures applied in the poisoned patients. The main situations that favor metformin-associated lactic acidosis are renal impairment and tissue hypoxia, and the intervention is adapted to the particular patient condition and symptoms, such as marked hypotension and cardiac arrest. Although there are commonalities in describing the consulted patients, the final prognosis is not dependent on the dose or metformin plasma levels, but rather on the associated pathologies and medication. **Keywords:** DIABETES MELLITUS, METFORMIN, LACTIC ACIDOSIS, RENAL IMPAIRMENT, HYPOXIA

Diabetes is probably one of the first illnesses known to man. It was mentioned for the first time in Egyptian manuscripts 3000 years ago, and in 1988 type 2 diabetes was described as a component of the metabolic syndrome. It represents one of the most common forms of diabetes, characterized by hyperglycemia, insulin resistance and insulin deficiency. This illness results from the interaction of genetic, social and behavioral risk factors.

It is estimated that, in the year 2011, 366 million people had diabetes. This number is thought to rise up to 552 by 2030. For the same year, 2010, it is stated that the number of deaths attributed to diabetes at a global level is around 3.96 million for 20-79 age group that is roughly 6.8% of the global mortality rates for all age categories (1).

Metformin, a biguanide compound with antidiabetic action, was first described in the literature in 1922 by Werner and Bell, as a product in the synthesis of N, N-dimetilguanidine. In 1929, researchers Slotta and Tschesche observed the substance to lower blood glucose in rats, and they described the substance as the most effective biguanide compound of the ones

they studied (2).

Metformin has been accepted as an antihyperglycemic agent in England in 1958, in Canada in 1972, and in USA in 1995. Currently, metformin is the first-line drug in patients with type 2 diabetes who do not have specific contraindications. Only in 2005 more than 42 million prescriptions for metformin were issued in the United States (3).

Besides its use in diabetic patients, metformin is also effective in polycystic ovary syndrome and is being researched as an antiviral and anticancer adjuvant.

Metformin activates an important enzyme called protein kinase AMP-activated (AMPK), which plays an essential role in body energy balance by regulating the metabolism of carbohydrates and lipids. Latest researches show that metformin inhibits mitochondrial respiration by activating AMPK and the synthesis of fatty acids. Metformin improves hyperglycemia by reducing insulin resistance and plasma insulin levels in the fasting state.

Known side effects of metformin include abdominal discomfort, nausea, vomiting, diarrhea, constipation, flatulence, indigestion, heartburn (4). Another adverse effect that may occur in long term metformin administration is vitamin B_{12} deficiency. Studies confirm that metformin can cause malabsorption of vitamin B_{12} and thus lower serum levels of this vitamin (5).

Lactic acidosis is a rare but serious adverse effect of metformin associated with its therapeutic use and overdose (6).

Lactic acidosis can be classified as follows: Type A (associated or caused by inadequate oxygen transport to tissues) and Type B (with adequate oxygen transport to tissues). Type B has 3 sub-categories: B1 - lactic acidosis associated with a disease (eg, diabetes, asthma etc.), B2 - lactic acidosis caused by drugs or toxins (e.g., cyanide, metformin, epinephrine, etc.), B3 - lactic acidosis caused by congenital metabolic disorders.

Depending on the cause, hyperlactatemia is defined as lactate levels between 2 and 5 mmol/L, although it is mentioned that lactic acidosis is present when lactate levels are above 5 mmol/L and arterial pH is lower than 7.35. These definitions can however be arbitrary (7).

The lactate is the final product in anaerobic metabolism (it represents the product obtained from the reduction of pyruvate by lactate dehydrogenase enzyme). It is initially obtained in skeletal muscles, intestine, brain and circulating erythrocytes, with a production of approximately 1 mmol/kg/h. The healthy liver takes the largest part of the lactate and recycles it through three main pathways: conversion to glucose (Cori cycle), pyruvate oxidation, which can then be oxidized to CO_2 (Krebs cycle), and transamination to alanine. The reduced oxygen transport to tissues and cells cause damage in oxidative phosphorylation, with increasing intracellular amounts of NADH, cofactor in the conversion of pyruvate to lactate. Due to the close connection with anaerobic metabolism the lactate was considered to be the end product of glycolysis due to hypoxia (7).

Risk factors for the development of metformin-associated lactic acidosis, such as kidney failure, pre-existing heart disease, chronic lung injury with hypoxia, and congestive heart failure, are usually considered contraindications to metformin therapy. Age may be associated with decreased renal functions and the increase of co morbidities (8). Figure 1 outlines the mechanism of lactic acidosis production, in

particular circumstances.

In patients who develop severe lactic acidosis the symptoms are characteristic: agitation, confusion, absent corneal reflexes, fixed dilated pupils, lethargy, convulsions, coma, and ultimately death (10).

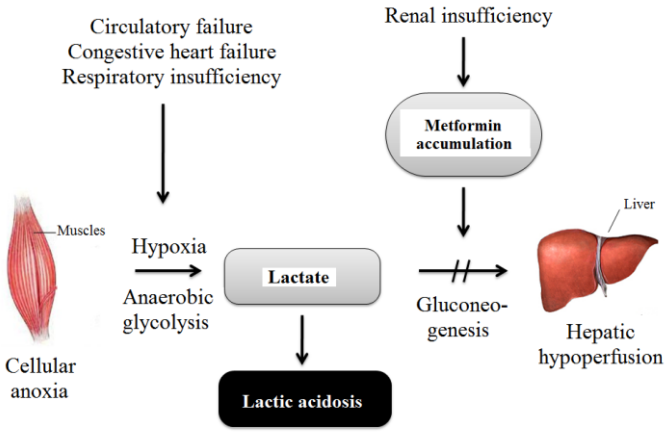

Fig. 1. Lactic acidosis and the circumstances which may increase the risk associated with metformin therapy (9)

We analyzed 13 cases of acute metformin poisoning associated with lactic acidosis reported in the literature.

The circumstances that led to lactic acidosis are presented in Table I. This severe adverse effect also occurred in attempted suicide by drug overdoses and chronic administration to treat hyperglycemia. Also, metformin-associated lactic acidosis was present both in patients with or without renal impairment. With regard to associated medication, incriminated in the development and/or worsening of metformin-induced adverse effects, a definite link has been established in the case of creatine co administration (11).

The most frequent symptom of metformin poisoning is gastrointestinal upset when nausea, vomiting, diarrhea, abdominal cramps, anorexia, epigastric discomfort and pain, and loss of appetite occur. The occurrence of lactic acidosis causes lethargy, confusion, dyspnea, hypothermia, hypotension, and hemodynamic instability. Table II lists all clinical observations in patients with acute metformin poisoning.

The laboratory parameters reported for acute metformin poisoning illustrate the presence and course of lactic acidosis from the time of diagnosis to the end of drug treatment and hemodialysis. Table III shows the evolution of laboratory values in the patients. The therapeutic approach entailed the normalization of acid-base imbalance, the acceleration of lactate metabolism process, the elimination of metformin, simultaneously treating related diseases. Following the patients evolution, metformin-associated lactic acidosis proved reversible when diagnosis and initiation of treatment are immediate so that therapeutic measures to be effective.

1 - Blood pressure 2 - Body temperature * Not specified.

Synthesizing the data in the literature it comes out that metformin-associated lactic acidosis is a very rare complication when no co morbidity is present (chronic kidney disease, myocardial infarction, sepsis, which can cause lactic acidosis even in the absence of metformin use).

Associated pathologies and particular conditions were encountered in case of: creatine administration, kidney damage

caused by associated medication (e.g., diclofenac), kidney failure. The literature mentions that approximately 25% of the patients treated with metformin have at least one contraindication for this drug, contraindication that may favor the occurrence and even worsen the evolution of a lactic acidosis case (13, 20). This complication may occur both in case of metformin overdose and during chronic treatment with normal therapeutic doses. No correlations were found between metformin plasma levels and the severity of lactic acidosis poisoning (20). This supports the importance of associated pathology and clear contraindications in the administration of metformin.

It is known that tissue hypoxia and kidney disease are common factors for lactic acidosis. Moreover, patients suffering from diabetes may have an ineffective glycemic control with high levels of glycated hemoglobin which causes kidney damage due to diabetic nephropathy. Thus, attempting an effective metformin treatment in the presence of early chronic complications of diabetes can have serious consequences. According to studies, even with prompt intervention, the mortality rate of lactic acidosis ranges between 60% and 90% (11).

Some studies have even pointed out a biological explanation for metformin-associated lactic acidosis. The genetic changes that may occur in the OCT1 protein may affect the pharmacokinetics of metformin. OCT1 or the organic anion transporter 1 facilitates the hepatic uptake of metformin and a single polymorphic nucleotide of OCT1 may be associated with increased intracellular levels of metformin, and therefore an increased risk of developing metabolic acidosis at therapeutical plasmatic concentrations (14).

Intervention regimens for metformin associated lactic acidosis include the intravenous administration of sodium bicarbonate. It aims to correct acidosis and restore fluid and electrolyte balance, but sodium bicarbonate can present some disadvantages: the occurrence of hypervolemia caused by sodium, the aggravation of intracellular acidosis, and the decomposition of oxy hemoglobin.

Hemodialysis is another treatment used in metformin-associated lactic acidosis, but since metformin has a large volume of distribution, hemodialysis only removes a small amount of the drug; this therapeutic approach is effective especially when correcting the serious effects associated with acidosis. When initiating hemodialysis a rebound effect was observed. Metformin is stored in the intestine and erythrocytes and produces and increases the serum lactate concentration. Continued hemodialysis is recommended when subsequently serum lactate levels normalize and lactic acidosis is corrected.

Metformin itself does not cause hypoglycemia but the treatment plan typically includes an antidiabetic sulfonylurea. The situations in which metformin alone can cause hypoglycemia are: fasting, sustained physical exercise, kidney failure. Hypoglycemia may occur under these conditions and can be corrected by administering intravenous glucose. However, some authors assert that the administration of glucose may worsen lactic acidosis because intracellular glucose metabolism is directed towards the formation of lactate.

In addition, it was found that insulin has beneficial effects in metformin-associated lactic acidosis, but blood glucose levels should be monitored closely (17).

Impaired vision in metformin therapy is also very rare, but reversible by optimal intervention. It is explained by the occurrence of metformin-associated lactic acidosis, which causes damage to retinal cells, whose function may be pH dependent (15). Blood pH adjustment resulted in the resumption of normal function and return of normal vision.

Hypothermia is another symptom seen in metformin-associated lactic acidosis and it is also reversible. It is probably related to severe hypoglycemia and an acid-base imbalance in the blood.

It must be pointed out that according to studies metformin-associated lactic acidosis is rare, with a frequency of 1 to 9 patients per 100,000 people (6). If with chronic metformin administration lactic acidosis is an exceptional phenomenon, its occurrence being attributed especially to present co morbidities, in the cases of accidental or suicidal metformin overdoses, lactic acidosis is very likely to occur, and the state of the patient and the severity of poisoning are differentiated on a case to case basis.

The minimum diagnostic tests in case of metformin overdose include the determination of serum electrolytes, serum bicarbonate, renal function tests, arterial blood gas test to determine pH, and determination of blood glucose and serum lactate. Furthermore, all patients with acidosis should be tested for possible salicylates intoxication, to exclude this variant (6).

In conclusion, the phenomenon of lactic acidosis may be associated with metformin administration, but there are a variety of special conditions that have an influence on its occurrence and outcome. Thus, we can conclude that there is no correlation between the amount of ingested metformin, plasma metformin and lactate levels, and the degree of patient impairment and outcome.

INHALED CORTICOSTEROIDS AND PNEUMONIA

Inhaled corticosteroids (ICS) are used for treatment of chronic bronchitis, emphysema and asthma. But prolonged treatment increases the risk of associated pathologies: vitamin D deficiency, bone fractures, type 2 diabetes and pneumonia. A study, conducted by Dean Eurich and colleges during 5 year, has showed an increased risk of recurrent pneumonia for elderly patients which used ICS in the treatment of chronic obstructive pulmonary disease. The study has included 653 recurrent pneumonia cases and 6244 controls and show that 14% of current ICS users had developed recurrent pneumonia compared to 9% never-users. These findings suggest that ICS use increases the risk of recurrent pneumonia with 90% for the patients who survived after an initial episode of pneumonia. These data are useful in establishing optimal regimens, depending on patient characteristics (Eurich DT, Lee C, Marrie TJ et al. Inhaled Corticosteroids and Risk of Recurrent Pneumonia: A Population-Based, Nested Case-Control Study. *Clinical Infectious Diseases*, 2013; DOI: 10.1093/cid/cit472).
